- Dimensions of nanostructured materials are comparable to characteristic length scales such as domain size and exchange length;
- Nanostructured materials exhibit higher number of surface/interface atoms with broken symmetry and low coordination numbers.

Another factor that alters the magnetic behavior in nanostructured materials is contact with other physical systems such as for thin films and multilayers. Interactions with the substrate cause perpendicular or in-plane anisotropy depending on the nature of the substrate; For example, in thin films, the thermal response of a nanostructured magnetic material is changed due to its contact with the substrate, leading to a reduction in the Curie temperature [12.28]. Thermal effects become important in a single particle of volume V and effective anisotropy K_{eff} ; superparamagnetism is observed when $K_{\text{eff}}V = 25k_B T$.

Magnetic Moment

The magnetic moment can be affected by several nanoscale mechanisms. Ferromagnetism may be observed in noble metals; in contrast to diamagnetism in gold, thiol-capped gold nanoparticles show ferromagnetism due to localization of 5d holes through Au-S bonds [12.1]. Observation of the magnetic moment of $1.0\mu_B$ in nitrogen atoms due to spin polarization by neighboring atoms is another example of the effect of nanomagnetism [12.33]. Similarly, DFT calculations of Cu-doped GaN predict spin polarization in Cu [12.34]. This spin polarization further magnetizes the p electrons of the four neighboring N atoms through p-d hybridization and causes ferromagnetic coupling in Cu dopants.

The value of magnetic moment also depends on the dimensionality of the structure [12.29, 35]. The mag-

netic moments of Fe and Ni are listed in Table 12.2. There is a large variation in magnetic moment from 0-D to 3-D bulk state; For example, the magnetic moment is calculated to be $3\mu_B$ for an isolated Fe atom, but the bulk value is found to be $2.2\mu_B$, and this decrease in moment is due to the increase in coordination number and partial delocalization of 3d electrons [12.32, 36]. However, the coordination number is still low at the surface. So, when the number of surface atoms is large, as in nanostructured materials, the moment becomes comparable to the atomic moment value. Moreover, the spin-orbit coupling in nanostructured magnetic materials is also comparable to the crystal field energy, and hence a large orbital contribution of magnetization results [12.35]. This results in increased magnetic moment in nanostructures compared with bulk magnetic materials. The enhancement of surface magnetization is explained in terms of itinerant exchange [12.32, 36]. For clusters comprising a few tens to hundreds of atoms, most of the atoms are at the surface and hence are more magnetic compared with the bulk. It is observed that the average moment per atom decreases with cluster size, e.g., see the magnetic moment variation for Fe nanoclusters with cluster size in Fig. 12.3 [12.32].

Often, magnetic thin films are deposited on a non-magnetic substrate. Due to different chemical or electronic environments, the interaction of the magnetic film with different substrates can vary and change the magnetic moment [12.37]; For example, the interface moment of Fe is enhanced when in contact with Cu, Pd, Ag, and Au, and the moment of Co is enhanced for Co/Cu monolayers but decreases for

Table 12.2 Variation of magnetic moment (in μ_B) with dimensionality (after [12.29])

Element	Dimensionality			
	0-D	1-D	2-D	3-D
Fe	4.0	3.3	2.96	2.27
Ni	2.0	1.1	0.68	0.56

Fig. 12.3 Magnetic moment per atom as a function of cluster size at $T = 120$ K (after [12.32])

multilayers. The moment of a Ni monolayer is decreased for Cu and Au substrates but enhanced for Pd and Ag substrates [12.37]. The substrate–magnetic layer interactions affect the Curie temperature T_C ; the Curie temperature of the Fe/W thin-film system is lower than that of the Fe/Ag system, and layers with identical thickness grown in different crystallographic planes exhibit different T_C values as the crystallographic orientation of the film changes from (100) to (110) to (111) [12.37]. Disordered two-phase nanostructures usually exhibit a single Curie temperature that is close to the Curie temperature of the phase having the strongest exchange coupling [12.28].

Magnetic Anisotropy

Preferential orientation of magnetization in a particular crystal axis direction is called magnetic anisotropy. Hard magnetic nanostructures are characterized by high magnetic anisotropy, while soft magnetic nanostructures possess low anisotropy. Magnetic anisotropy consists of two major components: crystalline anisotropy and shape anisotropy. Shape anisotropy is more important in polycrystalline nonspherical magnetic materials [12.9, 38–40]. Shape anisotropy is prominent in very small particles, but in large particles it is minimized by internal flux closure [12.9]. Magnetocrystalline anisotropy is of atomic origin and originates from interaction of spin–orbit coupling with crystal field energy. The lowest-order uniaxial anisotropy energy is given by [12.28]

$$E_a = K_1 V \sin^2 \theta, \quad (12.22)$$

where K_1 is the first uniaxial anisotropy constant. For low symmetry (orthorhombic, monoclinic, triclinic), the lowest-order anisotropy energy is

$$E_a = K_1 V \sin^2 \theta + K'_1 V \sin^2 \theta \cos(2\phi), \quad (12.23)$$

where θ and ϕ are the magnetization angles. Breaking of symmetry at the surface or interface introduces lower-order anisotropy and is termed surface anisotropy [12.37], first pointed out by Neel and expressed as

$$E_s = K_s \cos^2 \theta + K_{s,p} \sin^2 \theta \cos^2 \phi, \quad (12.24)$$

where the first term is out-of-plane anisotropy and the second term is in-plane surface anisotropy. Due to the large number of surface atoms in nanostructured materials, surface anisotropy dominates over bulk anisotropy. In thin films, normally surface anisotropy originates at the surface layer and extends to the first few monolayers. Therefore, the anisotropy energy of thin films is the

sum of the anisotropy terms that scale with volume and surface area [12.38, 41], i. e.,

$$E_a = K_{\text{eff}} \sin^2 \theta, \quad K_{\text{eff}} = K_V + \frac{2K_s}{t}, \quad (12.25)$$

where t is film thickness, K_V is volume anisotropy and K_s is surface anisotropy. For uniaxial anisotropy perpendicular to the plane, $K_V = 2\pi D_m M_s^2 + K_1$, where K_1 is the bulk uniaxial anisotropy and D_m is the out-of-plane demagnetization factor ($D_m \approx 1$ for thin film). For in-plane anisotropy, another term ($B_{\text{me}}\varepsilon$) due to strain is added to the volume anisotropy term as

$$K_V = 2\pi M_s^2 + B_{\text{me}}\varepsilon + K_1,$$

where B_{me} is the magneto-elastic coupling coefficient and ε is the strain. The critical thickness at which the in-plane and the out-of-plane anisotropy switch can be estimated from the ratio of the surface and volume terms of the anisotropy, expressed as [12.37]

$$t_{\text{SRT}} = -\frac{2K_s}{2\pi M_s^2 + K_1}. \quad (12.26)$$

The existence of surface anisotropy and its dependence on thickness have been studied [12.37]. Epitaxial Ni/Cu(001) shows interesting magnetic anisotropy behavior with thickness: below 1.5 nm, Ni shows in-plane anisotropy, but above, it changes to perpendicular anisotropy. Beyond the case of thin films, surface anisotropy applies to atoms located at the surface of any nanostructure, e.g., nanowires.

Coercivity/Magnetization Process of Nanostructured Materials

Magnetization changes due to applied field can be represented by an M versus H plot, known as the hysteresis loop (Fig. 12.4). The characteristic parameters are saturation magnetization M_s , remanent magnetization M_r ,

Fig. 12.4 Hysteresis loop of a ferromagnetic material

and coercivity H_c . Coercivity is the field needed to bring the magnetization back to a zero state from a previously saturated state, and remnant magnetization is the magnetization remaining at zero applied field.

The starting point for the study of hysteresis in magnetic materials is the Stoner–Wohlfarth (S–W) model, which assumes uniform rotation of magnetization. Considering the lowest-order twofold uniaxial anisotropy, the total energy is the sum of two competing energy terms, the anisotropy energy $K_1 \sin^2 \theta$ and the Zeeman energy $-M \cdot H$ [12.42], i.e.,

$$E = K_1 \sin^2 \theta - \mu_0 M_s H \cos(\phi - \theta), \quad (12.27)$$

where K_1 is the magnetocrystalline anisotropy constant that tends to align the moment in the easy axis direction, whereas the Zeeman energy due to the external field orients the moment in the field direction. ϕ is the angle between the easy axis and applied field, and θ is the angle between magnetic moment and applied field (Fig. 12.5a). Energy minimization with respect to θ of this total energy expression results in the following expression for the anisotropy field H_a [12.42]

$$H_a = \frac{2K_1}{\mu_0 M_s}. \quad (12.28)$$

The anisotropy field H_a is the maximum field needed to align the magnetic moments in the field direction. When $\theta = 0$, the coercivity is equal to the anisotropy field, resulting in a perfect square (Fig. 12.5b); depending upon the value of ϕ , the switching field is either equal to (for $\phi < 45^\circ$) or more than (for $\phi > 45^\circ$) the coercive field [12.41].

Hysteresis of Magnetic Nanostructures. Magnetic properties derived from the hysteresis loop are extrinsic properties, because they describe the real structure of the magnet. In the absence of interactions, magnetization reversal in small magnetic particles is S–W like, though the coercivity tends to be lower than the S–W prediction. In real nanostructured ferromagnets, the switching units are not strictly independent. To predict the hysteresis of real magnetic nanostructures, exchange effects, dipolar effects, and local magnetization as a function of applied field need to be considered, and the derivation of the micromagnetic free energy by modeling nanostructures remains a key problem [12.9].

In nanostructured materials, exchange coupling tends to suppress inhomogeneous magnetization states, leading to coherent rotation of magnetization. If shape anisotropy is considered, the free energy of uniaxial ellipsoids of rotation having symmetry axis parallel to the

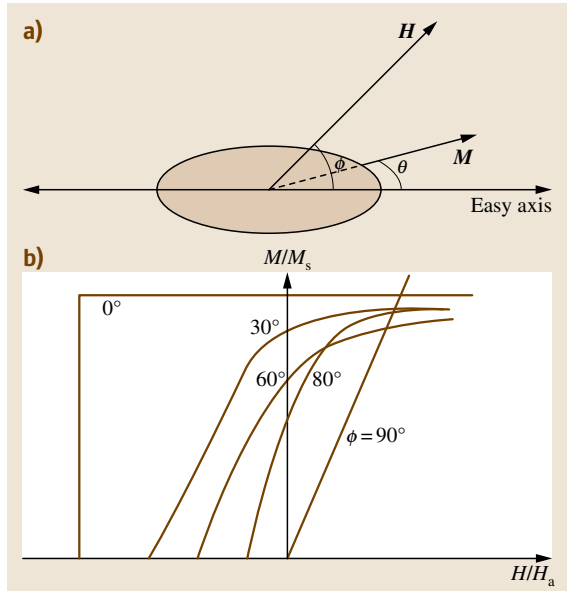

Fig. 12.5 (a) Coordinate system for magnetization reversal in SW particle. (b) M – H loop of Stoner–Wohlfarth particle for various angles ϕ (after [12.26])

external field is expressed as [12.9]

$$\frac{E}{V} = K_1 \sin^2 \theta + \frac{\mu_0}{2}(1 - 3D)M_s^2 \sin^2 \theta - \mu_0 M_s H \cos \theta, \quad (12.29)$$

where D is the demagnetization factor. The solution to (12.29) is obtained by setting the free energy minimum at $\theta = 0$, which yields the S–W coercivity as [12.9]

$$H_c = \frac{2K_1}{\mu_0 M_s} + \frac{1}{2}(1 - 3D)M_s. \quad (12.30)$$

For spherical S–W particles ($D = \frac{1}{3}$), $H_c = 2K_1/(\mu_0 M_s)$. As the radius of the particle increases, the magnetization process changes from coherent rotation to curling mode and the expression for coercivity becomes [12.9]

$$H_c = \frac{2K_1}{\mu_0 M_s} - DM_s + \frac{c(D)A}{\mu_0 M_s R^2}. \quad (12.31)$$

Here, R is the mean radius of the ellipsoid, and $c = 8.666$ ($D = \frac{1}{3}$) for a sphere and $c = 6.678$ ($D = 0$) for a needle.

Although coherent rotation is one of the primary processes of magnetization reversal, other competing processes such as domain wall propagation and domain nucleation may dominate depending on the sample size

and shape. For most magnetic materials, coercivity does not reach the theoretical limit calculated using the nucleation mechanism developed by *Brown* and termed the Brown paradox [12.43]. *Kronmüller* [12.44] introduced the α factor into Brown's equation to obtain quantitative information on the influence of microstructure. The coercive field expression now becomes

$$\mu_0 H_c = \alpha \frac{2K_1}{M_s} - N_{\text{eff}} J_s. \quad (12.32)$$

Here, α is a microstructural parameter and depends on the dimensionality and easy axis orientation, N_{eff} is the demagnetization coefficient, and $J_s = \mu_0 M_s$ is the saturation polarization. The parameters α and N_{eff} can be determined experimentally. The value of α is 1 for aligned particles with easy axis in the direction of applied field. For 3-D and 2-D randomly oriented particles, α is 0.48 and 0.254, respectively [12.46]. In general, the parameter α consists of three subparameters: $\alpha = \alpha_K \alpha_\psi \alpha_{\text{ex}}$; α_K describes the anisotropy reduction at the grain surface, the grain boundary, and in the intergranular phases, α_ψ describes the coercive field reduction due to misaligned grains, and α_{ex} reflects exchange coupling between grains [12.47, 48]. For a complete understanding of coercivity, it is necessary to correlate it with microstructural parameters. From the temperature dependence of the coercivity H_c (12.24), and plotting the experimental

data for $H_c(T)/M_s$ versus theoretical $2K/M_s^2 \alpha$, the magnetization reversal mechanism can be identified as nucleation, pinning, or single-particle rotation; For example, the nucleation-controlled magnetization reversal mechanism was observed in Pr-Fe-B magnet by *Kronmüller* [12.49].

Random Anisotropic Effect. Magnetic nanostructures exhibit a particularly rich extrinsic behavior, including effects such as random anisotropy scaling, remanence enhancement, and exchange coupling effects. The key to the extrinsic behavior is the magnetocrystalline anisotropy and its dependence on local atomic structure. In the actual microstructure, the magnetization cannot adapt the local anisotropy from grain to grain, due to exchange stiffness which favors homogeneous magnetization; this leads to variation in magnetization orientation over the structural correlation length. This local magnetization process can be modeled by the random anisotropy model. The anisotropy of grains averages out over several structural units and is reflected in the coercivity of nanomaterials [12.50, 51].

The length scale below which the random anisotropy effect is observed is given by the exchange length L_{ex} . The typical value of L_{ex} is 20–40 nm for Fe-based alloys and 5–10 nm for Co-based alloys. The anisotropy of the grains within the exchange coupled volume is averaged out and scales as

$$K_{\text{eff}} = \frac{K_1}{\sqrt{n}} = K_1 \left(\frac{D}{L_{\text{ex}}} \right)^{3/2}, \quad (12.33)$$

where N is the average number of grains within a volume of the exchange length L_{ex} , which is given by substituting

$$L_{\text{ex}} = \sqrt{\frac{A_{\text{ex}}}{K_{\text{eff}}}},$$

into (12.33) to give

$$K_{\text{eff}} = \frac{K_1}{A_{\text{ex}}^3} D^6.$$

The coercivity for coherent rotation can be expressed as

$$H_c = p_c \frac{K_{\text{eff}}}{M_s} = p_c \frac{K_1 D^6}{M_s A_{\text{ex}}^3}, \quad (12.34)$$

where p_c is a dimensionless quantity related to crystal structure; $H_c \propto D^6$ when $D \leq L_{\text{ex}}$.

However, for large D ($D \geq \pi L_{\text{ex}}$), $H_c \propto 1/D$ [12.32] and the coercivity is

$$H_c = p_c \frac{\sqrt{AK_1}}{M_s D}.$$

Fig. 12.6 Coercivity versus grain diameter plot for Fe (after [12.45])

For magnetic thin films, where thickness is smaller, K_{eff} becomes [12.50]

$$K_{\text{eff}} = K_1 \left(\frac{D}{L_{\text{ex}}} \right),$$

and the coercivity is

$$H_c = P_c \frac{K_{\text{eff}}}{M_s} \approx P_c \frac{K_1 D^2}{M_s A_{\text{ex}}}. \quad (12.35)$$

When the grain diameter D is less than the exchange length L_{ex} , the coercivity of magnetic nanoparticles follows the sixth power of D , while thin films follow the second power of grain diameter D . The variation of coercivity for Fe nanostructures is presented in Fig. 12.6 [12.45]. The transition of coercivity change with grain size defines the exchange length, which for Fe is 20 nm.

12.4 Magnetic Nanostructures

Magnetic nanostructures exhibit many interesting magnetic phenomena; For example, exchange coupling in hard–soft nanocomposite magnets leads to high remanence and high energy product (BH_{max}), disappearance of random anisotropy effects is observed in oriented magnetic nanostructures, e.g., nanorods, and multilayer thin films exhibit high saturation magnetization. More recently, it has been shown that single-domain superparamagnetic nanoparticles can play a significant role in novel biomedical applications such as drug targeting and gene delivery [12.17, 23].

Magnetic nanostructures can be produced in a wide range of geometries such as nanoparticles, nanoparticle arrays, nanowires, nanodots, nanorings, nanotubes, and thin films [12.28]. In nanoparticles, all three dimensions are in the nanoscale range, while nanorods and nanodots are examples of low-dimensional systems. Magnetic nanoparticles can be embedded in a medium to form a composite and then self-assembled onto a substrate surface to form a particle array. Future high-density magnetic recording may rely on two-dimensional arrays of nanoparticles. Magnetic nanoparticles can form stable colloidal suspensions in organic liquid or water to form a ferrofluid. Very small nanoparticles are known as clusters; the magnetic properties, e.g., magnetization and anisotropy, of such clusters exhibit strong size dependence due to their high surface to volume ratio [12.28].

Based on the correlation between structure and magnetic properties, magnetic nanostructures are broadly classified as [12.52]:

- Isolated particles with nanoscale diameters
- Bulk materials with nanoscale structure.

In isolated particles, the magnetic properties are due to reduced dimensions, with no contribution from interparticle interactions. In bulk nanostructures, the magnetic properties are dominated by interactions and critically dependent on the nature of the interfaces.

Thin-film or multilayer magnetic nanostructures have only one dimension in the nanoscale range. Magnetic and nonmagnetic layers are stacked to make heterostructured thin films, which have applications in spin valves, tunnel junctions, GMR, etc. Magnetic thin films show interesting magnetic phenomena such as perpendicular anisotropy, moment modifications at surfaces and interfaces, and thickness-dependent domain wall motion.

In a nanowire structure, two dimensions are nanoscale and exhibit interesting magnetic properties due to shape anisotropy, magnetostatic interactions, magnetic mode localization, spin waves, and current-induced magnetization reversal [12.28]. Magnetic nanowires can be obtained by deposition on a surface by exploiting surface anisotropy or by electrodeposition of magnetic materials into porous templates [12.28]. Magnetic nanowires have potential applications in patterned magnetic media and microwave applications.

Another class of magnetic nanostructures are molecular nanomagnets, sometimes termed single-molecule magnets. Magnetic molecular clusters are intermediate between classical and quantum magnets and show unusual properties [12.9]. Molecular nanomagnets are mainly organic molecules that are bonded to metals with unpaired electrons. Molecular nanomagnets are promising candidates for observations of quantum phenomena due to their well-defined structure and well-characterized spin state. Thermally activated quantum tunneling of magnetization was first observed in molecular nanomagnets [12.9].

12.4.1 Processing of Magnetic Nanostructures

Processing of magnetic nanostructures can be performed by a variety of physical methods, e.g., mechanical milling, melt spinning, lithography, and spark

erosion, as well as chemical synthesis methods such as self-assembly and coprecipitation. Conventional lithography allows fabrication on the micron scale; more recently, new techniques such as x-ray lithography, electron beam lithography, and nanoindentation have been developed to achieve nanoscale resolution. Bombardment by heavy ions of a matrix and the focused atom jet deposition technique have been successfully applied to synthesize low-dimensional systems such as nanowires. Due to the exciting magnetic properties of hard-soft multilayered structures and **GMR**, magnetic thin films are of considerable interest; sputtering, molecular beam epitaxy, and electrodeposition are some of the techniques used for thin-film magnetic nanostructure development.

Lithography

Lithography is a technique in which patterns are recorded onto a substrate using a resist. Depending on the radiation used to record the pattern, lithography is classified as optical, e-beam, x-ray or ion beam lithography [12.53–55]. The substrate to be patterned is coated with radiation-sensitive resist. The resist is then exposed to high-energy radiation with small spot size and subsequently developed in an appropriate solvent medium to leave the desired pattern on it. Finally, the pattern in resist is transformed to the substrate by etching, and the magnetic nanostructure is developed by deposition into the pattern. The small spot size of the electron beam in electron beam lithography enables fabrication of nanosized patterns in magnetic materials [12.53]. There are several other varieties of lithography techniques that can be applied to achieve nanopatterning (Fig. 12.7) [12.53, 54]: Interference lithography is useful for magnetic array development, while nanoimprint lithography is generally employed for nanowires. In interference lithography, an interference pattern of two standing laser beams is used to generate a pattern on the resist. In nanoimprint lithography, however, patterns are developed by physical deformation of the resist. *Chou* and *Krauss* recently fabricated quantum magnetic discs of nickel by lithography [12.56]. **AFM** nano-oxidation lithography is an effective technique for nanodevice fabrication on patterned NiFe thin film [12.57]. Nanosphere lithography, another modification of the lithography technique, has shown promise for metallic nanostructure preparation [12.58].

Sputtering

Direct current (**DC**) and radio frequency (**RF**) magnetron sputtering have become standard procedures in

thin-film preparation of metals and ceramics. Magnetic films for recording (**FeAlSi**, **FeNiMo**, and **FeSi**) can be prepared by sputtering [12.59]. During sputtering, a target material is bombarded with high-energy argon plasma so that target material is removed and allowed to condense on the substrate, forming the thin film. In magnetron sputtering, a magnetic field is applied parallel to the target surface for electron trapping. This helps in producing high-density plasma near the cathode and accelerates the sputtering rate. Use of a magnetic bias substrate in magnetic film deposition induces uniaxial anisotropy [12.59]. There are a number of reports on controlling magnetic properties of sputtered films by applying a voltage bias on the substrate [12.60–63]. Reactive sputtering, which is carried out in a reactive gas or reactive gas-argon mixture, is used to prepare oxide and nitride films of a metal target. The sputtering rate of a metal oxide or nitride in conventional sputtering is usually low; the process of reactive sputtering can be used to resolve this issue [12.64]. The main advantage of sputtering is that it is a fairly easy technique for preparation of a large number of layers within a short period of time. The quality of the deposited films (roughness, thickness, stoichiometry, and grain size) depends on variables such as argon pressure, deposition pressure, etc. Sputtering can produce a large range of mean cluster size ranging from 200–15 000 atoms.

Molecular Beam Epitaxy

In molecular beam epitaxy (**MBE**), materials are evaporated by thermal energy or high-energy electrons and deposited on a substrate, forming the thin film. This technique is used for epitaxial growth via interaction of one or several atomic or molecular beams on a heated substrate. It provides a unique capability to study crystal growth in real time and on a subnanometer scale and to produce complex, artificially layered crystals with high degree of control and reproducibility. The characteristics of **MBE** are: low growth rate, low growth temperature, smooth growth surface, precise control of surface composition and morphology, and in situ control of crystal growth at atomic scale. A variety of magnetic thin films and nanoparticles arrays can be fabricated by this technique [12.65–68]. Control over microstructure and excellent magnetic properties are advantages of the **MBE** technique for patterned media applications [12.66, 68].

Electrodeposition

In contrast to sputtering and **MBE**, electrodeposition is a low-cost and simple technique to fabricate magnetic

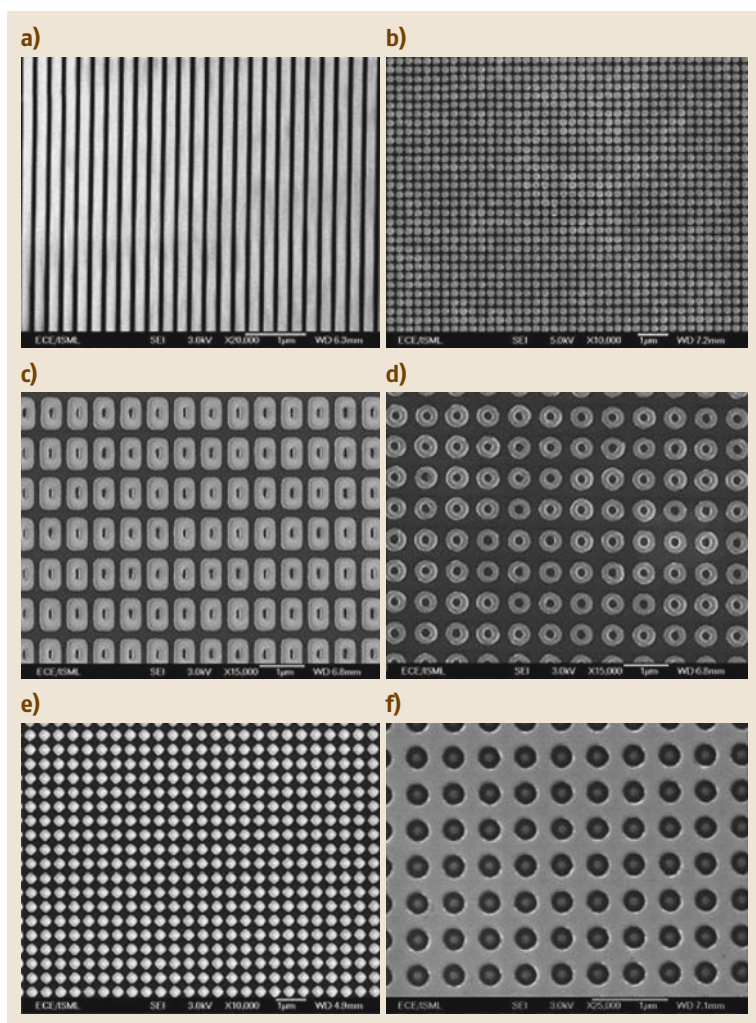

Fig. 12.7a–f Magnetic nanostructures developed by lithography (after [12.54]): (a) nanowires, (b) circular dots, (c) elongated rings, (d) circular rings, (e) magnetic nanodiamonds, and (f) circular dots encircled with antidots

nanostructures [12.69, 70]. Electrochemical processes have many advantages such as room-temperature operation, easy scale-up and maintenance, low-cost, relatively rapid deposition rate, and the capability to handle complex geometries. By applying a voltage between the substrate (working electrode/cathode) and counterelectrode (anode), the metal ions are reduced and become deposited at the substrate surface. The deposition potential is controlled by the reference electrode, and the layer thickness is controlled by the potential applied and time of deposition. Hard/soft magnetic thin films and template-supported nanowires have been synthesized by electrodeposition [12.71–74]. Lee et al. prepared Fe–FeO_x core-shell nanowires by an-

odized aluminum oxide template-supported electrode deposition of iron and subsequent annealing [12.75]. Soft magnetic film such as Fe, Co, Ni, or their alloys can be successfully fabricated by electrodeposition. However deposition of hard magnetic materials with good magnetic properties remains difficult, and reduction of rare-earth elements such as neodymium (Nd) and samarium (Sm) by electrodeposition is challenging due to their high reduction potential. Moreover, appropriate complexing species, such as glycine and other aminocarboxylates, are usually required to codeposit rare earths with high reduction potentials along with transition metals having relatively low reduction potentials.

Chemical Synthesis

The simplicity and high yield of chemical synthesis have drawn attention for wide applications in nanostructure material preparation. Chemical techniques have the advantage of particle size control by controlling nucleation and growth during synthesis. Chemical synthesis of magnetic nanostructured materials is presented in literature [12.52, 76–79]. The common chemical synthesis coprecipitation, microemulsion, sonochemistry, self-assembly, and surface modification of nanocrystals for biological application.

In the reduction process, several reducing agents are used, e.g., an alkali metal (Na) in a suitable solvent (liquid ammonia), NaBH_4 , N_2H_4 , polyol, etc.; there are several reports on Fe, Ni, and Co nanopowder synthesis by the reduction method using these reducing agent [12.80–83]. However, there is one issue associated with the NaBH_4 reduction method: the chemical reaction may produce borides instead of pure metal nanoparticles [12.78, 81]. The coprecipitation method is generally used to synthesize oxide-based nanostructures [12.84–86]. In this method, a metal salt is treated with a strong alkali to obtain the hydroxide, which is heated in air to produce the oxide. If these reactions are carried out inside a micelle, which acts as a microreactor, size can be controlled by confining the growth of reaction products [12.87, 88]. In a microemulsion, by varying the concentration of surfactant and solvent, different microstructures can be synthesized [12.88].

Magnetic nanostructures have also been prepared by high-temperature decomposition of organometallics such as $\text{Fe}(\text{CO})_5$, $\text{Co}_2(\text{CO})_8$, and $\text{Ni}(\text{CO})_4$ in a non-aqueous medium in the presence of a stabilizing surfactant [12.88–90]. Size and morphology can be controlled by controlling the reaction temperature, time, and aging period [12.77, 91]. Another well-studied process for magnetic nanostructure preparation is the polyol process [12.77, 91, 92]. In this process, a polyol is used as a reducing agent to obtain Fe, Co, Ni, or FePt magnetic nanoparticles from their corresponding organometallic salts. In this process, a solvent having a relatively high boiling point is required, since reduction takes place at temperatures of 200–300 °C. Recently, another technique, solution-based synthesis followed by high-temperature reduction, has become popular to produce nanocrystalline powders. Rare earths, due to their high reduction potential, are difficult to reduce by high-temperature decomposition or polyol-based reduction processes; the technique of solution-based synthesis and subsequent reduction is a more effective method

for synthesizing rare-earth-based nanopowders [12.93–95].

HDDR Process

The hydrogenation–decomposition–desorption–recombination (HDDR) process is mainly used for preparation of anisotropic $\text{Nd}_2\text{Fe}_{14}\text{B}$ nanocrystalline powders [12.9]. This process involves a series of heat treatments of bulk $\text{Nd}_2\text{Fe}_{14}\text{B}$ in hydrogen and in vacuum. The anisotropy is induced by the orientation relationship between newly formed and parent grains. This process involves four steps: hydrogenation of $\text{Nd}_2\text{Fe}_{14}\text{B}$ at low temperatures, decomposition of $\text{Nd}_2\text{Fe}_{14}\text{BH}_x$ into Nd_2H_x , Fe, and FeB, desorption of hydrogen gas from Nd_2H_x , and recombination of Nd, Fe, and FeB into $\text{Nd}_2\text{Fe}_{14}\text{B}$. This technique is also used to prepare SmFe-based alloys [12.96].

Melt Spinning

This technique is very useful to produce magnetically soft alloys as well as hard–soft exchange-coupled magnetic nanocomposites. Both amorphous and nanocrystalline precursors can be prepared by melt spinning by controlling the quenching rate [12.52, 97]. Heating of the amorphous precursor produces small crystallites in an amorphous matrix [12.52]. Tuning the annealing conditions permits control of the grain size. The resultant microstructure is a function of the processing parameters and alloy characteristics. The process parameters are the ejection and chamber pressure, diameter of crucible orifice, distance of crucible from the wheel, wheel speed, melting temperature of the alloy, thermal conductivity of the melt, and heat capacity of the alloy.

In melt spinning, the water-cooled rotating Cu wheel extracts heat from the ribbon. Upon leaving the Cu wheel, cooling is via convective heat transfer. At high wheel speeds, this allows a reduced solidification rate in unsolidified portions or reheating of the initial solidified region and suppresses nucleation of crystalline phase. This allows the melt to be transformed into an amorphous structure. At optimum wheel speeds during melt spinning, the nanocrystallites nucleate and coexist with an amorphous matrix. The melt-spinning technique is used in synthesis of rare-earth-based permanent magnetic materials, especially $\text{Nd}_2\text{Fe}_{14}\text{B}$, SmCo compounds, and their alloys. This technique has also been successfully utilized to prepare ribbons of FePt alloys. Nanocrystalline soft magnetic materials (Finemet, Nanoperm, and Hitperm) have been prepared by partial devitrification of a melt-spun amorphous precursor.

Mechanical Milling

Using this technique, nanostructured as well as amorphous magnetic powders can be produced in large quantities at room temperature by repeated mechanical deformation and alloying in a ball mill [12.52]. Amorphous precursors can be annealed to achieve nanostructured magnetic powders. The advantage of mechanical milling over other physical methods such as sputtering and melt spinning is that milling produces powders which can be readily consolidated to manufacture magnets of desired shapes. A surfactant can be used during milling to obtain better control over the shape and size of the powder particles.

High-energy ball milling is a promising and commercially viable method for large-scale fabrication of Nd-Fe-B, and SmCo magnetic nanostructured powders. Nanocrystalline soft magnetic materials (FeZr and CoFeZr) have also been prepared by this technique. A variation of mechanical milling is reactive milling (RM) or mechanochemical synthesis, which involves reduction/oxidation reactions, decomposition of compounds, and phase transformations. This process has been used to prepare nanoparticles of a number of ferrites such as Fe₃O₄, NiFe₂O₄, CoFe₂O₄, etc. Sm₂Co₁₇ has also been produced by mechanochemical synthesis, by coreduction of Sm₂O₃ and CoO by Ca metal during milling [12.98]. However, wide size distribution and contamination are two barriers to the application of the mechanical milling process for fabricating nanostructured magnetic powders.

Self-Assembly

Self-assembly is a bottom-up fabrication approach to produce materials with highly uniform morphology for various advanced application. In self-assembly, atoms, molecules, or particles organize themselves into functional structures. 1-D, 2-D, and 3-D ordered nanostructured magnetic materials have been synthesized by self-assembly techniques [12.82, 99–101]. The physical forces which drive self-assembly are Coulomb interactions, van der Waals interaction, magnetostatic interactions among particles, hydrogen bonding, and steric repulsion of surfactant [12.88]. Self-assembled magnetic nanocrystals are formed by solvent evaporation, either using the reverse micelle technique or by applying a magnetic field during synthesis [12.52, 88, 102–104]. The product of solvent evaporation-induced self-assembly is dependent on the solvent composition, evaporation temperature, and evaporation rate. It also depends on the wettability of the substrate. Self-assembly by reverse micelle synthesis provides better

size control and surface passivation to prevent oxidation. The interparticle spacing can be tuned by the surfactant chain length. Self-assembly on a patterned, textured, or structured template can control the diffusion of atoms and growth, resulting in control of the shape and size of the nanostructures [12.105]. For the growth of complex 3-D structures, nanostructures themselves can act as templates [12.79].

Magnetic nanoparticles coated with surfactants can form close-packed arrays on a substrate. As the solvent is allowed to evaporate, magnetic nanoparticles interact by van der Waals and dipolar interactions and self-assemble. In this process, three interactions need to be considered: between solvent and substrate, between particle and substrate, as well as between particle and particle. If the surfactant is hydrophobic, only nonpolar solvents can be used for dispersion; such dispersions spread on hydrophobic surfaces only, such as carbon or Si-H [12.9]. If the substrate is hydrophilic in nature, isolated islands of particles will form due to the dewetting nature of the hydrophobic surfactant.

FePt nanoparticles prepared by solution-phase synthesis and stabilized by oleic acid and oleylamine are ideal building blocks for FePt superlattice formation by self-assembly [12.92]. Self-assembly of iron dots with a narrow size distribution on the insulating surface of NaCl(001) was reported by *Gai* et al. [12.106]. Such dots can be used as model systems for micromagnetism. As they display simple flux-closure magnetic states, they can bridge the gap between nanomagnetism (single domain) and macroscopic materials (with a large number of domains and domain walls). Self-assembled Fe, Co, Ni, and Co-Pt nanowires have been synthesized by electrodeposition using a porous substrate [12.107]. A key challenge in self-assembled magnetic patterned media development is the placement and alignment of the magnetic dot arrays at the predetermined positions; this can be achieved by lithography.

A substrate functionalized with proper molecules can be used to anchor particles onto its surface via exchange reaction, known as polymer-mediated self-assembly [12.9]. Polyethylene amine-mediated self-assembly of FePt has been reported by *Sun* et al. [12.108]. Polyethylene amine is a NH-based polymer that can replace oleic acid/oleyl amine molecules around FePt nanoparticles and attached to a hydrophilic substrate. PEI/FePt assemblies have been prepared by dipping the substrate alternately in PEI and dispersed FePt particles. By manipulation of the protecting polymer, the interparticle distance can be readily manipulated.

Surface Modification for Biological Application

Magnetic nanostructures, e.g., superparamagnetic particles, are used in biomedical engineering for imaging and hyperthermia application. To make magnetic nanoparticles biocompatible, their surfaces are modified to be hydrophilic by surfactant addition [12.30]. For specific applications different molecules such as drugs, targeting agents, fluorescent molecules, etc. should be bonded to the magnetic nanostructure surfaces [12.109]. For these applications, the surface needs to be functionalized for biocompatibility and to facilitate interactions with molecules. The functionalizing molecule should have two functional groups: one to interact with the magnetic nanoparticles, and the other for molecule bonding. Besides the bonding interactions, surface functionalization ensures stabilization against agglomeration in an aqueous medium.

Organic surfactants are frequently used for stabilization and coating. One of the common approaches is to use fatty acid (oleic acid or stearic acid) to stabilize magnetic nanoparticles. Both dicarboxylic acid and tricarboxylic acid are used for surface functionalization and stabilization of iron oxide-based nanoparticles. Some functional groups are attached to the nanoparticles; the remaining functional groups provide charged surfaces and thus improve the hydrophilicity of the nanoparticles. Polymers with multifunctional groups are also used for surface modification. Due to their good solubility and biocompatibility, polysaccharides such as dextran and carboxydextran are used for stabilization of magnetic nanoparticles. Chitosan, polylactic acid, and polyethylene glycol (PEG) are biocompatible and biodegradable and are of particular interest to coat magnetic nanoparticles for use in MRI.

12.4.2 Characterization of Magnetic Nanostructures

To understand the structure–property relationships in magnetic materials, it is essential to know the distribution of magnetization at various length scales. A variety of instruments and techniques have been developed to achieve these objectives. These methods involve applications of electron optical techniques, including differential phase-contrast imaging and spin-polarized electron microscopy in a scanning transmission electron microscope [12.10, 110], electron holography, quantitative Lorentz microscopy in a trans-

mission electron microscope [12.111], magnetic force microscopy [12.112], as well as x-ray and neutron-based techniques [12.113].

Nondestructive surface analysis of ferromagnetic materials is performed by spin-polarized scanning electron microscopy and magnetic force microscopy; however, for quantitative study of domains, differential phase-contrast microscopy is preferred [12.10]. In electron holography, the phase shift of electrons passing through a thin foil ferromagnetic specimen is analyzed, which provides contour maps corresponding to lines of force distribution and quantitative data on flux distribution [12.10]. Imaging of magnetic domain walls and thereby determination of their structure is usually performed by Lorentz microscopy in defocus mode. These techniques are used in conjunction with transmission electron microscopy (TEM), which provides nanoscale spatial resolution, making direct imaging of magnetic nanostructures possible.

Magnetic Structures Using Scanning Electron Microscopy

Scanning electron microscopy is applied to investigate the magnetization distribution near the surface [12.114]. The surface domains in the ferromagnetic sample interact with secondary electrons and deflect them. When the sample is oriented in an appropriate direction, it becomes possible to detect the Lorentz deflection of the scattered electrons. There are generally two geometrical arrangements for detecting Lorentz deflection (Fig. 12.8) [12.10]. Since it is easy to manipulate the sample in the chamber of a scanning electron microscope, in situ hysteresis or heating experiments, as well as direct real-time observation of domain wall dynamics under an applied field can be conducted.

Unlike Lorentz microscopy in a transmission electron microscope, the geometry of scanning electron microscopy permits alignment of the incident beam and the detection system along arbitrary angles to the surface normal, and thus investigation of the magnetization distribution at an angle to the surface normal becomes easier.

More recently, rather than observing the Lorentz deflection of secondary electrons in a scanning electron microscope, the idea of observing their polarization has attracted considerable attention [12.115]. The alignment of magnetization vectors in different domains on the surface of the ferromagnetic sample is different; hence, polarization of backscattered electrons occurs

Fig. 12.8a,b Schematic showing geometrical configuration of a scanning electron microscope for detection of Lorentz deflection. **(a)** The field inside the domains gives rise to Lorentz deflection; magnetization is parallel to the surface. **(b)** The field outside the sample gives rise to Lorentz deflection; magnetization is normal to the surface (after [12.10])

Fig. 12.9a,b Schematic showing **(a)** the formation of electron hologram and **(b)** the formation of contour maps and Lorentz images, using optical image reconstruction from the hologram (after [12.10])

in different directions. The difference in magnetization distributions between different surface domains contributes to the image contrast.

To form images of magnetic domains and domain walls, the instrumentation in a field-emission scanning electron microscope needs to be augmented.

A Mott detector and a quadrant electron detector [12.10] are included for spin-polarization analysis and image reconstruction, respectively. This setup allows observation of surface domain configurations in thin-film recording heads and other applications where surface magnetism is important.

Fig. 12.10a–c Schematic showing (a) the magnetization distribution on surface domains and tip geometry in a magnetic force microscope, (b) the calculated magnetic dipolar force between the tip and the sample, and (c) the force gradient corresponding to (b) (after [12.10])

Interference Electron Microscopy and Electron Holography

In this technique an electron hologram is formed, which is subsequently optically reconstructed using a laser beam to create Lorentz images [12.10, 111, 116]. An electron biprism is employed to split the incident electron beam. One-half of the beam traverses the regions outside the specimen, while the other half passes through the specimen. Interference between these two beams gives rise to the formation of the electron hologram. Figure 12.9a,b schematically represent the processes of hologram formation and optical reconstruction, respectively [12.117]. Optically reconstructed images yield counter maps which provide quantitative information about the distribution

of magnetic lines of force. This technique usually has the disadvantages [12.10] that it does not permit high holographic spatial resolution (≈ 5 nm) and the maximum thickness of the specimen that can be examined by this technique does not usually exceed several tens of nanometers.

Atomic Force Microscopy

In this technique a sharp ferromagnetic tip is scanned across the surface of the specimen, which contains domain walls [12.117–121]. The tip is usually made up of nickel and is attached to a small cantilever. When the tip scans different regions of the surface of the magnetic specimen, the force and the force gradient on the tip change, depending upon the local magnetization distribution. These changes directly correspond to the actual domain distribution on the surface; the relationship between the two [12.10] is shown in Fig. 12.10. A modification of the atomic force microscopy (AFM) technique is magnetic force microscopy (MFM) [12.112, 122–124], in which the tip is maintained at a constant distance from the sample surface and the change in the force on the cantilever spring required to maintain this constant distance is measured and plotted.

The instrumentation of scanning tunneling microscope has been improved, and it has been demonstrated that in the field-emission mode it can provide resolution of 2–3 nm [12.120]. The secondary electrons emitted from the surface of the ferromagnetic sample can subsequently be analyzed using a Mott detector, and images can be formed using spin-polarized electrons.

Magnetic Structures by Transmission Electron Microscopy

Lorentz images are formed in a transmission electron microscope, when the electron beam is deflected by in-plane magnetization vectors that change in direction as well as in magnitude [12.110]. In a cluster of crystals, deflection of the electron beam by the in-plane component of magnetization is usually dominated by those crystals which have nearly horizontally oriented magnetization vectors. Such clusters of crystals interact with the incident electron beam as though they were a single domain separated from the adjacent domains by a domain wall.

A drawback of this technique [12.10] is that it cannot provide quantitative information about domain wall thickness, since precise representation of magnetization vectors or anisotropy constants of individual crystals is not usually possible in Lorentz images. This issue,

Fig. 12.11 Cross-sectional (parallel to the press axis) transmission electron micrograph of a die-upset Nd-Fe-B magnet showing a stack of platelet-shaped $\text{Nd}_2\text{Fe}_{14}\text{B}$ crystals; *arrows* indicate the Nd-rich phase surrounding these crystals (after [12.10]) ▶

however, can be resolved, and equilibrium domain wall thickness can be determined with good accuracy using specimens comprising large crystals, having preferred orientation in a given direction.

The cross-sectional transmission electron micrograph in Fig. 12.11 shows oriented platelet-shaped $\text{Nd}_2\text{Fe}_{14}\text{B}$ crystals [12.10]. The sample is an Nd-Fe-B magnet, consolidated by die-upsetting and sectioned parallel to the press axis. The Lorentz microscopy micrograph corresponding to this microstructure is shown in Fig. 12.12. By combining the information in Figs. 12.11 and 12.12, the hysteresis behavior of the ferromagnetic material during cyclic magnetization–demagnetization processes can be understood.

The alignment of the magnetization vectors in platelet-shaped $\text{Nd}_2\text{Fe}_{14}\text{B}$ crystals is parallel or antiparallel. The domain walls separating domains of opposite magnetizations pass through a number of grains. These walls have a zigzag shape owing to local pinning but otherwise cross from grain to grain easily. To obtain a quantitative measurement of domain wall width from the wall width measurements in Fig. 12.12, it is necessary to compute the wall image profile from saturation magnetization data and microscope operating parameters for the specific specimen thickness and orientation [12.10].

The advantage of Lorentz microscopy is that it can be combined with other imaging modes of TEM to obtain crystallographic and magnetic information simultaneously. This combined information is often essential to reveal the correlation between the magnetic domains and crystallographic microstructures, and it has led to significant progress, e.g., in the field of ferromagnetic shape-memory alloys (SMAs) [12.111, 125–127], which provide large magnetostriction under an applied magnetic field. Similarly, the combination of Lorentz microscopy with conductivity measurements provides an effective method for determination of physical properties of transition-metal oxides in which the magnetic structure can have considerable effect on conductivity. A new TEM-based system for conductivity measurements, which can be combined with Lorentz microscopy, has recently been developed [12.111] to undertake such investigations.

Fig. 12.12 Lorentz microscopy micrograph showing the magnetic structure of a die-upset Nd-Fe-B magnet. The micrograph was taken in Fresnel mode showing domain walls oriented at 180° and defocused crystals as in Fig. 12.11. The vertical domain walls, designated by “w”, change their shape as they get pinned while passing near the crystal edges; other walls, however, move from one crystal to the next without interruption (after [12.10])

12.4.3 Hard Magnetic Nanostructures

The hard magnetic nanostructures discussed in this section are based on FePt and rare-earth transition metal-based NdFeB hard magnetic materials. In light of their important magnetic properties and applications, the following section focuses on synthesis processes of nanostructured FePt, FePt/FeCo, Nd-Fe-B, and Nd-Fe-B/FeCo hard magnetic materials. Their compositional, morphological, and magnetic properties are discussed. Magnetic properties of exchange-coupled–decoupled nanostructured materials are also discussed.

Nanoparticles and Nanowires

Due to their potential applications in multi-terabit data storage, ferrofluids, and high-energy-density permanent magnets, nanoparticles of ferromagnetic materials have received immense research interest. Magnetic nanoparticle synthesis of hard magnetic FePt, and Nd₂Fe₁₄B (high magnetocrystalline anisotropy) alloys has been carried out by several methods [12.90, 94, 102, 103]; however, reports on Nd-Fe-B nanoparticles showed much lower room-temperature coercivity than expected for perfectly exchange-coupled nanoparticles due to their relatively large crystal size, structural inhomogeneity, and sometimes chemical instability [12.94].

There are a number of reports on chemical synthesis of FePt nanostructures [12.92, 102, 128–131].

Fig. 12.13 Room-temperature hysteresis of FePt-SiO₂ core-shell (after [12.128])

As-synthesized FePt possesses the low-coercivity face-centered cubic (fcc) crystal structure. When heated to transform from fcc to face-centered tetragonal (fct) with high magnetocrystalline anisotropy, nanoparticle agglomeration occurs [12.129]. By controlling the synthesis parameters and using surfactant, Sun et al. [12.102] prepared FePt particles with tuneable size of 3–10 nm. Magnetic properties such as coercivity, which reflects the extrinsic and intrinsic properties of magnetic materials, are size dependent. The maximum coercivity is observed near the single-domain size (Stoner–Wohlfarth particle).

Measurements of magnetic properties show that coercivity increases after annealing and due to the phase transformation from fcc to high-anisotropy fct structure (Fig. 12.13) [12.102, 128, 129]. There have been efforts to reduce the phase transformation temperature and conduct annealing in a salt matrix to reduce particle agglomeration [12.130–132]. To retain the particle ordering, a capping material can be attached to the FePt nanoparticles [12.128].

FePt nanowires have also been synthesized by template-supported electrodeposition [12.132, 133]; however, the coercivity observed was lower than the expected value in spite of the fact that nanowires possessed shape anisotropy [12.134, 135]. Coercivity of 25 kOe was observed in randomly oriented nanocrystals, indicating high magnetocrystalline anisotropy [12.134], but this is much lower than the coercivity value of 100 kOe for randomly distributed Stoner–Wohlfarth FePt particles [12.135]. This large discrepancy in coercivity suggests incomplete atomic ordering of fcc to fct [12.135]. It could also be due to a large contribution from exchange interactions within nanowires and dipole–dipole interactions between two different nanowires [12.136].

The interparticle interactions (exchange/dipole–dipole), can be determined by calculating δM [12.137, 138], defined as

$$\delta M = \left(\frac{M_d(H)}{M_r(\infty)} \right) - \left(1 - 2 \times \frac{M_r(H)}{M_r(\infty)} \right). \quad (12.36)$$

For noninteracting single-domain particles, δM is zero [12.137]. If δM is positive, the interparticle interaction is exchange coupling, while negative δM suggests that magnetostatic interaction is dominant. Annealing of assembled FePt nanoparticles leads to a decrease in interparticle spacing and formation of polycrystalline aggregates, due to which magnetic interactions switch from magnetostatic to exchange coupling and remanent magnetization is enhanced [12.139].

Fig. 12.14a–c TEM micrographs of $\text{Fe}_{46}\text{Pt}_{54}$ annealed at (a) 600 °C, (b) 650 °C, and (c) δM plot (after [12.140]) ►

Ordered FePt nanocrystals, synthesized by *Lu et al.* and *Gao et al.* [12.140, 141], showed coercivity of 10 kOe. A negative value of δM (Fig. 12.14c) for annealed FePt suggests the absence of exchange coupling, indicating well-separated ordered nanoparticles; TEM micrographs (Fig. 12.14a,b) substantiated this fact [12.140]. As the separation between particles increases, the particles are less affected by interparticle interactions and approach the Stoner–Wohlfarth condition, resulting in high coercivity [12.135].

Nanowires. Shape control of nanoparticles such as nanowires and nanotubes provides an opportunity to tune shape anisotropy. Progress in experimental techniques has made it possible to synthesize nanowires with high aspect ratio. Among the methods used for fabrication of nanowire arrays, template-assisted electrodeposition is a low-cost and high-yield technique, and FePt nanowire preparation by electrodeposition and solvothermal synthesis has been reported [12.134, 142–146]; due to the high reduction potential of Nd, however, it is difficult to synthesize $\text{Nd}_2\text{Fe}_{14}\text{B}$ nanowires by electrodeposition.

In the solvothermal synthesis process, by controlling the surfactant concentration, different shapes and sizes of FePt nanoparticles can be synthesized (Fig. 12.15) [12.134]. Due to the high anisotropy of nanowires, high coercivity of FePt nanowires is expected. However, the coercivity observed is much smaller than the anisotropy field [12.134, 144], suggesting that magnetization rotation is not coherent but involves domain nucleation and domain wall motion.

The coercivity/magnetization reversal mechanism of nanowires is different from that of the bulk. The easy magnetization direction of nanowires is along the nanowire axes, and the overall magnetic anisotropy is dominated by the shape anisotropy [12.147]. Hysteresis loops exhibit greater squareness for fields applied parallel to the nanowire arrays compared with when the applied field is perpendicular. However, *Cagon et al.* [12.144] observed no significant difference between curves with the field applied parallel or perpendicular to the wires. The magnetization reversal and coercivity of the nanowires are sensitive to the nanowire diameter [12.136]. Magnetization reversal may occur by coherent rotation, magnetization curling, and buckling. The critical diameter below which coherent rotation oc-

Fig. 12.15a–f FePt prepared by solvothermal synthesis (after [12.134]): (a) wires, (b) nanorods, (c) oval nanoparticles, (d) spherical, (e) nanocube, and (f) multipod

curs is given by [12.136]

$$d_{\text{coh}} = \sqrt{\frac{24A}{\mu_0 M_s^2}}. \quad (12.37)$$

In larger-diameter nanowires, the magnetization reversal process occurs by magnetization curling mode or buckling mode [12.136]. The dependence of coercive fields on diameter is expressed by (12.38) (for the curling mechanism) and (12.39) (for the buckling mechanism) [12.136]

$$H_{\text{cc}} = \frac{2\pi kA}{\mu_0 M_s d^2} + H_a, \quad (12.38)$$

$$H_{\text{cb}} = \frac{2\pi kA}{\mu_0 M_s d^{2/3}} + H_a, \quad (12.39)$$

where A is the exchange stiffness, k is the geometric parameter, and d is the diameter of the nanowires. The

coercivity decreases with increasing wire diameter, irrespective of reversal mechanism (Fig. 12.16) [12.136].

Single-Domain Particles. The critical single-domain radius is an equilibrium property, involving comparison of single-domain state energy with multidomains. Whether the material will be in a single-domain state or a multi-domain state, is determined by the competition between the magnetostatic energy and domain wall energy. The critical radius below which single-domain state is favored is given by

$$R_c = \frac{36\sqrt{A_{\text{ex}}K}}{\mu_0 M_s^2}.$$

Due to the high magnetocrystalline anisotropy K , the critical radius for hard magnetic nanostructures is large. For $\text{Nd}_2\text{Fe}_{14}\text{B}$ the critical radius is 107 nm, while for

Fig. 12.16 Variation of coercivity parallel to c -axis with wire diameter (after [12.136])

FePt it is 340 nm; however, it should be noted that the critical domain size is geometry dependent. Magnetization reversal in single domains is favored by coherent rotation because reversal by nucleation propagation involves the formation of a nonuniform magnetic state similar to magnetic wall formation.

FePt nanoparticles of single-domain size or less, embedded in a carbon matrix, have been prepared by sputtering [12.9, 148]. Coercivity is found to be dependent on layer thickness and annealing temperature, which control the size and interparticle separation. Deposition of Fe and Pt on heated $\text{MgO}/\text{Al}_2\text{O}_3/\text{NaCl}$ substrate by electron beam epitaxy leads to FePt island formation [12.149]. Each island is a single-crystal FePt grain smaller than the single-domain size. By considering a random distribution of noninteracting single-domain particles with uniaxial anisotropy, the coercivity of the particles should follow the relationship $H_c = 2K/(\mu_0 M_s)$; these FePt islands showed extremely high coercivity (> 4 T).

Thin Films

Study of magnetic thin films provides understanding of magnetic properties of nanostructured materials in 2-D systems. The magnetic characteristic length is dependent on the dimensionality as well as on the surface/interface electronic structure, due to which interesting effects are observed. Examples are moment enhancement, surface anisotropy, change in Curie temperature, and thickness-dependent domain wall formation. The electrons are more localized at surfaces or interfaces as compared with the bulk, and moment is enhanced.

The strength of spin-orbit coupling is changed at the surface, hence the surface anisotropy is altered. The interface chemistry controls the magnetic properties by controlling the coupling phenomena. At the interface, due to atomic orbital hybridization, magnetic moment is induced at nonmagnetic elements such as Pd, Pt, etc.

An ideal thin film is characterized by smooth layer-by-layer growth with high degree of epitaxial order and a smooth interface. The interlayer diffusion has to be minimized, and an overlayer of immiscible elements may have to be used to obtain a smooth interface. The technique of RF/magnetron sputtering is usually employed for Nd-Fe-B and FePt thin-film preparation [12.149–152]. Synthesis of FePt thin films with excellent magnetic properties has also been achieved by electrodeposition [12.153, 154].

For thin films with perpendicular magnetic anisotropy, the saturation magnetization in the perpendicular direction is higher than that in the parallel direction. The perpendicular magnetic anisotropy in thin films is thickness dependent and vanishes with increasing film thickness, due to multidomain particle formation at larger thickness [12.155]. At low thickness, Nd-Fe-B films are single domain and magnetization reversal is dominated by coherent rotation of magnetic domains, resulting in high coercivity. However, for larger thickness, the magnetization/demagnetization mechanism is different (domain wall motion) and results in low coercivity [12.155].

The anisotropy strength of film can be expressed by a quality factor Q as [12.156]

$$Q = \frac{K_1}{2\pi M_s^2} \quad (12.40)$$

For Q smaller than 1, the demagnetizing energy exceeds the anisotropy energy and the magnetization vector lies in the film plane; for Q greater than 1, magnetization is out of plane. For soft magnetic materials, anisotropy is small resulting in $Q < 1$, and magnetic anisotropy lies within the plane. However, for hard magnetic materials such as Nd-Fe-B and FePt alloys, the anisotropy energy is high, hence $Q > 1$ and perpendicular anisotropy is observed in an extended thickness range (i. e., 35–1500 nm for Nd-Fe-B) [12.157]. However, Leva et al. [12.156] reported a critical thickness of 30 nm for FePt thin films; below this thickness, magnetization orientation is in plane, while above this thickness it is out of plane.

Liu et al. [12.158] observed that (001) planes of tetragonal $\text{Nd}_2\text{Fe}_{14}\text{B}$ grown on the (110) planes of W exhibit prominent perpendicular magnetic anisotropy

within 30 nm film thickness. Magnetization reversal is dominated by incoherent rotation, resulting in high coercivity. $\text{Nd}_2\text{Fe}_{14}\text{B}$ film deposited on a Mo buffer layer shows coercivity as high as 19.5 kOe when the film thickness is ≤ 8 nm [12.155]. In this thickness range the film consists of a mixture of single- and multiple-domain particles. Below this thickness, particles are single domain and hard to magnetize. The low coercivity at low thickness is attributed to crystal imperfections. The coercivity can be further enhanced by particle isolation [12.155]. Wei and Yao [12.159] reported coercivity enhancement in FePt films by reducing exchange coupling in the presence of a Cu top layer; Cu diffuses into grain boundaries during annealing, and the magnetization reversal mechanism shifts from the domain wall mechanism to coherent rotation. A similar phenomenon was observed by Yan et al. [12.160]. By increasing the silver content in FePt/Ag thin films, the coercivity increases due to exchange decoupling between FePt grains. Magnetic hardening may also arise due to the pinning mechanism caused by crystal imperfections [12.161] or due to nonmagnetic phase formation [12.162].

It is also observed that addition of some nonmagnetic additives to thin films can lead to enhancement of magnetic properties [12.163, 164]. Addition of Nb to Nd-Fe-B thin films resulted in grain refinement [12.163], giving rise to enhanced exchange coupling and remanent magnetization. However, in certain cases, addition of nonmagnetic elements can enhance dipolar interactions; For example, in FePt/C multilayers or in FePt/Cu bilayers [12.135, 164], the layer structure breaks down into a dispersion of FePt particles in the carbon/copper matrix during annealing. In the case of FePt/C multilayer, the particle separation makes dipolar interactions predominant and high coercivity results due to the more Stoner–Wohlfarth particle-like behavior. However, in FePt/Cu bilayers [12.164], Cu addition creates a high density of pinning centers, resulting in coercivity enhancement. Addition of a ferromagnetic layer (e.g., Fe or Co) to Nd-Fe-B or FePt thin films results in interesting magnetic properties due to exchange coupling between the hard and soft phases [12.150, 154, 165].

Exchange-Coupled Nanocomposites

Kneller and Hawig in 1991 put forward the theory of remanence enhancement and high energy product in exchange-coupled hard–soft nanocomposites [12.166]. Remanence enhancement compared with conventional magnet was first reported experimentally by Coehoorn et al. in melt-spun $\text{Nd}_4\text{Fe}_{78}\text{B}_{18}$ alloys [12.167]. The

hard phase with high anisotropy provides high coercivity, and the soft phase provides high saturation magnetization resulting in high energy product. In exchange-coupled nanocomposites, the easy axis of the soft phase aligns with the magnetization direction of the hard phase through exchange interactions, leading to a considerable enhancement of remanent magnetization [12.168]. The remanence of a nanocomposite magnet is given by

$$M_r = f_h M_h + f_s M_s, \quad (12.41)$$

where f_s , f_h and M_s , M_h are the volume fraction and magnetization of the hard and soft phase, respectively. In exchange-coupled magnets, magnetization reversal originates at the soft phase center and propagates towards the hard phase. The magnetization rotation induced in the hard phase due to the soft phase by exchange coupling leads to a decrease in the nucleation field/coercivity. The effective nucleation field is expressed as [12.168]

$$\mu_0 H_n = 2 \frac{f_s K_s + f_h K_h}{f_s M_s + f_h M_h}, \quad (12.42)$$

where f and K represent the volume fraction and anisotropy constant, respectively. When the soft phase size is small enough, the hard phase *stiffens* the magnetization direction of the soft phase and a high nucleation field is needed for demagnetization [12.168]. This results in high remanence and coercivity, and a high energy product.

For exchange coupling to be effective, the grain size of both the hard and soft phases should be of the order of the hard phase domain wall thickness. The ideal microstructure for enhanced exchange coupling is homogeneous precipitates of the hard phase in a soft matrix [12.166]. To obtain the optimum microstructure, melt spinning, mechanical milling, sputtering, electrodeposition, and chemical synthesis methods have been explored in $\text{Nd}_2\text{Fe}_{14}\text{B}/\alpha\text{-Fe}$, $\text{Nd}_2\text{Fe}_{14}\text{B}/\text{FeCo}$, $\text{FePt}/\alpha\text{-Fe}$, and FePt/Co nanocomposites. In $\text{Nd}_2\text{Fe}_{14}\text{B}/\alpha\text{-Fe}$ nanocomposites, the RE content generally has to be reduced compared with the stoichiometric composition (8–12 at.%).

The magnetization reversal process in nanocomposite RE-Fe-B alloys has been proposed to occur by nucleation of reverse domains [12.49]. In melt-spun Nd-Fe-B nanocomposites with nonideal microstructures, the coercive field can be described by a modification of Brown's equation [12.44]

$$\mu_0 H_c = \alpha \frac{2K}{\mu_0 M_s} - N_{\text{eff}} J_s, \quad (12.43)$$

Fig. 12.17 Experimental versus theoretical nucleation field plot for $(Nd_{0.25}Pr_{0.75})_8(Fe_{1-x}Co_x)_{86}B_6$ alloys (after [12.169])

Fig. 12.18 Henkel plot of a $(NdPr)(FeCo)B$ alloy (after [12.169])

where α is a combination of three factors and is given as $\alpha = \alpha_K \alpha_\psi \alpha_{ex}$. α_{ex} results from the influence of exchange coupling on magnetic properties. The value of α_{ex} for melt-spun ribbons can be calculated from the nucleation field plot (Fig. 12.17) [12.171]. It has been observed that the value of α_{ex} depends on the volume fraction of the soft phase, grain size, and grain size distribution [12.169, 171]. With Co addition the value of $\alpha_K \alpha_{ex}$ reduces, indicating enhanced exchange inter-

Fig. 12.19 TEM micrograph of a $Nd_9Fe_{84}Ta_2B_5$ alloy obtained by melt spinning (after [12.170])

actions [12.169]. The improved exchange coupling is attributed to decreased anisotropy constant and hence increased L_{ex} through $L_{ex} = \sqrt{A/K}$.

The strength of coupling between the hard and soft phase can be quantified by using the Henkel plot (Fig. 12.18) [12.169]. The value of δM for the nanocomposite is positive, though much weaker than the single-phase magnet. In composite magnets, after reversal, δM becomes more negative with higher FeCo content; magnetostatic interactions increase with FeCo content. Optimum microstructure for Nd-Fe-B magnet with enhanced exchange coupling can be obtained in optimally quenched melt-spun ribbons (Fig. 12.19) [12.170]; both $Nd_2Fe_{14}B$ and α -Fe phases are almost equal in size (< 50 nm) and are homogeneously distributed. However, size control is difficult when these materials are synthesized by annealing the amorphous precursors; α -Fe grain growth is usually unavoidable due to the large difference in crystallization temperature of $Nd_2Fe_{14}B$ and α -Fe. However, small concentrations of elemental additions have been reported to be useful in grain refining [12.169, 170], resulting in enhanced magnetic properties.

The magnetic properties of exchange-coupled nanocomposite materials depend on microstructure as well as on composition [12.169, 170, 172, 173].

Appropriate choice of composition leads to higher $(BH)_{\max}$, the value depending strongly on the volume fraction of the hard phase and intrinsic properties of the hard phase and the microstructure. Micromagnetic calculations using finite-element analysis can predict quantitative correlations between the microstructure and magnetic properties [12.174, 175]. Exchange spring magnets are characterized by the high degree of reversibility in their demagnetization behavior. The *spring back* phenomenon is observed when the soft phase grain diameter is smaller than $2b_s$, where b_s is given by [12.166]

$$b_s = \pi \sqrt{\frac{A_s}{2K_h}}. \quad (12.44)$$

When the soft phase grain diameter is less than or equal to $2b_s$ (of the order of ≈ 10 nm), strong exchange coupling is observed. Another interesting property observed is the Curie temperature enhancement of the hard phase due to exchange coupling [12.176, 177]. For an ideal exchange-coupled composite (hard phase precipitation in soft phase matrix), the effective anisotropy is (for grain size smaller than 40 nm) [12.178]

$$\langle K \rangle = K_1 v \left(\frac{D}{L_0} \right)^6, \quad (12.45)$$

where L_0 is the intrinsic exchange length, and D and v are the grain diameter and volume fraction of the hard phase. By decreasing the grain diameter D and volume fraction, $\langle K \rangle$ will decrease and in turn the exchange length ($L_{\text{ex}} = \sqrt{A/\langle K \rangle}$) will increase, enhancing the exchange coupling between the hard and soft phase. The amorphous phase at the grain boundaries decreases the effective anisotropy through the random anisotropy effect. Hence, an enhanced exchange coupling is observed [12.178]. This is true for small grain sizes (≤ 40 nm), but when the grain diameter is greater than 50 nm, dipolar interactions play a major role in the demagnetization of the exchange-coupled magnet. Due to its large size, the magnetization at the center of the soft phase is not aligned with the hard easy axis. In such a situation, the coercivity is decreased due to the low nucleation field of the soft phase and demagnetization pinning at hard-soft interfaces [12.175].

Nanocomposite Bulk Metallic Glasses. Bulk metallic ferromagnets are a novel group of engineering materials having unique mechanical, thermal, and magnetic properties. Devitrification of bulk metallic glass (BMG) precursors is another simple technique to prepare nanocomposite magnetic alloys [12.172, 179–181].

This process is used to prepare high-density nanocomposites with unique magnetic properties, unlike other techniques where magnetic properties can degrade during consolidation [12.172]. To fabricate bulk metallic glass by this method a high glass formability has to be achieved. To the mother alloy system of Nd-Fe-B, different elements with large lattice parameter variation are added to increase the glass formability. However, in these systems due to low rare-earth content, the mass fraction of hard phase as well as the coercivity observed are low. The rare-earth content can be increased but at the cost of glass formability [12.179].

Thin-Film Nanocomposites. A simple approach to produce exchange-coupled nanocomposites in the FePt/ α -Fe and FePt/Co systems is to use multilayers of the hard and soft phases [12.172, 182, 183]. In FePt thin films, the FePt/Fe multilayers, due to the higher degree of chemical homogeneity in their microstructure, produce better exchange coupling than the Fe/Pt multilayers [12.182]. Coercivity increases with decreasing thickness of the Fe layers. Theoretical calculations predict a high anisotropy, high coercivity, and thereby an enhanced energy product of ≈ 700 kJ/m³ for 8 nm α -Fe in an aligned FePt matrix [12.166, 172, 184].

During the last decade, considerable effort has been made to synthesize thin-film nanocomposites based on Nd-Fe-B and FePt alloys [12.150, 165, 172, 182–187]. The nature of interlayer coupling investigated by Henkel plots [12.150, 186] revealed that, in Nd-Fe-B and FePt thin films, as in bulk composites, the coupling is dominated by exchange interactions. Sun et al. observed that the degree of this exchange coupling depends on the thickness of the soft layer [12.188].

12.4.4 Soft Magnetic Nanostructures

Soft magnetic materials can be readily magnetized and demagnetized. Their applications fall in the areas where there is a requirement to enhance and/or channel the flux produced by an AC/DC current. In DC applications the material is magnetized, and as a result it performs an operation; when the operation is complete, it is demagnetized. In AC applications, however, the material is first magnetized in one direction and then in the other; this cycle is continued throughout the period of operation [12.189–192].

For such applications the material should have high saturation magnetization and the ability to respond promptly to an external applied magnetic field, being characterized by high permeability. Moreover, for

AC applications, the energy loss encountered while the material is continuously cycled around its hysteresis loop should also be minimized [12.193]. This energy loss, apart from hysteresis loss, stems from two more sources:

1. Eddy current loss, which is the result of flux-induced electric currents in the magnetic material and the concomitant resistive losses
2. Anomalous loss, which is attributed to energy loss arising from the motion of domain walls.

Eddy current losses can obviously be minimized by decreasing the electrical conductivity; however, to reduce hysteresis and anomalous losses, the intrinsic coercivity of the material and the hindrance to motion of domain walls should be reduced [12.194].

The performance of soft magnetic materials is therefore characterized by high combined permeability and magnetization and low values of coercivity and energy losses arising from hysteresis, eddy current, and anomalous effects [12.195]. For high permeability, the microstructure should facilitate easy domain wall motion as well as easy rotation of magnetic moments. These requirements result in the demand for low magnetocrystalline anisotropy energy and low magnetostriction in a soft magnetic material. Low magnetic anisotropy leads to easy saturation in magnetization, while low domain wall energy results in small pinning forces and thereby low coercivity [12.196–198].

Soft magnetic materials used in industrial settings should also have good mechanical properties and corrosion resistance, and may be required to retain these properties at high temperatures [12.199]. Most of these properties are a function of alloy composition, crystal structure, and microstructural features; hence, to fabricate soft magnetic materials with good properties, factors pertaining to alloy chemistry, atomic structure, and alloy microstructure must be optimized [12.200].

It is usually difficult to meet all the different requirements for soft magnetic materials described above; this limits the alloy selection, and there are only a few classes of materials which fulfill these criteria. Transition metals (TM) and alloys, such as body-centered cubic (bcc) Fe, face-centered cubic (fcc) α -Co, Fe-Si, and Fe-Co alloys, have received considerable attention due to their high magnetizations and high Curie temperatures [12.201–205]. However, the permeabilities of these alloys are smaller compared with those of corresponding nanocrystalline/nanocomposite (nanocrystalline–amorphous) alloys; hence, the choice of soft magnetic materials has been dictated by de-

velopments in the field of TM-based metallic glasses and nanostructured alloys. The overall soft magnetic properties of the Co- and Fe-based amorphous and nanocrystalline alloys developed during the past decade now exceed those of the counterpart bulk metals and alloys [12.189].

Nanocrystalline Soft Magnetic Alloys

The composition of soft magnetic nanocrystalline alloys is generally represented using the formula $TL_{1-x-y-z}TE_xM_yNM_z$, where TL, TE, M, and NM indicate a late ferromagnetic transition-metal element (TL = Co, Ni, or Fe), an early transition-metal element (TE = Zr, Nb, Hf, Ta, etc.), a metalloid (M = B, P, Si, etc.), and a noble metal (NM), respectively. The rationale for adding TE and M elements is to promote the glass-forming ability, while the NM elements are added to provide nucleation sites for the ferromagnetic nanocrystalline phase. TE elements are also known to act as growth inhibitors [12.189].

The soft magnetic nanocrystalline alloys are broadly classified into two types [12.189]. Type I corresponds to single-phase ferromagnetic nanocrystalline alloys. Type II alloys, on the other hand, comprise two phases; one phase is a nanocrystalline ferromagnet, while the second phase is the residual amorphous phase at the grain boundaries. Figure 12.20 compares the performance of some important soft magnetic materials on the basis of magnetic permeability and saturation magnetization. It is clear from this comparison that TM-based nanocrystalline alloys (both type I and type II alloys) are superior to other alloys such as Mn-Zn ferrites, as well as the counterpart bulk or amorphous alloys, since they simultaneously exhibit relatively large values of magnetic permeability and saturation magnetization. The enhanced soft magnetic properties of such alloys are usually attributed to the synergistic effect of refined grain size, the intergranular amorphous matrix phase, and the composition of each phase [12.206].

Yoshizawa and coworkers [12.207–210] and Naitoh et al. [12.211] developed nanocrystalline alloys having excellent soft magnetic properties with low coercivity (< 2 A/m), near-zero magnetostriction coefficients, and saturation magnetization of more than 1.3 T. The magnetic properties of these novel Fe-Si-B-Nb-Cu alloys were comparable to those of commercial Co-based amorphous alloys which possessed excellent magnetic softness. Another great advantage of these alloys was that they had Fe-rich compositions leading to a huge reduction in costs compared with the expensive Co-based amorphous alloys.

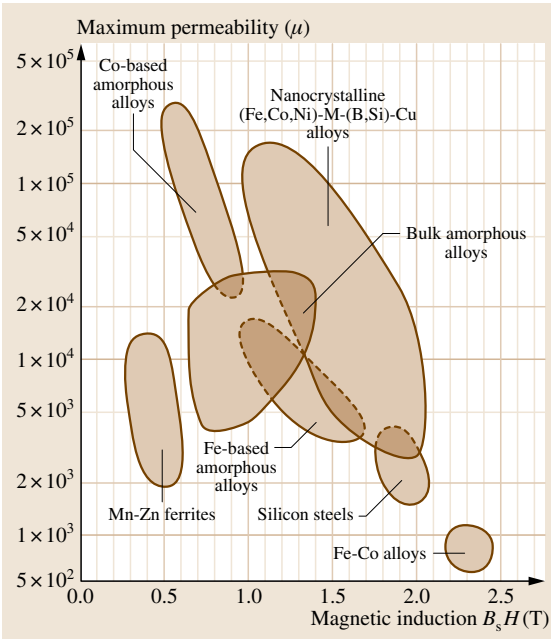

Fig. 12.20 Magnetic permeability plotted against saturation magnetization ($\mu_0 M_s$) for some important soft magnetic materials (after [12.189])

These alloys were patented under the trade name Finemet. The nominal composition of these alloys was optimized to obtain high glass formability and to control the nucleation and growth kinetics of the nanocrystalline phase, leading to lower Fe concentration and high B concentration, with addition of a different non-magnetic element such as Nb and Cu, respectively, which resulted in a decrease in saturation magnetization [12.207–211].

Inoue and coworkers developed a different class of Fe-based nanocrystalline alloys based on the Fe-Zr-B system. These alloys, which were patented under the trade name Nanoperm, had larger concentrations of Fe (83–89 at.%) compared with the Finemet alloys (≈ 74 at. % Fe), and as a result they exhibited much higher values of saturation magnetization

(≈ 1.6 – 1.7 T) [12.211,213,214]. Nanoperm alloys also showed low magnetostriction coefficient, high permeability, and very low energy losses at power frequencies (60 Hz), making them promising candidate soft magnets for use in electrical power distribution transformers. The synthesis of nanocrystalline Hitperm alloys was the next development in this field. These (Fe,Co)-TE-B-Cu (TE = Nb, Hf, or Zr) based alloys, showed relatively low permeability but high Curie temperatures combined with high saturation magnetization [12.211,213,214].

Alloy Chemistry and Microstructure of Nanocrystalline Soft Magnetic Alloys

The magnetic properties exhibited by these various nanocrystalline alloys depend on the phase composition and microstructural features. Both Finemet and Nanoperm alloys comprise a grain boundary amorphous phase along with nanocrystals: ≈ 15 nm α -FeSi nanocrystals with a DO₃ structure in Finemet alloy and ≈ 25 nm α -Fe nanocrystals with a bcc structure in Nanoperm alloy [12.215]. Table 12.3 presents the nanocrystalline phases as well as saturation induction and Curie temperature of Finemet, Nanoperm, and Hitperm alloys.

The grain boundary amorphous phase facilitates exchange interactions between the nanocrystals, resulting in high saturation magnetization. When this amorphous phase is not present to envelope the nanocrystals, they become magnetically decoupled, leading to deterioration in magnetic properties. Thus, an optimum grain size and the degree of encapsulation of nanocrystals by the amorphous phase play a key role in determining the efficiency of the spatial averaging of anisotropy, which in turn governs the soft magnetic behavior. Figure 12.21, which is a field ion image of an annealed Finemet alloy, shows the encapsulation of nanocrystals by the grain boundary amorphous phase [12.189, 215].

Thus, enhancement in soft ferromagnetic properties of nanocrystalline materials can be achieved by tailoring the alloy chemistry and optimizing the microstructure, which involves the creation of appropriate

Table 12.3 Typical composition, saturation induction, and Curie temperature of various nanocrystalline soft magnetic alloys (after [12.212])

Alloy name	Typical composition	Primary phase	Saturation induction (T)	Curie temperature (°C)
Finemet	Fe _{73.5} Si _{13.5} B ₉ Nb ₃ Cu ₁	α -FeSi (DO ₃)	1.0–1.2	< 770
Finemet2	Fe _{76.9} Si ₁₁ B ₉ Nb _{2.5} Cu _{0.6}	α -FeSi (DO ₃)	1.45	< 770
Nanoperm	Fe ₈₉ Zr ₇ B ₄	α -Fe	1.5–1.8	770
Hitperm	Fe ₈₉ Zr ₇ B ₄	α -FeCo (B2)	1.6–2.1	> 965

interfaces and crystal size reduction. When the crystal size exceeds the domain wall thickness, grain boundaries cause hindrance in domain wall motion, resulting in high intrinsic coercivity. However, when the crystal size is smaller than the domain wall thickness, fluctuations in magnetic anisotropy on the crystal size length scale become irrelevant to domain wall pinning, and as a result intrinsic coercivity decreases rapidly with decreasing crystal size. This explains why nanocrystalline and amorphous alloys have significant potential as soft magnetic materials [12.189].

The degree of the intergrain exchange coupling, which determines the saturation magnetization of soft nanocrystalline materials, can be enhanced by creating a grain boundary amorphous phase, as well as by increasing the interaction volume by consolidating free-standing nanoparticles. *Kojima et al.* [12.217] were the first to report compaction of $\text{Fe}_{84}\text{Nb}_7\text{B}_9$ and $\text{Fe}_{90}\text{Zr}_7\text{B}_3$ alloys using the warm extrusion technique at high temperature (300–500 °C) and pressure (800–1200 MPa). To avoid coarsening of nanocrystals due to the high temperature, *Kojima et al.* in a subsequent report [12.218] employed spark plasma sintering and were able to consolidate the $\text{Fe}_{90}\text{Zr}_7\text{B}_3$ alloy at a much lower temperature of ≈ 600 °C. More recently, there have been several reports [12.219, 220] on consolidation of soft nanocrystalline materials employing rapid consolidation at ultrahigh pressure (≈ 5 –6 GPa).

This method has been reported to achieve better size control of the nanocrystalline phase (10–16 nm), as well as high relative density ($\approx 98.3\%$). Both conventional and novel consolidation methods take advantage of the flow behavior of amorphous alloys, which tend to soften in the vicinity of the crystallization temperature.

Thin-Film Nanocrystalline Soft Magnetic Alloys

Thin films and multilayer structures permit more flexibility in terms of alloy chemistry, and as a result considerable efforts have been made to synthesize such structures to explore a wider range of alloy compositions and magnetic properties [12.221]. These systems are particularly promising for magnetic storage devices and other micromagnetic device applications such as passive circuit elements, micromagnetic sensors, and read/write heads for magnetic disk memories. Along with high saturation magnetization and high permeability, another important property for high-frequency applications is high ferromagnetic resonance (FMR). FMR is defined as the maximum permissible frequency at which the film can be used in an inductive device [12.222].

Fig. 12.21 Ne field ion image of $\text{Fe}_{73.5}\text{Si}_{13.5}\text{B}_9\text{Nb}_3\text{Cu}_1$ melt-spun alloy annealed at 500 °C for 60 min. Dark and bright areas correspond to the bcc-FeSi nanocrystalline particles and the residual/amorphous matrix phase, respectively (after [12.216])

Using sputtering, *Klemmer et al.* [12.223] synthesized magnetically soft amorphous FeCoB thin films, having low coercivity (1–2 Oe) and high saturation magnetization of 17.5 kG. Interestingly, the anisotropy field of the films was found to be a function of the target–substrate arrangement, and samples sputtered using an oblique incidence configuration were found to have an additional anisotropy component. While this additional anisotropy did not influence the coercivity and resulted in a decrease in permeability, it allowed the synthesis of thin films with FMR values lying beyond 1 GHz.

FeXN (X = Hf, Ta, Al, Rh) thin films with nanocrystalline structure have also been thoroughly investigated as promising soft materials for high-frequency applications [12.224–226]. Nitrogen diffuses into 3d metals and 3d–4f intermetallic compounds as an interstitial atom, leading to lattice expansion and concomitant enhancement in ferromagnetic properties. The as-deposited films are amorphous, and usually the desired magnetic properties are only obtained after annealing, which results in the formation of α -Fe nanocrystals. Transition-metal nitrides are also formed during annealing and act as nucleation sites and/or pinning sites which impede crystal growth.

Using magnetron sputtering, Kim et al. [12.226] synthesized a series of FeN and FeXN (X = Ti, Al, Hf, CoHf, CrHf) thin films having good soft magnetic properties with low coercivity (< 2 Oe) and high saturation magnetization (15–20 kG). Shin et al. [12.227] reported synthesis of Fe-Co-Ta-N soft magnetic thin films with thickness of 250 nm, which exhibited high saturation magnetization (21 kG), low coercivity (< 3 Oe), and good high-frequency characteristics. Pan and Du [12.228] fabricated nanocrystalline (FeCo/CoNbZr)_n and (FeCo/CoZr)_n multilayers by sputtering; magnetic annealing of these structures yielded excellent saturation magnetization (22.5 kG), low coercivity, and good high-frequency performance. On the basis of cross-sectional transmission electron microscopy, the authors suggested that the soft magnetic Co-M (M = Zr, Nb, etc.) amorphous layers play two roles:

1. They act as pinning sites, which helps to control crystal growth.
2. They encapsulate the FeCo layers, resulting in enhanced exchange coupling and thereby high saturation magnetization.

More recently, Greve et al. [12.229] explored the possibility of using hybrid materials, consisting of metal nanoparticles dispersed in a dielectric matrix, as soft ferromagnetic materials. They reported synthesis of thin multilayer films of sputtered polytetrafluoroethylene (Teflon) and Fe₅₄Ni₂₇Co₁₉ with different layer thicknesses using the vapor-phase tandem deposition technique. The films showed excellent FMR values ranging from 3.0 to 4.7 GHz, with almost negligible losses up to 700 MHz.

Synthesis of Nanocrystalline Soft Magnetic Alloys

Synthesis of amorphous and nanocrystalline soft magnetic alloys requires an appropriate processing method able to drive the initial polycrystalline material to an amorphous state without oxidation/contamination, preferably with minimum processing steps. A brief description of the synthesis routes that have been employed to produce such alloys is given below:

1. Powder synthesis techniques: These techniques, (e.g., carbon-arc synthesis, plasma torch synthesis, gas atomization, and mechanical milling) can be used to produce nanocrystalline soft magnetic alloys in the form of freestanding powders or nanocapsulates. The as-synthesized materials, however,

subsequently need to be consolidated to reduce porosity and increase relative density while retaining their nanocrystalline structure [12.221].

2. Rapid solidification processing: Rapid solidification techniques (e.g., splat quenching, melt spinning) involve fast quenching from the liquid melt and can be used to produce amorphous alloys in the form of ribbons. These ribbons are then pulverized and consolidated to manufacture magnets of desired shapes. The as-quenched ribbon is sometimes also used as a precursor; annealing of this ribbon yields the desired nanostructure [12.222].
3. Conventional solidification processing of bulk amorphous alloys: Metallic amorphous materials having larger dimensions (1–4 mm) than the thickness of rapidly solidified ribbon (10⁻⁶ μm) are termed bulk amorphous alloys. The chemistry of these alloys is optimized to provide them with very high glass-forming ability; hence, their solidification requires slower cooling rates, and they can be cast by the conventional solidification techniques (e.g., suction casting). The demand for high glass-forming ability results in the requirement for adding high concentration of metalloids such as B and Si, as well as heavy elements such as Zr and Nb, leading to a decrease in saturation magnetization [12.223].

12.4.5 GMR and Spin Valves

GMR is the change in electrical resistance in response to an applied magnetic field and was first discovered in an epitaxially grown Fe-Cr multilayer by Fert [12.230]. When two ferromagnetic layers separated by a nonmagnetic layer are coupled (ferromagnetic/antiferromagnetic coupling), the phenomenon of GMR is observed (Fig. 12.22a). The GMR effect is also observed in magnetic multilayers of varying co-

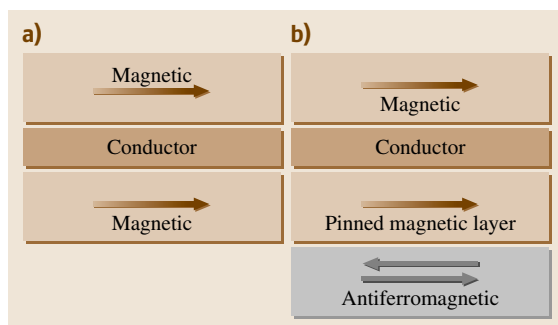

Fig. 12.22a,b Basic structure of (a) GMR and (b) spin valves

ercivities [12.230, 231]. In spin valves, an additional antiferromagnetic (pinning) layer is added to the top or bottom part of the structure (Fig. 12.22b). The magnetization direction of the pinned layer is fixed by the exchange-coupling field from the antiferromagnetic layer.

The electric current in a magnetic multilayer consisting of thin magnetic layers separated by a thin nonmagnetic metallic layer is strongly influenced by the relative orientation of the magnetization of the magnetic layers. When the two magnetic layers are ferromagnetically coupled, the electrical resistance will be lower than if they are coupled antiferromagnetically. When ferromagnetic films are separated by a metallic spacer layer, the magnetizations of the layers are coupled to each other by an exchange interaction through the electrons of the spacer layer. This coupling is known as the Rudermann–Kittel–Kasuya–Yosida (RKKY) interaction [12.28].

The cause of this giant variation of the resistance is the scattering of electrons at the layer interfaces. The change of electrical resistance ($\Delta R/R$) can be tailored by changing the layer thickness. In such multilayers, the resistance of current in the plane (CIP) is found to be much larger than current perpendicular to the plane (CPP). Current in-the-plane (CIP) GMR is most commonly used in magnetic read heads, whereas current perpendicular-to-the-plane (CPP) GMR is the basis of tunnel magnetoresistance (TMR). In spin valves, the free layer magnetization rotates depending on the input signal and changes the electrical resistance accordingly [12.232].

There are several potential applications of devices based on GMR or spin valves, such as magnetic field sensors, read heads, and random-access memories [12.232–237]. Spin valve-based read heads have shown much promise for achieving magnetic recording beyond 100 Gbit/inch² [12.233]. Magnetic field sensors based on GMR can also be used in position detection, e.g., distance, speed, angle, and angular speed [12.234]. GMR has also found several applications in biomedical engineering such as in magnetic switches [12.237] and biosensors [12.238].

12.4.6 Applications

Magnetic nanostructures have a number of potential applications in various diverse fields; for example, magnetic thin films with magnetization perpendicular to the plane are potential candidate recording media; perpendicular magnetization allows smaller domains and

bit size and increases data storage density. Moreover, Kerr rotation of polarized light is larger when the magnetization is perpendicular to the plane compared with in-plane magnetization; this property is used in high-density magneto-optical recording. A new class of applications is magnetic random-access memory (MRAM), which consists of magnetic tunnel junctions; each tunnel junction is one bit. MRAM is faster than semiconductor RAM and is nonvolatile. Functionalized magnetic nanostructures also have important biological applications such as in drug targeting, gene delivery, hyperthermia, MRI, magnetic cell sorting, etc. Another interesting application is the magnetic tweezers used to manipulate molecules and thereby investigate intermolecular interactions.

Data Storage

Important applications in magnetic data storage are to write, store, and read magnetic information in recording media. With the advent of nanostructured magnetic materials, data storage has been advancing rapidly. Storage densities in hard disk drives continue to increase, aiming to reach 1 Tbit/inch². The write head aligns the spins of the grains into tiny patches; data are stored as the magnetic moment orientation of these patches, being termed a bit. Increasing the areal density requires the bit size to be as small as possible. The bit length a depends on the thickness δ , remanence magnetization M_r , and the coercivity H_c of the material and is expressed as $a = \delta M_r / (2\pi H_c)$.

For the bit size to be small, the coercivity H_c must be high and the product of remanence and thickness (δM_r) must be small. At the same time, high remanence is required to ensure a sufficient readout signal. With nanostructuring, it has become possible to optimize these parameters. The current research focus is in perpendicular recording media, patterned media, hybrid recording, and self-organized magnetic arrays [12.102, 239–242]. In perpendicular recording media the easy axis of magnetization is perpendicular to the film surface. Uniform easy axis orientation and high thermal stability would permit higher data densities [12.242]. The stability of magnetization orientation of each bit depends on the anisotropy constant K and volume V . The magnetization becomes unstable when the anisotropy energy of the bit becomes comparable to the thermal energy ($KV = k_B T$), i. e., at the superparamagnetic limit, resulting in loss of data. Single-domain particle magnetism plays an important role in the field of magnetic recording; the thermal stability limit for magnetic recording is $KV > 25k_B T$ [12.9].

To bypass this superparamagnetic limit, use of discrete patterned media of highly anisotropic magnetic materials is required. Permanent magnets such as $\text{Nd}_2\text{Fe}_{14}\text{B}$, SmCo , and FePt can support data storage at grain size as low as 2.5 nm without thermal loss. However, the high coercivity of these materials can inhibit writing the data bits; **GMR** or spin valve is a potential solution to this problem.

Sun et al. [12.102] demonstrated that assemblies of high-coercivity FePt of ≈ 4 nm size can support stable magnetization, a future hope for multi-terabit data storage. The key requirement for technical applications of this approach is long-range order of self-assembly. For good signal-to-noise ratio (**SNR**), grains need to be small, isolated (to reduce exchange coupling), and uniformly distributed. To achieve high **SNR**, antiferromagnetically coupled (**AFC**) media have been developed. **AFC** media are composed of two magnetic layers antiferromagnetically coupled through a non-magnetic layer to improve thermal stability and thereby increase storage density [12.242].

Environmental Applications

Functionalized magnetic nanomaterials have been developed for removal of pollutants such as heavy ions (Cd^{2+} , Cu^{2+} , and Hg^{2+}), radioactive pollutants, and organic pollutants such as organic dyes, pesticides, and drugs from the environment [12.21, 243, 244]. Extraction of environmental pollutants by magnetic nanomaterials involves capture of the pollutant and its subsequent manipulation by external magnetic fields. The bonding between pollutant and magnetic nanoparticles is based on hydrophobic interactions, electrostatic attraction, and/or covalent bond formation [12.243]. The pollutants adsorbed on the surface are released by ligand or H exchange or by adding organic solvent or acid. Magnetic nanoparticles containing thiol groups at the surface easily bind heavy-metal ions by coordination bonding, and the absorbed metal ions can be liberated by adding HCl . Naturally occurring magnetotactic bacteria remove organic pollutants from water by enzymatic reactions [12.244]. Pesticides, drugs, and organic pollutants get adsorbed onto magnetic nanoparticle surfaces by electrostatic interactions or hydrophobic/hydrophilic interactions depending on the nature of surfactant used [12.243].

Magnetic Biosensor

Magnetic nanoparticles such as superparamagnetic particles are used as biomolecular labels; because of their comparable size, they can be manipulated inside com-

plex biological fluids to achieve the desired detection and sensitivity. For example, magnetic particles of size ≤ 20 nm can be used to detect **DNA** molecules [12.21].

The mechanism of detection involves binding of magnetic nanoparticles with molecular targets, thereby inducing a change in proton relaxation rate. This technique is analogous to magnetic resonance imaging (**MRI**) [12.245]. Another method is to use magnetic relaxation switching (**MRSw**) [12.21, 245, 246]. Magnetic nanoparticles react with molecular targets and assemble into clusters, thereby affecting the bulk magnetic relaxation rate. **MRSw** has been used to detect nucleic acids, proteins, enzymes, viruses, cells, etc. [12.21, 245, 246].

MRI Contrast Agent

MRI, one of the most powerful imaging methods, is based on the relaxation of protons in tissues. Magnetic nanoparticles are being increasingly used to improve **MRI** contrast. Most imaging techniques offer a single contrast mechanism, but **MRI** contrast is generated from the local physicochemical environment [12.21, 247]. Magnetic nanoparticles enhance the image quality by altering the magnetic resonance of protons and hence enhance the signal intensity. Superparamagnetic iron oxides have been used for **MRI** of liver, spleen, bone marrow, kidney, etc. [12.21], because of their chemical stability, nontoxicity, and biodegradability. The success of such in vivo imaging techniques is highly dependent on the molecular imaging agents; e.g., T cells in mouse spinal cord labeled with iron oxide nanoparticles complexed to poly-L-lysine were detected by **MRI** [12.248]. Due to high saturation magnetization, cobalt may have a larger proton relaxation effect compared with iron oxide. However, due to toxicity effects it has less applicability [12.249]. Another advantage of **MRI** is the dynamic imaging modality in which magnetic nanoparticle-loaded cells can be monitored in vivo using **MRI** [12.21].

Tissue Engineering

Cells labeled with magnetic nanoparticles can be manipulated using magnets to create artificial tissue [12.21, 22]. Cell can be cultured to reconstitute human tissue. Magnetically labeled keratinocytes can be accumulated to form sheet-like **3-D** constructs using a magnet [12.21]. Tubes of the cultured cells can be created by using a rotating cylindrical magnet to attract the **2-D** cell layer and then rolling it into the desired configuration. This ability to manipulate cells and tissues has opened up a new field of regenerative medicine [12.21].

Fig. 12.23 Schematic diagram of the magnetic tweezers setup (after [12.250])

Drug and Gene Delivery

Targeted drug delivery by an external magnetic field can reduce the dosage by 50–80% [12.9, 18, 21, 23]. The ideal magnetic particles for drug targeting should be biocompatible, form a stable suspension, and incorporate high amount of the drug. The drug may be encapsulated or adsorbed onto the surface and must be released at the targeted site by degradation or by heating. In magnetofection or magnetic nanoparticle-assisted exogenous DNA incorporation into a cell, magnetic targeting helps to overcome the difficulty of diffusion through the cell membrane [12.9, 23], helping to enhance drug uptake in the targeted tissues.

Hyperthermia

Hyperthermia is a promising approach to cancer therapy and is based on heating of the target tissue to slightly above body temperature. Magnetic nanoparticles can be used as heat sources for magnetic hyperthermia. Magnetic nanoparticles in an external AC magnetic field generate heat through Neel and Brown relaxation processes. The main challenge lies in control heating to

cancer cells in vivo without damaging normal cells and tissues. One approach is to use magnetic materials with Curie temperature in the range 42–47 °C [12.9]. Another approach in hyperthermia that has gained substantial attention in recent years is multimodal cancer therapy [12.20, 251, 252]. In this process, magnetic nanoparticles coated with a thermoresponsive polymer are used as drug targeting agents, followed by simultaneous hyperthermia and drug release.

Magnetic Tweezers

Magnetic tweezers are an advanced tool to manipulate single DNA or RNA molecules. In magnetic tweezers, DNA strands are attached to a glass surface on one end and to superparamagnetic beads on the other end (Fig. 12.23) [12.250, 253]. Magnetic beads can provide a *handle* that can be used to manipulate molecules and investigate intermolecular interactions [12.9].

Magnetic fields can be used to apply linear or torsional force to DNA, allowing investigation of the extension and elasticity of the molecule. The reliability of this measurement is influenced by the nature of the bonding of the magnetic bead to the DNA [12.9].

12.5 Conclusions

Much of the recent progress in magnetism and magnetic materials is due to nanostructuring and the interesting magnetic properties of magnetic nanostructures. Understanding the magnetic phenomena at nanoscale requires knowledge of physics, materials science, and chemistry, and the work reviewed here substantiates this point.

We have discussed some fundamental aspects of nanomagnetism such as the effect of nanostructuring on magnetic moment, anisotropy, coercivity, and Curie temperature. As an example, nanostructuring of mag-

netic materials induces surface anisotropy, and this in turn controls the demagnetization process and the hysteresis loop. Many interesting properties already demonstrated for magnetic nanostructures, such as superparamagnetism, GMR, shape anisotropy, and Curie temperature enhancement, hold immense promise for advanced technological applications. The energy product for a hard–soft nanocomposite is predicted to be much higher than for a single-phase magnet. Advanced fabrication techniques are needed to obtain optimal

microstructure with enhanced coercivity as well as magnetization.

The requirements for precise shapes and sizes of magnetic nanostructures have resulted in the development of new fabrication or synthesis techniques. We have presented various bottom-up and top-down approaches for fabrication of magnetic nanostructures. Bottom-up approaches such as mechanical milling, melt spinning, sputtering, MBE, and electrodeposition as well as various top-down chemical synthesis methods have been successful in producing nanostructured thin films, nanowires, nanorods, and nanopowders. Nanolithography has made it possible to fabricate

various sophisticated nanostructures such as nanorings, circular dots, and nanodiamonds. In addition to synthesis/fabrication, structural and magnetic characterization is a basic step in establishing structure–property relationships. Therefore, characterization techniques such as electron optical techniques, including differential phase-contrast imaging and spin-polarized electron microscopy, electron holography, and quantitative Lorentz microscopy, AFM/MFM, and SEM/TEM have been reviewed. The wide range of applications of nanostructured magnets in the fields of data storage and biomedical engineering have also been illustrated.

13. Nanocrystalline Functional Oxide Materials

Rakesh Shukla, Dimple P. Dutta, Jayshree Ramkumar, Balaji P. Mandal, Avesh K. Tyagi

Nanoparticles are small clusters of atoms about 1–100 nm long. The term “nano” derives from the Greek word *nanos*, which means dwarf or extremely small. A nanometer is a billionth of a meter or 10^{-9} m. Nanostructured materials have attracted the attention of different types of people such as scientists, engineers, etc. Essentially, the reason is that nanocrystals in the 1–10 nm range make up a new realm of matter in which physical and chemical properties change as size changes. Metal oxide nanoparticles are an important class of materials for their optical, magnetic, and electronic properties and have a wide range of applications such as in catalysts, sensors, optical materials, electrical materials, and magnetic storage. Synthesis routes for nanoparticles can be broadly classified into solid-state and soft chemical routes such as gel combustion, coprecipitation, sol–gel, hydrothermal/solvothermal, sonochemical, template synthesis, etc. This chapter deals with the various properties of nanoparticles syn-

thesized using different techniques. The application of nanooxides as sorbents for environmental remediation is also discussed in this chapter.

Traditionally, materials can be classified based on their bonding, fundamental properties or structures, or origin. They can be either crystalline or amorphous depending on the long or short range of crystallographic ordering.

Furthermore, based on their surface finishing and dielectric properties, they are termed as opaque, transparent, semitransparent, or reflecting materials. They can also be classified based on the processing techniques, leading to thin films, single crystals, ingots, powders, slurries, aerosols, etc. Materials can also be classified based on size and shape. This conventional classification of materials fails miserably when different types of materials are used for the same function. The contemporary emphasis is on materials that simultaneously exhibit two or more properties. Sometimes,

these properties can be antagonistic properties also; for example, multiferroics are a class of materials that are supposed to be ferromagnetic and ferroelectric at the same time. This greatly changed scenario calls for a more practical classification of materials. In view of this, a new scheme has been proposed wherein materials (more appropriately now termed *functional materials*) comprising representatives from different existing classes are categorized solely based on their functional properties and their prospective applications [13.1]. Functional materials have assumed a very prominent position in several high-technology areas. Such materials are not classified on the basis of their origin, nature of bonding, or processing techniques but rather on the basis of the functions they can perform. This is a significant deviation from the earlier

Table 13.1 Classification of materials

Material	Type	Sensing action for	Sensing mechanism	Reference
In ₂ O ₃	Semiconductor	Toxic gases (H ₂ S)	Resistivity	[13.2]
Yttria-doped thoria (YDT)	Insulator	Water ingress in liquid Na coolant used in fast breeder reactors	Ionic conductivity	[13.3]
Calixarene	Organic	Cs-137 in nuclear waste	Electrochemical	[13.4]
Ag@R6G	Hybrid material	Pb ²⁺ in potable water	Fluorescence	[13.5]
Conducting polymers (polyaniline (PANI))	Organic	Thyroid hormone	Radioimmuno-assay (RIA)	[13.6]

mentioned traditional classifications. According to this new scheme of classification, a material will be termed as a gas sensor irrespective of whether it is organic, inorganic, or hybrid in origin, and the sensing mechanism may be either resistive, luminescent, or by surface modification; for example, several altogether different materials have been clubbed together in Table 13.1 owing to the fact that they have the same functionality, i. e., sensing action. The probing mechanism is also different, but the end functionality classifies them according to their sensing action, irrespective of their origin and properties.

Nanoparticles are small clusters of atoms about 1–100 nm long. Nanostructured materials have attracted the attention of different types of people such as scientists, engineers, etc. Essentially, the reason is that nanocrystals in the 1–100 nm range make up a new realm of matter in which physical and chemical properties change as size changes. Although it is still difficult to understand such property changes theoretically, this phenomenon presents enormous opportunities for advances in science and technology. Contemplating that any nanostructured solid material can have variable properties based simply on size essentially makes the Periodic Table of elements *three dimensional*. Actually, the potential new materials based on nanostructure are even broader than the solid elements of the Periodic

Table, since metal oxides, metal sulfides, tellurides, arsenides, bimetallics, and of course metals themselves need to be considered. The properties that change in the nanoregime include bandgaps (for semiconductors), magnetic moments (for ferro- and ferrimagnetism), specific heats, melting points, surface chemistry, and morphology/particle shape. For consolidated nanoparticles, metal pieces can be harder, and ceramic pieces can be more plastic than normal materials made from microcrystal–polycrystal consolidation.

Metal oxide nanoparticles are an important class of materials for their optical, magnetic, and electronic properties [13.7, 8]. These properties make nanostructured metal oxides useful for a wide range of applications such as in catalysts, sensors, optical materials, electrical materials, and magnetic storage [13.9–20]. Hence, over the past half-decade, research in functional oxide-based nanostructures has attracted considerable attention due to their unique and innovative applications in optics, optoelectronics, catalysis, and piezoelectricity. Metal oxides can act as semiconductors or insulators depending on their bandgap values. When the bandgap value is below 3.5 eV, they behave as semiconductors, whereas a bandgap value above 3.5 eV categorizes them as insulators. Oxides of iron are colored due to the small bandgap, whereas those of zinc have no color as the bandgap is large.

13.1 Synthesis Methods

Synthesis is an important part of any work. The preparatory routes for nanoparticles are broadly classified into two categories: the solid-state route and the soft chemical route.

13.1.1 Solid-State Route

The solid-state process is a conventional and widely used synthesis method to prepare polycrystalline ce-

ramic materials. This method is not only common but also most promising for scaling up of compound production. Solid-state diffusion is an inherently sluggish process. It involves the mechanical mixing of the solid constituents (oxides/carbonates) with repeated grindings and annealing at elevated temperatures, generally over a long duration [13.21, 22]. Solid-state reaction is different from solution reaction, since in solution all ions and molecules are available for reaction. However,

Table 13.2 Comparison of solid-state reaction and solution reaction

Solid-state reactions	Solution reactions
Kinetically slow	Kinetically fast
Mostly need higher temperatures	Room temperature (RT) or slightly above RT
Diffusion controlled	Diffusion is not very important
No well-defined rate laws	Well-defined rate laws
Sample history influence	No sample history influence
Defects' role is important	No such concept exists
Progress of reaction is difficult to monitor	Progress of reaction easy to monitor
Larger particles are obtained	Fine particles are obtained

this is not the case in a solid-state reaction. Here, the reaction takes place only at that point where the reactants are in intimate contact with each other. Once the product layer is formed at the interface between the reactants, further progress of the reaction depends upon the diffusion of one or both reactants through this product layer. This depends on various factors such as the size of the diffusing ions, the structure of the product as well as of the reactants, the reaction temperature, and also the presence of defects and the history of the sample.

Before proceeding with an experimental solid-state reaction, a few important points have to be considered. The melting temperature, decomposition temperature, vapor pressure, etc. of the reactants need to be compiled. Heating should be done in pellet form preferably. A proper atmosphere needs to be selected, depending upon the requirement and the stability of the reactants. Crucible material selection is also important, as the material should be chemically inert even at high temperature, e.g., Al_2O_3 or platinum. Selection of the heating temperature is done by considering the compound with the lowest melting point or decomposition temperature.

In case of powder reactions, grinding of the reactants continuously peels off the product layer formed at the interface, hence providing fresh contact area for the reaction to take place. Grinding homogenizes the reaction mixture, reduces the particle size, and in turn increases the surface area and also reduces the diffusion path. Hence, thorough grinding plays an important role in case of powder reaction. However, mixing and grinding of the reactants may sometimes give rise to nonuniform composition and local stoichiometric variations.

Also, the purity of the product is limited by the impurities introduced during grinding. Powder products

obtained by solid-state synthesis are larger in size, usually in the micrometer range. A brief comparison of solid-state versus solution reaction is tabulated in Table 13.2.

The shortcomings of the solid-state synthesis method can be overcome by employing solution chemistry techniques.

13.1.2 Soft Chemical Routes

Nanocrystalline ceramics are generally synthesized by soft chemical routes, wherein the homogeneity of the reacting constituents can be achieved at atomic level. These methods employ a solvent medium from which the required product can be obtained by precipitation, solvent evaporation, etc.

Gel-Combustion Synthesis

This is a facile synthesis technique that can be employed on a laboratory scale to prepare nanocrystalline ceramic powders with reproducible characteristics. Combustion is basically a redox reaction between the oxidant and fuel and is controlled by various factors such as the nature and amount of fuel. This preparative method consists of two steps, which are described as follows:

1. Preparation of fuel–oxidant precursor or gel formation. In this step, nitrate/oxy-nitrate salts of the metals, in the required molar ratio, are mixed together in an aqueous media to produce a transparent mixed metal nitrate solution. A suitable fuel (glycine, citric acid, urea, etc.) is then added in an appropriate amount to this solution. The aqueous solution of fuel and oxidants is then thermally dehydrated on a hot plate (at about 80–100 °C) to obtain a viscous liquid (hereafter termed as gel). This thermal dehydration and gel formation process is an important step, because any excess water left behind would lead to sluggish combustion, deteriorating the phase purity and powder quality. The nature of the fuel, its amount, and the pH of the starting solution are some of the important process parameters to obtain a transparent viscous gel without any phase separation or precipitation.
2. Combustion of the fuel–oxidant precursor or auto-ignition. The gel, as formed in the first step, is further heated at a higher temperature (200–250 °C) that initiates self-propagating combustion. The exothermic decomposition of the fuel–oxidant precursor is visible in the form of flame, which rapidly propagates throughout the gel, therefore this step is

also termed as *auto-ignition*. The auto-ignition is a very short-lived phenomenon as the flame persists for only a few (5–10) seconds. It is within this short duration that the product formation takes place.

The auto-ignition of the gel results in a large voluminous powder. However, the resultant product may be the desired phase, or semi-decomposed precursor having a considerable carbonaceous residue, depending on the nature and amount of fuel used in the process. During auto-ignition, gaseous products are evolved which dissipate the heat and fragment the solid residual product, resulting in ultrafine powders of oxide.

Fuel in Gel Combustion

A fuel can be defined as a substance that is consumed to produce energy in a reaction. In other words, any substance which on its consumption provides heat or energy is termed as a fuel. Thus, there are naturally occurring fuels such as coal, petroleum, natural gas, etc., which are prime source of energy in day-to-day life. These materials burn in the presence of oxygen, releasing energy in the form of heat and light. However, the basic characteristics of the fuel in the combustion process are that it should be able to maintain compositional homogeneity among constituents and should undergo combustion with an oxidizer (i.e., nitrates) at low ignition temperature. A large variety of organic materials can serve as fuel for the combustion process. These include carboxylic acids such as citric acid, tartaric acid, ascorbic acid, glycine, ethylenediaminetetraacetic acid (EDTA), etc., and materials such as urea, hydrazine, dimethyl urea ($C_3H_8N_2O$), hexamethylenetetramine (HMTA), etc.

Glycine (NH_2CH_2COOH). This is one of the cheapest α -amino acids and is known to act as a complexing agent for a number of metal ions, as it has a carboxylic acid group at one end and amino group at the other. This zwitterionic character of the glycine molecule enables it to effectively form complexes with metal ions of varying ionic sizes, helping to prevent their selective precipitation to maintain compositional homogeneity among the constituents.

Aspartic Acid ($C_4H_7NO_4$) and Glutamic Acid ($C_5H_9NO_4$). These are commonly available acidic α -amino acids with two carboxylic ($-COOH$) and one amino ($-NH_2$) group for coordinating metal ions to maintain compositional homogeneity through gel formation. These are low-cost materials and can be combusted with nitrates

at low ignition temperatures (200–250 °C). In addition, the combustion reactions involving these acids are found to be of comparatively controlled nature, due to their somewhat sluggish combustion, which helps in scaling up of the process.

Arginine ($C_6H_{14}N_4O_2$) and Tryptophan ($C_{10}H_{10}N_2O_2$). Arginine is a strong basic α -amino acid, while tryptophan is a weakly basic α -amino acid. Arginine contains two amino ($-NH_2$) groups and one carboxyl ($-COOH$) group, whereas tryptophan contains one amino group and a heterocyclic moiety containing nitrogen as the heteroatom. The characteristic feature of α -amino acids is that they contain one amino group at the α -position to the carboxyl group. They are capable of complex formation with metal ions to give a homogeneous gel and undergo combustion at low ignition temperature.

Valine ($C_5H_{11}NO_2$) and Phenylalanine ($C_9H_{11}NO_2$). These two compounds are neutral α -amino acids like glycine, carrying one amino and one carboxyl group at α -position to each other. Therefore, they also behave in the same manner as glycine when used as a fuel. All these compounds are used as fuels.

Citric Acid ($C_6H_8O_7H_2O$). Citric acid is also a good complexing agent due to its multidenticity. The combustion reaction with this fuel gives mostly flameless combustion with lots of evolution of gases.

Concept of Fuel-to-Oxidant Ratio

The oxidant-to-fuel molar ratio has a significant bearing on the product phase as well as the product powder properties. This is because the extent of exothermicity associated with the combustion process is governed by the oxidant-to-fuel ratio used. Based on the so-called concept of propellant chemistry, the ratio of oxidizing and reducing valencies should be unity to achieve maximum exothermicity [13,23, 24]. The calculation of these valencies and the ratio satisfying this concept can be illustrated by means of a typical example of nanocrystalline lanthanum oxide (La_2O_3). The oxidizing valency calculated for the oxidant in this case, viz. $La(NO_3)_3 \cdot 6H_2O$, is 15–, whereas the reducing valency of the fuel, viz. glycine, is 9+. These oxidizing and reducing valencies can be calculated as:

1. $La(NO_3)_3 \cdot 6H_2O$:
 - Oxidizing valency of Ce = 3+, N = 0
 - Reducing valency of O = 2–.
 Thus, the net oxidizing valency = 15–.

2. $\text{NH}_2\text{CH}_2\text{COOH}$:

- Oxidizing valency of N = 0, H = 1+, C = 4+
- Reducing valency of O = 2–.

Thus, the net reducing valency = 9+.

The valencies of C and N are taken as 4+ and 0, as these species are lost as CO_2 and N_2 , respectively, during the combustion process [13.25]. The ratio of oxidizing to reducing valency then turns out to be 1 : 1.66, which is the propellant chemistry ratio. An oxidant-to-fuel ratio less than 1.66 is termed as fuel deficient, and any ratio greater than 1.66 is termed as fuel rich. For other fuels, the stoichiometric ratios can be calculated in a similar manner.

Powder properties such as crystallite size, nature and extent of agglomeration, surface area, sinterability, etc. are primarily dependent on the nature and amount of fuel used, which are the two main parameters responsible for controlling the exothermicity or flame temperature and gas evolution nature of the auto-ignition part of the combustion reaction.

Nature and Amount of Fuel

The selection should be based on the following points.

Fuels should be capable of forming multidentate complex with the metal ion. The fuel should be such that it binds to most of the metal ion. The bond formed should be stable enough to prevent precipitation. The gel formed should have lower auto-ignition temperature, so that the combustion process occurs at lower temperature.

A lower amount of fuel, i.e., use of a fuel-deficient ratio (with higher amounts of nitrates), helps in single-step decomposition of the precursors. A very high rate of combustion is observed in such cases, but at the same time, due to effective cooling of the powders by evolution of a large volume of gaseous molecules, the local temperature is reduced quickly. Thus, the crystallite size is not increased much, due to insufficient time for aggregate formation.

Using a higher amount of fuel (or lesser amount of nitrates), i.e., a fuel-excess ratio, leads to the formation of dense structure in the agglomerates as a result of poor heat dissipation and longer time of high local temperature in the sluggish combustion that takes place in such cases. The presence of large amounts of remaining carbonaceous residue can deteriorate the powder properties during calcination.

If the system under study has a high phase formation temperature and is also difficult to form, the stoichiometric oxidant-to-fuel (O/F) ratio gives the best result,

due to its higher exothermicity along with single-step decomposition of the precursor to produce the desired phase with improved powder characteristics.

A few advantages of the aforementioned steps of gel combustion synthesis are listed here:

1. The possibility of local composition variations in combustion-synthesized powders is very low, as formation of the homogeneous gel prevents a random redox reaction between the fuel and oxidant.
2. Atomic-level blending of the constituent elements is achieved, which facilitates formation of the compound.
3. The gel precursor does not require any special processing such as washing as it undergoes exothermic decomposition.
4. Although the auto-ignition exists for a very short time, the heat of combustion is sufficiently high to produce the required phase in most cases. Hence, the combustion technique can be considered as time saving, low-temperature synthesis.

Thus, the combustion process is quite simple and can easily be carried out in a laboratory. However, a few precautionary measures are necessary while performing such experiments:

1. Combustion is a spontaneous and vigorous process wherein large amounts of heat and gases are released in a very short duration. Thus, it is necessary to carry out such reactions in a fume hood, which facilitates safe ventilation of the gaseous products.
2. It is advisable to use wide-mouthed and large-volume apparatus (beakers) to avoid poor heat dissipation and for easy liberation of the gaseous products. Also, a narrow-opening container might lead to an explosion, due to the large swelling of the viscous precursor.
3. Since combustion-synthesized powders are very reactive due to their high surface area, the right conditions for calcination (e.g., time and temperature) and their proper storage in desiccators are necessary to avoid any attack of atmospheric gases (e.g., formation of carbonates due to attack of atmospheric carbon dioxide) and moisture.

These combustion-synthesized powders are further calcined at $\approx 600^\circ\text{C}$ for 1 h to remove any carbonaceous residue and/or undecomposed precursor. Calcination involves heat-treating a powder at a temperature well below its melting point to effect decomposition, i.e., to liberate unwanted gases and/or chemically

bound waste, as well as structural transformations to produce the desired composition and phase product.

Coprecipitation Synthesis

Precipitation is a very simple preparative method employed to synthesize nanoparticles of a variety of inorganic compounds. Coprecipitation refers to simultaneous precipitation of more than one metal ion from the same solution. This gives more intimate mixing of cations as compared with that achieved by mixing oxides/salts of individual cations. Coprecipitation reactions tend to exhibit the following characteristics [13.20]:

1. The products of coprecipitation reactions are generally sparingly soluble species formed under conditions of high supersaturation.
2. Nucleation is a primary step in this process, wherein a large number of small particles are formed.
3. Secondary processes, such as Ostwald ripening and aggregation, dramatically affect the size, morphology, and properties of the products.

The key to any precipitation process is the degree of supersaturation (S) given by

$$S = \frac{a_A \times a_B}{K_{sp}}, \quad (13.1)$$

where a_A and a_B are the activities of solutes A and B, and K_{sp} is the solubility product constant. As nucleation begins in a supersaturated solution, there exists an equilibrium critical radius (R), which is given by

$$R = \frac{\alpha}{\Delta C}; \quad (13.2)$$

where ΔC is the difference in solute concentration at saturation (C) and equilibrium (C_{eq}).

The term α is given by

$$\alpha = \left(\frac{2\sigma_{SL}}{kT \times \ln S} \right) \times vC_{\infty}, \quad (13.3)$$

where σ_{SL} is the surface tension at solid–liquid interface, k is the Boltzmann constant, T is temperature, v is the atomic volume of solute, and S is the supersaturation as given in (13.2). Nucleated particles with radius $> R$ will continue to grow, while those with radius $< R$ will dissolve. In the majority of precipitation reactions, the growth process of the precipitated particles is found to be diffusion limited. Concentration gradients and temperature become the predominant factors determining the growth rate as new material is supplied

to the particle surface via long-distance mass transport. Ostwald ripening is the phenomenon by which smaller particles are essentially consumed by larger particles during the growth process. Agglomeration of the precipitated nanoparticles can be prevented by addition of a stabilizer or capping agent or a grain growth inhibitor.

Coprecipitation of various salts (nitrates, chlorides, and sulfates) using a suitable precipitating agent yields the corresponding oxides. However, the products of coprecipitation reactions performed at or near room temperature are usually amorphous, insoluble precursors. Thermal decomposition of such compounds results in chemically homogeneous fine oxide powders with high surface area.

The coprecipitation technique offers various advantages:

1. It is a facile synthesis technique facilitating easy control of overall homogeneity, particle size, composition, etc.
2. Coprecipitation reactions can be easily performed in a small laboratory.
3. Because of the intimate mixing produced by coprecipitation, the calcination temperature required to produce the desired crystalline phase in the powder is usually lower than that required for calcination of the individual oxide powders.
4. This preparative method can be employed for synthesis of advanced multication powders, multi-component oxide systems, etc.

Coprecipitation of mixed salts from liquid solutions is a well-established method of ceramic powder synthesis. In this technique, a multicomponent liquid solution of soluble inorganic salts (metal nitrates, sulfates) is typically combined with a liquid solution of a precipitating compound. The precipitating agent is chosen in such a way that, when dissolved and combined with the metal solution, one of its radicals combines with the metal ions to form insoluble salts. These salts are precipitated in a very finely divided and intimately mixed state. Heating of the precipitate decomposes these salts, resulting in a chemically homogeneous and fine oxide powder.

In many coprecipitation procedures, the precipitated salts exhibit slight solubilities in the supernatant liquid, leading to incomplete precipitation. The coprecipitation process is governed by two competing factors, viz. nucleation and crystal growth. Thus, merely inducing precipitation of a compound does not ensure that the product will be nanoparticulate and/or monodispersed.

If nucleation is very fast and the subsequent growth rate is very slow, nanosized material can be obtained. Sometimes, soft templates are used as structure-directing agents in order to obtain nanoparticles with different morphologies such as nanorods, nanowires, etc. [13.26, 27]. The coprecipitation route is capable of producing powders with closely controlled stoichiometry, composition, and particle size on a large-scale commercial basis [13.28].

Sol-Gel Synthesis

The sol-gel process is a low-temperature approach for synthesizing solid-state oxide materials (usually polymeric). A sol is a colloidal suspension of solid particles in a liquid. The clusters in the sol are linked into frameworks. The gel is a solid whose pores contain liquid. A gel has been defined as a two-component system with a semisolid nature. Synthesis of SiO_2 from liquid silicon metalorganic precursors is probably the most investigated sol-gel process. It is generally a two-step process which involves hydrolysis of precursors followed by their condensation to form oxide frameworks. Product properties are affected by the rate of hydrolysis and condensation. Generally, slower and controlled hydrolysis leads to smaller particle sizes. Pore size, distribution, and interconnectivity are also affected by other processing parameters, such as the type and amount of solvent and/or catalyst, temperature, and in some cases the presence and arrangement of templating molecules. This low-temperature soft chemical method is safe and inexpensive, and can yield nanomaterials with complex shapes. In recent years, a variety of nanomaterials have been synthesized using the sol-gel process [13.29].

Hydrothermal/Solvothermal Synthesis

In a sealed vessel, it is possible to bring solvents to temperatures well above their boiling points by increase in their autogenous pressures resulting from heating. Performing a chemical reaction under such conditions is referred to as hydrothermal processing in case of water and as solvothermal processing in case of non-aqueous solvents. The process simply takes advantage of the increased solubility of metal salts and complexes at elevated temperatures and pressures (with or without bringing the solvent to its critical point). This type of processing allows many inorganic materials to be prepared at temperatures substantially below those required by traditional solid-state reactions. Unlike other low-temperature methods such as coprecipitation and sol-gel synthesis, the products of solvo/hydrothermal reactions are usually crystalline and do not require

subsequent annealing treatment. The mechanism of hydrothermal reactions usually follows a liquid nucleation model. It differs from the solid-state reaction mechanism in the process of diffusion of atoms or ions between reactants. In the hydro/solvothermal technique new materials can be obtained in an inexpensive manner, but it is generally difficult to have absolute control over the morphology and size of the nanoparticles. A variety of metal oxide nanoparticles have been synthesized using this method [13.30].

Template Synthesis

The template method involves fabrication of the desired material within the pores or channels of a nanoporous template. In the broadest sense, a template may be defined as a central structure within which a network forms in such a way that removal of the template creates a filled cavity with morphological and/or stereochemical features related to those of the template. Track-etch membranes, porous alumina, and other nanoporous structures have been characterized as templates. Nearly any solid matter can in principle be synthesized within nanoporous templates, provided a suitable chemical pathway can be developed. There are essentially five representative strategies to carry out template synthesis of nanostructures: electrochemical deposition, electroless deposition, chemical polymerization, sol-gel deposition, and chemical vapor deposition.

Sonochemical Synthesis

Ultrasound has become an important tool for synthesis of nanoparticles. When liquids are subjected to ultrasonic irradiation, ultrasonic cavitation occurs, involving the formation, growth, and implosive collapse of bubbles. Cavitation bubbles are vacuum bubbles. The vacuum is created by a fast-moving surface on one side and an inert liquid on the other. The resulting pressure differences serve to overcome the cohesive and adhesive forces within the liquid. Ultrasonic cavitation produces a variety of physical and chemical effects, such as high temperature ($> 5000 \text{ K}$), pressure ($> 20 \text{ MPa}$), and cooling rate ($> 1010 \text{ K s}^{-1}$), which could provide a unique environment for chemical reactions under extreme conditions. The sonochemical effects observed in chemical reactions and processes can involve increase in reaction speed, increase in reaction output, more efficient energy usage, sonochemical methods for switching of reaction pathway, activation of metals and solids, improvement of particle synthesis, and also coating of nanoparticles. The temperature

plays an important role in sonochemical reactions. The equation of an adiabatic implosion is

$$T_{\max} = T \frac{P_{\text{ex}}(\gamma - 1)}{P_{\text{bub}}}, \quad (13.4)$$

where T_{\max} is the temperature reached after the collapse of the bubble, T is the temperature of the sonication bath, $\gamma = C_p/C_v$, P_{ex} is the external pressure equal to the sum of the hydrostatic and acoustic pressure, and

P_{bub} is the pressure of the gas inside the cavity, at the radius at which it collapses. Lower P_{bub} (vapor pressure of the solute) results in higher temperatures and faster reaction rates. Thus, the temperature has a dual effect. Low temperatures increase the viscosity, making the process of bubble formation difficult, but at the same time also increases the rate of the sonochemical reaction. Over the last two decades, a variety of metal, metal oxide, and chalcogenide nanomaterials have been synthesized using the sonochemical technique [13.31].

13.2 Optical Properties of Oxide Nanomaterials

Among the various oxides, a lot of work has been done on TiO_2 , which has many promising applications in areas ranging from photovoltaics and photocatalysis to photo/electrochromics and sensors. The structural, thermal, electronic, and optical properties of TiO_2 nanomaterials have been reviewed extensively over the past decade [13.32–40]. Similarly, ZnO is another important compound semiconductor having a wide bandgap (3.37 eV) that is suitable for short-wavelength optoelectronic applications. It is transparent to visible light and can be made highly conductive by doping. The potential applications and novel nanodevices demonstrated for ZnO have been studied comprehensively [13.41].

Indium oxide (In_2O_3) is an n-type semiconducting material, and its observed optical transparency arises from its relatively wide bandgap. In_2O_3 has a direct, wide bandgap of ≈ 3.6 eV and an indirect bandgap of ≈ 2.6 eV [13.42–44]. Undoped In_2O_3 shows resistivity of $\approx 10^4 \Omega \text{ cm}$. However, it can be made highly conducting by doping with extrinsic impurities or by controlled stoichiometric deviation. Tin-doped indium oxide (ITO) corresponds to the former case, while the low resistivities observed in undoped, oxygen-deficient In_2O_3 are explained by the latter mechanism. Hence, it is a technologically important transparent conducting oxide, which is found to be an alternate choice for many interesting applications including for transparent electrodes in electroluminescence devices, solar cells, antireflection coatings, and optoelectronic devices and also in gas sensors [13.45–51]. Increasing interest has been shown in depositing transparent conductive oxide (TCO) materials on plastics substrates for light-emitting diode (LED), organic light-emitting diode (OLED), and flat-panel display applications. As an example, Shin et al. reported resistivities of $6 \times 10^4 \Omega \text{ cm}$ and optical transparencies of 85% at 550 nm for direct-current

(DC) magnetron-sputtered ITO films [13.52]. Doped conducting oxides also hold considerable potential from the physics and application points of view. Rare-earth-doped conducting oxides such as indium oxide may allow electrical excitation of rare-earth ions as well as optical excitation. Such materials have immense potential for application in the development of electrically driven light-emitting devices.

The technological utility of In_2O_3 has prompted considerable interest in the development of synthesis techniques that are capable of manufacturing nanoparticulate In_2O_3 powders with controlled particle size and low levels of agglomeration [13.53, 54]. High-quality nanoparticulate powders of In_2O_3 are characterized by enhanced physical properties and improved processing behavior compared with conventional coarse-grained powders; for example, nanoparticulate In_2O_3 powders exhibit heightened sinterability and show higher sensitivity in gas sensor applications [13.55–57]. It is also anticipated that low-dimensional In_2O_3 may exhibit some unique properties, including novel optical behaviors [13.58, 59]. Nanometer-sized In_2O_3 shows obvious differences in its optical properties (e.g., optical bandgap and luminescence properties) relative to bulk In_2O_3 [13.60, 61]. Consequently, In_2O_3 nanoparticles have been prepared by a variety of methods, including thermal hydrolysis, thermal decomposition, sol–gel technique, microemulsion, reactive magnetron sputtering, metalorganic laser photolysis, spray pyrolysis, template method, pulsed laser deposition technique, vapor-phase transport and condensation deposition process, carbothermal reduction, decomposition of the organometallic precursor, sonochemical method, etc. [13.62–73].

It is well known that bulk In_2O_3 cannot emit light at room temperature [13.74–77]. On moving down to the

nanoregime, a considerable change is observed in the optical properties.

However, the optical properties, such as the photoluminescence (PL), of In_2O_3 nanoparticles obtained by different synthesis techniques vary greatly. A consolidated account of the optical properties of these In_2O_3 nanoparticles of various size and shape is given here.

Bulk In_2O_3 exhibits a photoluminescence (PL) emission peak at 3.67 eV. Nanoparticles of indium oxide synthesized by pulsed laser ablation of a pure indium metal target show a strong PL emission peak at 3.78 eV. The weak size dependence revealed by this blue-shift of about 110 meV in the PL spectra is consistent with a particle size on the order of the Bohr exciton diameter [13.9]. The exciton Bohr diameter for In_2O_3 is reported to be in the range between 2.6 and 5 nm [13.78].

In_2O_3 nanoparticles synthesized by homogeneous precipitation using hexamethylenetetramine as ligand and indium nitrate or indium chloride as precursor exhibited photoluminescence emission at room temperature with peak onset at 315 nm as a consequence of the small size of the particles [13.79]. Thermal decomposition of $\text{In}(\text{acac})_3$ precursor in the presence of stabilizing surfactant oleylamine yielded In_2O_3 nanoparticles of different sizes depending on the molar ratio of the latter. On excitation at 275 nm, the PL emission maximum appear at 3.81 eV (325 nm) for 4 nm In_2O_3 , 3.76 eV (330 nm) for 6 nm In_2O_3 , and 3.73 eV (332 nm) for 8 nm In_2O_3 , thus being blue-shifted (60–140 meV) compared with the value of 3.67 eV (338 nm) for bulk In_2O_3 [13.80]. Thermal decomposition of $\text{In}(\text{dipy})_3\text{Cl}_3 \cdot 2\text{H}_2\text{O}$ in oleylamine and oleic acid under inert atmosphere yielded In_2O_3 nanoparticles with tunable size from 10–15 nm to 40–50 nm, depending on the molar ratio of precursor to combined solvent in the reaction system. When 10–15 nm In_2O_3 nanoparticles redispersed in cyclohexane were excited at 275 nm at room temperature, strong PL emission was observed at 378 nm, which is in fact red-shifted compared with that of bulk In_2O_3 [13.81].

In_2O_3 nanocrystals with controllable phases and morphologies have been synthesized by decomposing $\text{In}(\text{OH})_3$ under different reaction conditions. Well-defined cubic In_2O_3 nanocubes were fabricated by treating $\text{In}(\text{OH})_3$ in methanol at 250 °C for 25 h, whereas replacement of the solvent by ethanol yielded nanorods. In_2O_3 nanocubes displayed two blue emission peaks centered at 428 and 433 nm, which was attributed to the formation of new energy levels induced by oxygen vacancies. During the solution-based

synthesis method, a high density of oxygen vacancies will be induced because of incomplete crystallization. The In_2O_3 nanorods did not exhibit any luminescence, indicating that the luminescence properties of In_2O_3 nanocrystals are strongly dependent on their crystal phase, crystallinity, and morphology [13.82].

Synthesis of In_2O_3 nanostructures at different growth temperatures by using the thermal evaporation method has been reported [13.83]. The In_2O_3 nanostructures exhibited different luminescence peaks in the range of 400–600 nm with broad bands when using different growth temperatures. The optical transition energy of the In_2O_3 nanostructures becomes tunable owing to the different amount of oxygen vacancies provided by different growth conditions. This could render the material beneficial for possible applications in white-light illumination.

Since In_2O_3 has a high refractive index of 2, its one-dimensional (1-D) nanostructures are expected to function as waveguides for guiding and manipulating light on the micrometer scale. To utilize In_2O_3 nanowires in the field of nanoscale optoelectronic devices, different methods have been exploited to synthesize In_2O_3 nanowires and nanofibers [13.84–89]. In_2O_3 nanowires synthesized by the gas reaction method exhibit a wide ultraviolet (UV) emission and a blue emission at room temperature [13.76]. In_2O_3 nanowires synthesized by the template method exhibit a UV PL emission at room temperature [13.68]. Since short-wavelength ultraviolet laser plays an important role in the storage density of optical memory systems, a semiconductor material with a short-wavelength PL emission property is needed for optical memory systems. Very recently, In_2O_3 nanofibers have shown potential for application as a waveguide element for future photonic devices [13.90]. Thus, In_2O_3 nanowires may be one of the promising materials applicable for nanoscale optoelectronic devices, short-wavelength lasers, and nanosensors.

Liang et al. produced In_2O_3 nanofibers by heating an Au-coated InP substrate in an Ar-oxygen atmosphere at 1080 °C [13.90]. Li et al. produced In_2O_3 nanowires by an Au-assisted laser ablation technique using an InAs target [13.84]. In_2O_3 nanowires were also produced by evaporating In_2O_3 powder onto Ag nanoparticle-coated Si wafers in an N_2/H_2 mixed gas atmosphere [13.86]. The electrodeposition route has also been employed to fabricate In_2O_3 nanowire arrays [13.85]. Kam et al. produced various In_2O_3 nanostructures such as nanowires, nanotrees, and nanobouquets by carbon-assisted thermal evaporation of In and

In_2O_3 powder [13.88]. The optical properties of these 1-D and two-dimensional (2-D) nanostructures varied depending on the morphology of the product, the synthesis method, and the reactants used; For instance, *Liang* et al. used InP as the starting material to grow In_2O_3 nanofibers using a furnace, and their PL spectra exhibited emission at 470 nm [13.87]. *Zheng* et al. observed PL emission at 429 and 460 nm from their In_2O_3 nanowires using a three-probe DC method [13.85]. *Li* et al. measured the PL of In_2O_3 nanotubes, which exhibited emission at 593 nm [13.91]. The peculiar visible PL emissions in the blue to orange region from lotus-root In_2O_3 nanostructures have been explained on the basis of the novel hierarchical nanostructures [13.92]. In_2O_3 nanobelts synthesized without catalyst at low temperature using a simple physical vapor deposition, under excitation at 325 nm, showed a strong and broad emission at 570 nm with a shoulder at 630 nm [13.93].

The PL mechanisms of all these In_2O_3 nanomaterials were mainly attributed to the effect of oxygen vacancies or oxygen deficiencies, which are inevitable defects occurring in the crystallization process [13.76, 78, 86, 94]. Oxygen vacancies can induce the formation of new energy levels in the bandgap. Hence, the emission results from radiative recombination of a photoexcited hole with an electron occupying an oxygen vacancy [13.87, 95]. In general, emission spectra can be divided into near-band-edge (NBE) emissions and deep-level emissions [13.68, 96]. The emission peak position and strength depend upon the species of the oxygen vacancy and the intensities of PL. The near-band-edge UV emission is attributed to singly ionized oxygen vacancies in the In_2O_3 nanowires [13.68]. Hence, we can see that nanosized In_2O_3 materials exhibit tunability in the wavelength range from ultraviolet (UV) to visible blue-green, as well as yellow emission for optoelectronic devices [13.68, 78, 85, 92]. To achieve red emission from In_2O_3 , appropriate dopants need to be added. Red emission is important, as it can also be used for many commercial, industrial, and medical applications. It is also a necessary source of red laser eyesights for military weapons. Interstitially N-doped In_2O_3 nano/microstructures including nanorods, nanoellipses, microspheres, and microbricks have been synthesized recently by annealing the corresponding $\text{In}(\text{OH})_3$ precursors [13.97]. They show a unique and wide range of red light emission under 350 nm wavelength excitation, in addition to blue light emissions. These newly developed red light emission materials, N-doped In_2O_3 nano/microstructures, can be added to the red light emission semiconductor family and have sig-

nificant application potential for optoelectronic devices such as red light-emitting diodes and lasers.

Nanocrystalline indium oxide doped with rare-earth (RE) and transition-metal ions also exhibits optical properties which are significantly different from those of bulk materials [13.42–44]. Such differences are expected due to the confinement effects on the vibrational spectra of nanocrystals, the increased role of the impurity ions at the surface whose optical properties are modified by the disorder at the surface, and the alteration of the electronic bands of the matrix. Cr-doped In_2O_3 nanostructures with diverse morphologies including nanotowers, nanowires, and octahedrons, synthesized by using a vapor transport method, exhibit broad orange-red emission peak at ≈ 640 nm [13.98].

Optical properties of $\text{In}_2\text{O}_3\text{:RE}^{3+}$ microstructures and nanopowders have been reported recently [13.99–102]. Generally, rare-earth ions such as Eu^{3+} , Er^{3+} , etc. are incorporated into semiconductors to improve the luminescence efficiency by energy transfer processes. The optical properties of rare-earth ions trapped in host lattices have received much attention in terms of their fundamental and technological importance [13.103]. These matrices effectively reduce the quenching of surface rare-earth emission by shielding the rare-earth ions present on the surface of the nanoparticles from the external ligands. *Kim* et al. and *Choi* et al. observed Er^{3+} emission at around $1.54\text{ }\mu\text{m}$ in $\text{In}_2\text{O}_3\text{:Er}^{3+}$ under direct excitation of Er^{3+} ions [13.99, 100, 102]. The Eu^{3+} luminescence was observed in $\text{In}_2\text{O}_3\text{:Eu}^{3+}$ quantum dots (QDs) upon indirect excitation above 350 nm at room temperature, possibly due to host sensitization. However, the above luminescence lines of Eu^{3+} were broad [full-width at half-maximum (FWHM) of ≈ 9 nm for the 614 nm peak] and weak, indicating that the Eu^{3+} ions were probably located at (or near) the surface of In_2O_3 nanocrystals [13.101].

We have synthesized indium oxide and europium/dysprosium-doped indium oxide nanoparticles using a sonochemical technique where indium ethoxide was used as precursor [13.104]. Transmission electron microscopy (TEM) of the nanoparticles showed that they have mean diameter of 8.5 nm with standard deviation of 2.2 nm (Fig. 13.1). The emission spectrum of the In_2O_3 nanoparticles is shown in Fig. 13.2. On excitation at 235 nm, the pattern is characterized by a strong, broad asymmetric peak centered at 460 nm (blue) and two relatively lower-intensity peaks centered around 548 nm (yellow) and 618 nm (orange). The emission peaks in the visible region have been attributed to oxygen vacancies/defects present in the nanoparticles. The

Fig. 13.1 TEM micrograph of In_2O_3 particles obtained from sonochemical synthesis

PL spectrum of the $\text{In}_2\text{O}_3:\text{Eu}$ particles, obtained after excitation at 235 nm, showed weak emission bands corresponding to $^5D \rightarrow ^7F_0$ (≈ 575 nm), $^5D \rightarrow ^7F_1$ (587 and 601 nm) and $^5D \rightarrow ^7F_2$ (612 nm) transitions of Eu^{3+} . The excitation spectrum corresponding to the $^5D \rightarrow ^7F$ transition of Eu^{3+} consisted of a broad peak centered at 265 nm, which was attributed to the charge transfer transition between Eu^{3+} and O^{2-} ions. The absence of a In_2O_3 host band in the excitation spectrum of Eu^{3+} indicated that there was almost no energy transfer from the In_2O_3 host to the doped Eu^{3+} . The relatively weak Eu^{3+} emission detected in $\text{In}_2\text{O}_3:\text{Eu}^{3+}$ nanoparticles was possibly due to the highly strained and distorted environment around the lanthanide ions in the In_2O_3 lattice. $\text{In}_2\text{O}_3:\text{Dy}^{3+}$ nanoparticles, however, did not show any luminescence, possibly due to the fact that Dy^{3+} ions exhibit poor absorption and emission cross-section characteristics compared with Eu^{3+} . However, very recently Eu^{3+} ion-doped In_2O_3 nanocrystals have been synthesized via a facile solvothermal method, which showed intense and well-resolved intra-4f emissions of Eu^{3+} upon bandgap excitation [13.105]. This highlights the fact that, by altering the method of synthesis, it is possible to manipulate the optical properties of undoped and doped indium oxide nanoparticles and thus tune them according to the final application.

Cerium oxide or ceria (CeO_2) is a rare-earth metal oxide with an energy gap of 3.2 eV and high dielectric constant ($\epsilon = 26$) [13.106]. It is well known for its optical properties and ability to filter UV radiation [13.107, 108]. Cerium oxides have also been investigated in processes related to the production of hydrogen for fuel cells and the abatement of organic

Fig. 13.2 Emission spectrum after excitation at 235 nm for In_2O_3 nanoparticles

pollutants from industrial wastewater [13.109–113]. Additionally, they have been used as polishing materials in optics, as components of oxygen sensors, and as efficient catalysts in fuel-cell technology, catalytic wet oxidation, engine exhaust catalysts, NO removal, and photocatalytic oxidation of water [13.114–121]. Due to their nontoxic nature and excellent biocompatibility, ceria nanoparticles have the potential to be used in many biomedical applications. They find applications as radical-scavenging antioxidants, can protect healthy cells from radiation-induced damage during radiation therapy, and also provide neuroprotection to spinal cord neurons [13.122–124]. These properties are dictated to a large extent by their crystal structure and morphology as well as grain size. The physical and chemical properties of ceria nanocrystalline material often differ from those of crystalline or amorphous materials. Bulk CeO_2 is not generally considered as a semiconductor since its bandgap is usually attributed to an $\text{O}_{2p} \rightarrow \text{Ce}_{4f}$ transition. Hence, it is not regarded as a photoactive material. However, CeO_2 nanoparticles exhibit a photovoltaic response derived directly from the nanometric structure of the constituent particles. Thus, an important field of research is the development of new synthetic processes to produce ultrafine CeO_2 particles with nanocrystalline structure that will heighten the performance of the material.

Consequently, CeO_2 nanoparticles have been prepared using various methods such as sol-gel processing [13.125, 126], hydrothermal synthesis [13.127–130], homogeneous precipitation with urea or hexamethylenetetramine [13.131, 132], flame spray pyrolysis [13.133], a reverse micelle route [13.134,

[135], combustion synthesis [13.136], sonochemical and microwave-assisted heating routes [13.137], egg white solution route [13.138], a complex thermodecomposition method [13.139], a two-stage precipitation process [13.140], nonhydrolytic sol-gel synthesis [13.141, 142], solid-state reactions [13.143], mechanochemical reactions [13.144], etc. A semibatch reactor method was developed for synthesizing CeO₂ nanoparticles at room temperature [13.145]. Stable monodispersed cerium oxide nanoparticles have been synthesized in hydrocarbon solvents using oleic acid as surfactant [13.146]. The synthesis of some novel CeO₂ structures, including nanorods, nanowires, nanotubes, nanocubes, microplates, and other morphological structures, has also been reported by chemists [13.147–154, 154–166].

The estimated Bohr exciton radius for CeO₂ is about 78 nm [13.167]. Hence, for CeO₂ nanoparticles of sizes smaller than this, strong quantum confinement is expected. The optical properties of nanocrystalline CeO₂ vary widely depending on the size, shape, and morphology of the particles and also depend on the method of synthesis; For example, blue-shifts of the absorption peak and the absorption edges have been observed in the UV/Vis absorption spectra of sonochemically synthesized CeO₂ nanoparticles with mean particle size of 3.3 nm as a result of the quantum size effect [13.168]. However, the bandgap energy of reversed-micelle-synthesized CeO₂ nanoparticles changed little when the particle size was reduced from 4.1 to 2.6 nm [13.134]. The estimated bandgap of the CeO₂ nanoparticles (5–10 nm) prepared by a polymer complex method using cerium(III) acetate hydrate and polyvinyl pyrrolidone (PVP) was 3.44 eV. This value was within the range reported by Yin et al. ($E_g = 3.03\text{--}3.68$ eV for CeO₂ nanoparticles synthesized using sonochemical synthesis) [13.168]; Ho et al. ($E_g = 3.36\text{--}3.62$ eV for mesoporous CeO₂ nanostructures prepared using a polyol method) [13.169] and Chen and Chang ($E_g = 3.56\text{--}3.71$ eV for CeO₂ nanoparticles prepared using a precipitation method) [13.170]. However, the bandgap of CeO₂ nanoparticles (5 nm) synthesized using a self-assembly method was found to be 3.0 eV [13.171]. Ideally, quantum size effects arising from a reduction of the particle size predict a bandgap increase that is opposite to the effect observed here. However, simple quantum size effect calculations assume that no significant variation of the chemical structure of the metal oxide occurs during the particle size reduction. The discrepancy observed in this case is explained by the presence of oxygen vacancies and defects whose influence on the bandgap overcomes

the expected influence of the regular quantum size effect [13.172, 173].

The room-temperature photoluminescence properties of CeO₂ nanoparticles also show a lot of variation. On excitation with continuous-wave (CW) 325 nm laser light, an emission peak was displayed at room temperature by bulk CeO₂ in the range 2.4–2.7 eV, whereas no emission was observed from commercially available CeO₂ nanoparticles with mean size of 25 nm [13.174]. Hydrothermally synthesized CeO₂ nanoparticles with average size of 1.8 nm exhibited a strong blue emission at 425 nm (2.92 eV) [13.175]. On dilution of these CeO₂ nanoparticles with double-distilled water, the emission peaks shifted their positions with the changing concentration. This kind of dependence of the PL peak blue-shift on the particle concentration has also been observed for CeO₂ nanoparticles synthesized by reverse micelle route [13.127]. This arises due to charge transitions from the 4f band to the valence band of the CeO₂ nanoparticles. Broadband PL emission from 325 to 550 nm with four emission bands at ≈ 406 nm (3.06 eV), 420 nm (2.95 eV), a blue-green band at ≈ 483 nm (2.57 eV), and a weak green band at 530 nm (2.34 eV) were observed in case of CeO₂ nanoparticles synthesized using a polymer route [13.176]. CeO₂ nanoparticles synthesized by a surfactant cetyltrimethylammonium bromide (CTAB)-assisted coprecipitation process showed a strong photoluminescence peak at 469 nm (2.64 eV) and three relative weak peaks at 452, 483, and 493 nm, respectively [13.177]. These were explained on the basis of surface defects and oxygen vacancies present in the nanoparticles synthesized using the different techniques. CeO₂ nanoparticles obtained from the decomposition of cerium-oleate complex emitted strong violet/blue emission at 400 nm in the photoluminescence (PL) spectrum. The PL emission was found to be sensitive to the particle size and shifted to shorter wavelengths with decreasing size. This has been explained by charge transitions from the 4f band to the valence band of CeO₂ [13.178]. The emission pattern also depends on the morphology of the nanoparticles. For CeO₂ nanorods, three emission peaks located at 370, 414, and 468 nm can be found [13.179], while two peaks at 415 and 435 nm have been reported for flower-like CeO₂ [13.180].

Due to their nontoxic nature and excellent biocompatibility, ceria nanoparticles have the potential to be used in many biomedical applications. However, ceria shows weak emission characteristics, and various approaches have been used to improve its luminescence properties. Attaching a tag, such as a fluorescent dye,

Fig. 13.3 Emission spectrum after excitation at 290 nm for $\text{CeO}_2:\text{Dy}^{3+}(0.5\%):\text{Tb}^{3+}(5.5\%):\text{Eu}^{3+}(8\%)$ nanoparticles

like a shell to the surface of the nanoparticles provides reliable and consistent emission from the fluorescent tag, but modification of the surface may lead to biological inactivity of the nanoparticle [13.181]. It also makes the material more bulky and thus limits the penetration of cells by the nanoparticles. A better alternative involves doping of the parent matrix with elements that can emit themselves upon excitation in the UV-visible range of the spectrum [13.182]. Also, recently there has been a lot of interest in rare-earth ion-doped CeO_2 as a potential phosphor material. The luminescent properties of $\text{CeO}_2:\text{RE}^{3+}$ seem to depend on the preparation method. Europium (Eu) belongs to the rare-earth metal group and exhibits a strong red emission when doped in different matrices. The excitation spectrum of $\text{CeO}_2:\text{Eu}^{3+}$ lies at 373 nm when using a solid-state reaction, while it occurs at 340 nm in $\text{CeO}_2:\text{Eu}^{3+}$ prepared by the Pechini sol-gel process [13.183, 184]. Systematic investigation of nanocrystalline Eu^{3+} -doped CeO_2 prepared through a sol-gel process shows that the broad band in the excitation spectrum of $\text{CeO}_2:\text{Eu}^{3+}$ (353 nm) comes from the charge transfer (CT) transition from O^2 to Ce^{4+} , not from the oxygen vacancy or from the CT of O^2 to Eu^{3+} . The emission spectra were dominated by the ${}^5D \rightarrow {}^7F_1$ transition located at 591 nm [13.185]. $\text{CeO}_2:\text{Eu}^{3+}$ phosphor powders synthesized by the solid-state reaction method exhibited different behavior for direct excitation at 467 nm and indirect excitation of the CeO_2 host at 373 nm. Emission from Eu^{3+} was observed, but the intensity ratios of the various peaks were different in each case. The nature of this behavior is closely related to the defects

Fig. 13.4 CIE chromaticity diagram for $\text{CeO}_2:\text{Dy}^{3+}(0.5\%):\text{Tb}^{3+}(5.5\%):\text{Eu}^{3+}(8\%)$ nanoparticles

and symmetry distortion generated by Eu^{3+} replacing Ce^{4+} [13.183]. Undoped CeO_2 nanocrystals, and those doped with other lanthanide ions (Eu^{3+} , Tb^{3+} , Sm^{3+}), synthesized via a high-boiling-point solvent process exhibited unusual optical properties. The undoped CeO_2 nanocrystals showed a very weak emission band peaking at 501 nm, which was remarkably enhanced by doping additional lanthanide ions (Eu^{3+} , Tb^{3+} , Sm^{3+}) in the CeO_2 nanocrystals. The greatly increased emission band of $\text{CeO}_2:\text{Eu}^{3+}$ (Tb^{3+} , Sm^{3+}) nanocrystals (located at 500 nm) was not attributed to the characteristic emission of the lanthanide ions (Eu^{3+} , Tb^{3+} , Sm^{3+}) but to the presence of oxygen vacancies in the lattice of the CeO_2 nanocrystals [13.186].

We have synthesized a novel nanocrystalline $\text{CeO}_2:\text{RE}^{3+}$ ($\text{RE} = \text{Dy}$, Tb , Eu) phosphor which simultaneously emits blue, green, yellow, and red light from its active region on excitation of the host and consequently is expected to have tremendous applications in white light-emitting UV LEDs. These phosphors were synthesized using a sonochemical technique based on acoustic cavitation resulting from continuous formation, growth, and implosive collapse of bubbles in a liquid. The emission spectra of $\text{CeO}_2:\text{Dy}^{3+}(0.5\%):\text{Tb}^{3+}(5.5\%):\text{Eu}^{3+}(8\%)$ on excitation at 290 nm is illustrated in Fig. 13.3, which shows the presence of characteristic yellow, blue, green, and red emissions due to Dy^{3+} , Tb^{3+} , and Eu^{3+} ions, respectively, along with the blue emission of the host. As

seen in this spectrum, on excitation at the main host site (290 nm), there is efficient energy transfer from the host to the various dopants. The corresponding chromaticity diagram is shown in Fig. 13.4. On excitation at 290 nm, the emission appeared predominantly white with CIE 1931 chromaticity coordinates of $x = 0.308$, $y = 0.308$. The correlated color temperature (CCT) was found to be 6967 K. The International Commission on Illumination (CIE) standard illuminant D₆₅ has a CCT of 6500 K, representing standard daylight. For the present sample, excitation at 290 nm resulted in a CCT of 6967 K, near to that of D₆₅. Hence, this nanocrystalline CeO₂:Dy³⁺(2%):Tb³⁺(0.5%):Eu³⁺(1.5%) sample has tremendous potential application as a white light-emitting phosphor for deep-UV LEDs. Recently, there have been reports on undoped and rare-earth-doped CeO₂ nanoparticles exhibiting a photovoltaic response derived directly from the nanometric structure of the constituent particles [13.171]. These nanoparticles did not need photosensitization to have photovoltaic activity in the visible region, and the excitation spectrum depended notably on the presence of dopants. Consequently, operational organic-dye-free solar cells using nanometric ceria particles (in mesostructured or amorphous form) as the active component have been constructed with efficiencies that depend on the illuminating power.

Gadolinium oxide (Gd₂O₃), a rare-earth sesquioxide, has unique properties which can be utilized in a wide range of technological applications. Its high chemical stability, wide bandgap with transmission coefficient in the visible region of the solar spectrum, high neutron absorption cross-section, and relaxivity along with its ability to provide effective emission of radiation make it a very suitable material for use in solar cells, as phosphors in display devices, in reactors, neutron detectors, and neutron capture cancer therapy, and as a good contrast agent for medical imaging [13.187]. Such materials are also promising for use as labels in biotechnology because of their optical properties such as large Stokes shift, lack of photobleaching, and long fluorescence lifetime (about 1 ms). Gadolinium oxide (Gd₂O₃) is an attractive host lattice for several lanthanide ions to produce efficient phosphors emitting a variety of colors. Recently, Gd₂O₃:Eu³⁺ phosphor has been considered as one of the better phosphor candidate for flat-panel displays (FPDs) owing to its good color purity [13.188–190]. The red-emitting Eu-doped Gd₂O₃ phosphor is gaining importance due to its favorable low thermal expansion, phase stability, and high melting point [13.191]. It has been widely used as an

x-ray scintillator material and in high-definition projection televisions, flat-panel displays, and photoelectronic apparatus [13.192]. Over the past decade, Eu³⁺- and Tb³⁺-activated Gd₂O₃ phosphors have been investigated extensively [13.190, 193–195]. Tb³⁺, Dy³⁺, and Eu³⁺ ion-doped Gd₂O₃ particles have potential applications in immunoassays [13.196].

In view of this, a number of preparative methods have been explored for synthesis of doped Gd₂O₃ phosphors. Gd₂O₃:Eu nanoparticles have been prepared using a direct oxide precipitation method in high-boiling polyalcohol solutions, by a hydroxide precipitation method at 1073 K, and also by using soft chemical routes such as spray pyrolysis, sol–gel process, glycine–nitrate combustion, solid-state reactions, coprecipitation method, etc. [13.197–204]. The gas-phase condensation technique has been explored to individually dope Tb³⁺, Dy³⁺, and Eu³⁺ ions in Gd₂O₃ matrix. Nanocrystalline doped Gd₂O₃ phosphor films have also been prepared by the Pechini sol–gel soft lithography technique [13.205]. Gd₂O₃ exhibits a host absorption around 230–240 nm, and exciting the host might result in an energy transfer between the host and doped luminescent lanthanide ions. The rare-earth ions show abundant emission colors based on their 4f–4f or 5d–4f transitions. Eu³⁺ and Tb³⁺ show red/orange and green emission, respectively, at 611/590 nm and 544 nm. The characteristic emission of Dy³⁺ is dominated by two main groups of lines in the blue region (460–505 nm) and yellow region (570–600 nm). The optical properties exhibited by these nanoparticles differ slightly compared with their bulk counterparts. It is reported that the emission lifetime, luminescence quantum efficiency, and concentration quenching are strongly dependent on the particle size in the nanometer range [13.206, 207]. Gd₂O₃ nanocrystals of different sizes doped with 2.5 at. % Eu³⁺ synthesized by a sol lyophilization process exhibited a gap blue-shift with decrease in particle size [13.190]. Compared with the bulk material properties, some important changes in luminescence were observed. In particular, some lines were strengthened when the size of the nanoparticles diminished. A blue-shift in the ⁵D₀ → ⁷F transition in Gd₂O₃:Eu³⁺ nanoparticles synthesized by direct precipitation in high-boiling diethylene glycol (DEG) has been observed with decrease in particle size [13.197]. This has been attributed to the increasing Eu–O distance and associated decrease in the Eu–O bond strength.

Recently there have also been a few reports on synthesis of 1-D Gd₂O₃:Eu³⁺ nanomaterials, whose applications could be widely extended due to the shape-

specific and quantum confinement effects. $\text{Gd}_2\text{O}_3:\text{Eu}^{3+}$ nanotubes have been prepared via a wet chemical route with subsequent heat treatment [13.208]. The nanotubes exhibited strong red emission corresponding to the $^5D_0 \rightarrow ^7F_2$ transition of the Eu^{3+} ions under UV light or low-voltage electron beam excitation, which might find potential applications in fields such as light-emitting phosphors, advanced flat-panel displays, or biological labeling. Li et al. prepared $\text{Gd}_2\text{O}_3:\text{Eu}^{3+}$ nanowires via the anodized aluminum oxide (AAO) template method [13.209]. The decay time constant of the $^5D_0 \rightarrow ^7F_2$ transition became longer with increasing annealing temperature in $\text{Gd}_2\text{O}_3:\text{Eu}/\text{AAO}$. The lifetime of $^5D_0 \rightarrow ^7F_1$ in $\text{Gd}_2\text{O}_3:\text{Eu}/\text{AAO}$ composite films was more than that in the bulk powder. $\text{Gd}_2\text{O}_3:\text{Eu}^{3+}$ nanotubes synthesized using multi-walled carbon nanotube (MWCNT) templates emit strong red luminescence peaking at 610 nm, implying their potential application in the field of luminescence devices [13.210]. $\text{Gd}_2\text{O}_3:\text{Eu}^{3+}$ nanowires prepared by a simple solvothermal method in the presence of polyethylene glycol followed by a subsequent calcination process show a strong red emission corresponding to the $^5D_0 \rightarrow ^7F_2$ transition (610 nm) of Eu^{3+} under ultraviolet excitation (250 nm), with potential applications in red-emitting phosphors and field-emission display devices [13.211].

The photoluminescent properties of $\text{Gd}_2\text{O}_3:\text{Tb}^{3+}$ nanoparticles synthesized via the polyol method originate principally from the Tb^{3+} dopant, which exhibits a strong emission peak at ≈ 544 nm [13.212]. Similar emission spectra were observed for colloidal dispersions of the particles using fluorescent spectroscopy. These nanoparticles demonstrated the potential to be used both as fluorescent contrast agents in imaging fibroblast cells and macrophages and as magnetic resonance imaging (MRI) contrast agents. Nanostructured Tb^{3+} -doped Gd_2O_3 particles have also been synthesized from chloride precursors by NaOH addition in a polyol medium [13.213]. The typical emission spectrum on excitation at 275 nm showed four peaks from 470 to 640 nm, corresponding to the $^5D_4 \rightarrow ^7F_{6,5,4,3}$ transition of Tb^{3+} . The most intense peak of $^5D_4 \rightarrow ^7F_5$ was located at about 545 nm, and three other peaks were observed at 485 nm ($^5D_4 \rightarrow ^7F_6$), 585 nm ($^5D_4 \rightarrow ^7F_4$), and 620 nm ($^5D_4 \rightarrow ^7F_3$). $\text{Gd}_2\text{O}_3:\text{Tb}^{3+}/\text{Eu}^{3+}$ nanospheres and nanoplates have been synthesized using the hot solution nonhydrolytic procedure [13.214]. The shape was varied from nanospheres to nanoplates by changing the Gd precursor (acetates versus acetylacetonate), the major organic

Fig. 13.5 CIE chromaticity diagram for $\text{Gd}_2\text{O}_3:\text{Dy}^{3+}$ (1.95%): Tb^{3+} (0.05%) nanoparticles

surfactant (1,2-hexadecanediol (HDD) versus trioctylphosphine oxide (TOPO)), and the concentration ratio of precursor to surfactant. Though the PL peak energies were the same for nanoplates and nanospheres, the luminescent intensity from nanospheres was about 2–3 times higher than that from nanoplates, which has been explained in terms of the doping efficiency, crystal structure, and ratio of surface to volume.

Recently, we reported sonochemical synthesis of a novel nanocrystalline $\text{Gd}_2\text{O}_3:\text{RE}$ (RE = Dy, Tb) phosphor which simultaneously emits blue and yellow light from its active region on excitation of the host and consequently is expected to have tremendous applications in white light-emitting deep-UV LEDs [13.215]. The CIE chromaticity coordinates calculated from the emission curve of $\text{Gd}_2\text{O}_3:\text{Dy}^{3+}$ (1.95%): Tb^{3+} (0.05%) for 247 nm excitation were $x = 0.315$, $y = 0.316$ (Fig. 13.5). These values correspond almost exactly to the CIE coordinates of the balanced white-light region of the chromaticity diagram, where $x = 0.33$, $y = 0.33$. The corresponding CCT value was found to be 6508 K. The CIE standard illuminant D_{65} has CCT of 6500 K, which represents standard daylight. For this double-doped sample, excitation at 247 nm resulted in CCT of 6508 K, which is extremely close to that of D_{65} . Due to the nondispersibility of the sonochemically synthesized $\text{Gd}_2\text{O}_3:\text{Tb}^{3+}:\text{Dy}^{3+}$ nanoparticles in aqueous/organic solvents, the polyol method of synthesis was explored [13.216]. The CIE chromaticity coordinates

Fig. 13.6 $\text{Gd}_2\text{O}_3:\text{Dy}^{3+}(2\%)$ film on quartz under UV light with room lights switched off. Bright white emission is observed with the ultraviolet excitation

($x = 0.270$, $y = 0.328$) and the CCT value (9157 K) of the $\text{Gd}_2\text{O}_3:\text{Dy}^{3+}(1.95\%):\text{Tb}^{3+}(0.05\%)$ phosphor syn-

thesized by the polyol route was distant from that of the D_{65} point (6500 K). This proves that the method of synthesis plays a major role in the optical properties of nanomaterials. Dispersible $\text{Gd}_2\text{O}_3:\text{Dy}^{3+}(2\%)$ phosphor was then synthesized using the polyol technique. The phosphor showed white luminescence in solid form, as aqueous solution, and also when spin-coated onto quartz substrate. For the spin-coated sample, the CIE coordinates were $x = 0.313$, $y = 0.296$ and the correlated color temperature was 6815 K. Figure 13.6 shows a spin-coated $\text{Gd}_2\text{O}_3:\text{Dy}^{3+}(2\%)$ phosphor film on a quartz slide substrate and the bright white luminescence of this film observed under ultraviolet light with $\lambda_{\text{exc}} = 310\text{ nm}$. This demonstrates that $\text{Gd}_2\text{O}_3:\text{Dy}^{3+}(2\%)$ films are good candidate materials for new lighting devices.

13.3 Sorbent Properties of Oxide Nanomaterials

Residual surface hydroxides can also add to the rich surface chemistry exhibited by metal oxides such as MgO , CaO , SrO , BaO , Al_2O_3 , TiO_2 , Fe_2O_3 , ZnO , etc., and this chemistry is generally attributable to Lewis acid, Lewis base, and Brønsted acid sites of varying coordination, i.e., metal cations, oxide anions, and surface $-\text{OH}$, which can be isolated or lattice bound. Study of their use as adsorbents and catalysts has led to two important discoveries: (i) surface reactivities are inherently higher per unit surface area for nanocrystals versus microcrystals, and (ii) compaction of nanocrystals into pellets does not significantly degrade their surface area or surface reactivity when moderate pressures are employed, enabling these nanostructured materials to be employed as very fine powders or as porous, reactive pellets.

Though the surface chemistry of crystals has been of interest for a long time [13.217–221], the recent availability of nanocrystalline samples has allowed the demonstration of vast differences due to crystal size and shape that had not been imagined before. Therefore, new and deeper understanding is required, which in turn suggests additional work. Another approach to investigating the differences in surface reactivity of nano- versus microcrystals is to look at pH changes in water as a function of time.

Generally, nanomaterials cause pH adjustments more rapidly than normal powders, and this is especially true for MgO and Al_2O_3 . These results can be explained by surface area effects, and enhanced surface reactivity per m^2 is not indicated by these pH studies of

powder samples. On the other hand, in destructive adsorption studies in which polar organic molecules are adsorbed, nanomaterials do exhibit inherently more active surfaces.

Hydroxyl groups may form by the redox reaction in which the OH group with its electron pair appears bound by a Lewis acid site (M) and a hydrogen atom reacts with either lattice oxygen (a Lewis base) or an adsorbed oxygen molecule. The hydroxyl groups may be formed in two ways:

1. OH group with an oxygen atom from lattice oxygen plays the role of the electron donor. The reaction involves hemolytic dissociation of water on the surface and the reaction of a neutral hydrogen atom with a lattice oxygen, which is usually in the 2-state. The OH group formed may be ionized and become an electron donor.
2. According to the second mechanism, there is a possibility of the reaction between a hydrogen atom and a lattice oxygen, and the hydroxyl group thus formed may bind to a metal atom. In this case, an oxygen vacancy is ionized by providing an additional electron.
3. The third mechanism takes place at low temperatures and is related to the competition between water and oxygen molecules for the same adsorption sites.

In equilibrium conditions, some of the active sites are occupied by water molecules and the concentration

of chemisorbed oxygen decreases, which leads to the lower surface charge.

13.3.1 Sorbents for Environmental Remediation

First, we deal with new discoveries in the field of sorbents. Activated high-surface-area carbon is the *gold standard* in sorbent technology. A wide variety of carbon sorbents made from coal, wood, coconut shells, fruit seeds, polymers, etc. have been used for centuries for purification of chemicals, water, and air. Chemical additives to carbon sorbents often enhance their abilities to be more selective for certain sorbates. Also, recent developments in the field of fullerenes, carbon nanotubes, graphene, and carbon fibers have added greatly to the usefulness of carbon as a whole. Carbon is certainly an intriguing and amazing material, especially in nanostructured solid form. Nonetheless, there are some drawbacks to carbon sorbents. Since it mainly operates by physisorption (rather than strong chemisorption), many volatile sorbates are not trapped very well by carbon. Also, sorbates are usually not destroyed or detoxified by carbon, and eventual leaching or bleeding-off of sorbates is a common problem. There are, of course, many other solids that serve as high-surface-area (high-capacity) sorbents. This has become especially the case in recent years as new synthetic methods have allowed nanoscale metal oxides such as magnesium oxide (MgO), calcium oxide (CaO), titanium oxide (TiO₂), aluminum oxide (Al₂O₃), iron oxide (Fe₂O₃), and zinc oxide (ZnO) to be prepared [13.222–224]. These oxides in high-surface-area form, and their physical mixtures and intimate (molecular or nanoscale) mixtures, have proven to be excellent sorbents for many applications. We have used metal oxides as *destructive adsorbents* of organophosphorus compounds (chemical warfare agent mimics and pesticides). The metal oxide (MgO) was contained in a fixed bed reactor tube, and heated to temperatures hot enough to very rapidly destroy a series of organophosphorus chemicals. As an example, triethylphosphate [(CH₃CH₂O)₃P=O] adsorbed strongly on a MgO surface, and about four surface MgO moieties adsorbed one phosphate molecule [13.225, 226]. A wide variety of toxic industrial chemicals (TICs) have been found to be susceptible to treatment by these destructive adsorbents. Remediation of chemical spills, contaminants in commercial gases, and odors in air are now commonplace with this class of safe-to-use nanoscale metal oxides.

Biological toxins, including bacteria, bacterial spores such as anthrax, and viruses, are probably the most serious threats. The need is growing for broad-spectrum biocides that can decontaminate tough-to-kill spores, as well as other biological threats [13.227–230]. Indeed, these high-surface-area solids were very effective for destroying *Escherichia coli*, *Bacillus cereus*, and *Bacillus subtilis* spores, with MgO, Al₂O₃, TiO₂, and CeO₂. There were four modes of action discerned:

1. Electrostatic attraction of the spores to the nanoparticles
2. High local pH weakening the spore's protective outer layer
3. Abrasive action
4. Oxidative reactions with the attached zero-valent halogens.

The high surface area of the nanooxides makes them efficient adsorbents for toxic inorganic cations and anions also. Treatment processes make use of one or a combination of processes such as precipitation, membrane filtration, ion exchange, and adsorption. However, adsorption using simple and cheap adsorbents is gaining a lot of importance due to its economic benefits as well as the easy availability of different kinds of adsorbents [13.227]. There is always ongoing research for the development of sorbents that are cheap and easily synthesized to avoid expensive regeneration processes after use. Hence, research in developing new adsorbents is focused on the development of simple and economic procedures for their synthesis or reuse.

Environmental fluoride has received much attention on account of its known beneficial and detrimental effects on health. Lower levels of fluoride in drinking water may lead to dental caries, whereas excess injection through drinking water causes dental and skeletal fluorosis. The World Health Organization has specified the tolerance limit for fluoride content in drinking water as 1.5 mg/l. Hence, defluoridation of water is important to provide safe water. The presence of heavy metals in the environment is a serious global, social, and environmental problem. Many industrial facilities, such as metal plating and mining operations, fertilizer industry, tanneries, and textile industries, discharge heavy metals via their waste effluents. Toxic metal ions are a serious health hazard, and every possible care should be taken to prevent their contact with and mixing into air, water, and soil. High levels of lead damage brain and kidney,

mercury vapors lead to permanent brain damage at high concentration levels, higher concentration of copper in water can cause eye irritation, headache, dizziness, and diarrhea, and inhaling too much chromium causes fragile bones and probably acts as a human carcinogen. Therefore, in an effort to reduce heavy-metal levels in wastewater, drinking water, and water used for agriculture to the maximum permissible concentration, several methods such as ion exchange, adsorption, precipitation, and membrane separation have been adopted. Based on its toxicity, the US Environmental Protection Agency (EPA) has set the maximum permissible limit for lead ions in drinking water as 0.05 mg/l, and the Bureau of Indian Standards as 0.1 mg/l. The upper limit for lead in drinking water recommended by the World Health Organization (WHO) and the American Water Works Association (AWWA) is 0.05 mg/l. These limits suggest more stringent requirement for removal of lead from the aqueous environment, which necessitates the development of innovative and cost-effective treatment methods for effluents containing lead before discharging into natural water bodies.

Among various techniques, the ion-exchange process is used exclusively in water treatment, and many studies have been carried out to find inexpensive and chemically feasible adsorbents. Therefore, for an ion exchanger to be practical for removal of heavy metals from industrial wastewater containing other competing ions such as calcium and magnesium, it is essential that the chosen sorbent be sufficiently selective toward heavy metals against calcium and magnesium. Extensive studies on the adsorption and ion-exchange properties of hydrous oxides have been carried out from the point of view of analytical separation, as adsorbents for the recovery of trace metals present in natural waters, and as matrices for radioactive nuclear waste. The ion-exchange and adsorption properties of hydrous oxides arise from the pH-dependent protonation and deprotonation reactions of surface hydroxyl groups when in contact with solution.

The use of nanocrystalline compounds as simple adsorbents appeared as a good alternative. There is increasing interest in the field of nanoparticles as these are more efficient in processing as compared with thin films. Moreover, high-density pellets can be made from nanoparticles as compared with bulk. Thus, the sorption property could also be improved by using nanocompounds. In general, a decrease in particle size increases the surface area and hence increases the number of adsorption sites. There are a number of synthesis procedures that have been adopted

for synthesis of nanoparticles [13.231–234]. Combustion synthesis using an oxidant and fuel is one of the simplest and fastest procedures adopted. In the synthesis of magnesia–alumina mixed oxide, magnesium nitrate ($\text{Mg}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$, 99.9% pure) and aluminum nitrate ($\text{Al}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$, 99.9% pure) were used as the oxidants along with glycine as the fuel (35%) in fuel-deficient ratio. The reactants were mixed in deionized water in the required molar ratios, which on thermal dehydration resulted in the formation of a viscous liquid (gel). The viscous liquid swelled and auto-ignited on increasing the temperature ($\approx 250^\circ\text{C}$). This was accompanied with the rapid evolution of a large volume of gases, to produce voluminous powders. Since the duration of auto-ignition is short ($< 10\text{ s}$), the powders were calcined at 600°C in air to remove traces of any carbon impurities that could be present. Three different ratios (0.8 : 0.2, 1 : 1, and 1 : 2) of Mg and Al were taken, respectively. The x-ray diffraction (XRD) pattern of the compound indicated that the initial compound is periclase-type MgO structure with 20% Al solubility. The observed XRD pattern showed a shift in the peak from the standard MgO pattern, thus confirming the solubility of Al in the MgO, forming the $\text{Mg}_{0.8}\text{Al}_{0.2}\text{O}_{1.1}$ compound. The oxide $\text{Mg}_{0.8}\text{Al}_{0.2}\text{O}_{1.1}$ was found to be single-phasic and nanocrystalline (with low amorphous content). The crystallite size was calculated using Scherrer's formula, and the average crystallite size of the nanopowders was found to be 8 nm. Nanosize pure and mixed ferrite composites were synthesized by combustion of aqueous solutions containing stoichiometric amounts of iron nitrate and glycine (analytical grade, E. Merck) as the oxidant and reductant, respectively. The stoichiometric composition of the redox mixture was calculated based on the total oxidizing and reducing valencies of the oxidizer and the fuel, keeping the O/F ratio at unity. For synthesis of cobalt ferrite, cobalt carbonate as the cobalt source was added along with the redox mixture of ferric nitrate and glycine taken in stoichiometric ratio. CoCO_3 was dissolved in a minimum quantity of $\approx 50\%$ HNO_3 (fuming), and $\text{Fe}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$ and glycine in deionized water. In the synthesis of both pure and mixed ferrites, the homogeneous aqueous mixture of the nitrates and glycine was heated on a hot plate till it became dehydrated to form a viscous gel. When the obtained gel was introduced into a muffle furnace preheated to 300°C , the gel boils, foams, and undergoes smoldering (flameless) combustion to produce nanosized oxide particles. The synthesis was also carried out by using a fuel-deficient composition (1 : 0.5). The oxide pow-

ders obtained were calcined at 600 °C for 1 h to remove carbonaceous impurities. Structural elucidation studies showed that ferrite synthesized in the fuel-deficient condition (oxidant : fuel = 1 : 0.5) had a single phase of Fe₂O₃, whereas that synthesized in stoichiometric conditions (oxidant : fuel = 1 : 1.66) showed mixed phases containing Fe₂O₃ and Fe₃O₄ and the particle size was around 50 nm. The surface areas of α-Fe₂O₃ synthesized in fuel-deficient and stoichiometric conditions were 2.055 and 2.26 m²/g, respectively, and that of CoFe₂O₄ was 2.02 m²/g. Characterization of the oxide by zeta potential measurements was carried out at the pH at which sorption studies were carried out. For pure ferrite produced in the fuel-deficient and stoichiometric conditions, the zeta potential value was +34.6 and +32.4 mV, respectively, whereas for CoFe₂O₄, it was found to be -38.1 mV. α-Manganese oxide was prepared by hydrolysis of KMnO₄, and the particles were characterized using XRD and TEM. It was shown that the particles were spherical and the particle size was 6 nm. Sorption studies were carried out in batch mode wherein 10 ml of aqueous solution of the ion of interest or its mixture at a particular pH was equilibrated with a weighed amount of oxide sample for a known period of time, and the amount taken up was studied as a function of various experimental conditions. Nanocrystalline magnesia–alumina mixed oxide (Mg_{0.80}Al_{0.20}O_{1.10}) prepared by the combustion synthesis method was found to be an excellent adsorbent for uptake of fluoride anion of up to 120 mg/l concentration with uptake capacity of 10 mg F⁻/g. A bioinorganic composite of nanohydroxyapatite/chitosan (n-HApC) showed a defluoridation capacity (DC) of 1560 mg F⁻/kg in comparison with DC of 1296 mg F⁻/kg for nanohydroxyapatite (n-HAp).

Nanocrystalline cobalt ferrite and MnO₂ showed good uptake capacity for lead ion. Titania–silica (TiO₂/SiO₂) binary mixed oxide with surface area of 405.3 m²/g was found to be a good sorbent for lead ions. A novel hybrid adsorbent HMO-001 was fabricated by impregnating nanosized hydrous manganese dioxide (HMO) into a porous polystyrene cation-exchange resin (D-001) for enhanced removal of Cd(II) and Zn(II) ions from waters. The nanohydroxyapatite particles (nHAp) had sorption capacity of 1.17 mmol/g of Pb.

The sorption results were fitted using both kinetic and equilibrium modeling. For equilibrium modeling, Langmuir and Freundlich adsorption models were chosen, and the obtained experimental data were fitted to the equations of the two models. For this, the amount

of inorganic ion taken up by the oxide was calculated by the simple concentration difference method. Batch-mode experiments were carried out with *W* g of oxide and *V* ml of the ion solution. If the initial and final concentrations of inorganic ion are *C* and *C*₁ (mg/l), the ion uptake *q* (mg/g) is calculated from the mass balance using (13.5)

$$q = \frac{(C_0 - C_1) \cdot V}{W \cdot 1000} \quad (13.5)$$

The linearized form of the Freundlich equation [13.235] is given in (13.6), where *q_e* is the amount adsorbed at equilibrium (mg/g), *C_e* is the equilibrium concentration (mg/l), and *K_f* and *n* are constants indicative of adsorption capacity and adsorption intensity, respectively,

$$\ln q_e = \ln K_f + \frac{1}{n} C_e \quad (13.6)$$

The Langmuir equation [13.236] assumes that:

1. The solid surface presents a finite number of identical sites which are energetically uniform.
2. There are no interactions between adsorbed species, meaning that the amount adsorbed has no influence on the rate of adsorption.
3. A monolayer is formed when the solid surface reaches saturation.

The linear form of the Langmuir equation is given in (13.7), where *q_e* is the amount adsorbed at equilibrium (mg/g), *C_e* is the equilibrium concentration (mg/l), *b* is a constant, and *Q*⁰ is the mass of adsorbed solute required to saturate a unit mass of adsorbent (mg/g). *Q*⁰ represents a practical limiting adsorption capacity when the surface is fully covered with lead ion. By plotting *C_e/q_e* versus *C_e*, *Q* and *b* can be determined if a straight line is obtained

$$\frac{C_e}{q_e} = \frac{1}{Q^0 \cdot b} + \frac{C_e}{Q^0} \quad (13.7)$$

It is reported that, if the value of the Freundlich constant *n* lies between 1 and 10, it indicates favorable adsorption. The applicability of the Langmuir model indicates monolayer coverage, which indicates the possibility of an ion-exchange mechanism.

In the reaction-based modeling, the pseudo-first-order and pseudo-second-order models proposed by Lagergren and Ho and Mackay, respectively, were employed to explain the solid/liquid adsorption. To distinguish the kinetic equation based on the adsorption capacity of solid from the one that is based on the concentration of solution, the first-order and second-order

reactions in solution phase are termed pseudo first order and pseudo second order, respectively. It was Lagergren who first presented the first-order rate equation for adsorption [13.237], and thereafter it has been extensively used for the adsorption of an adsorbate from an aqueous solution. Lagergren's first-order rate equation has been called pseudo first order since 1998 [13.238] and is expressed as

$$\log(q_e - q_t) = \log q_e - \frac{k_{ad} \cdot t}{2.303}, \quad (13.8)$$

where q_e and q_t are the amount of inorganic ion on the surface of the sorbent beads (mg/g) at equilibrium and at time t , respectively, and k_{ad} is the equilibrium rate constant of pseudo-first-order sorption (h^{-1}). The slope

of the straight-line plot of $\log(q_e - q_t)$ against t will give the values of the rate constants (k_{ad}).

Ho's second-order rate expression, known as pseudo second order [13.239], is expressed linearly as

$$\frac{t}{q_t} = \frac{1}{K_{2ads}q_e^2} + \frac{t}{q_e}, \quad (13.9)$$

where q_t is the amount of ion on the surface of the bead (mg/g) at any time t , K_{2ads} is the pseudo-second-order rate constant (g/mg min) and q_e is the amount of ion sorbed at equilibrium (mg/g) and the initial sorption rate. The data obtained are fitted on a plot of t/q_t against t , which should be a straight line, and the values of q_e and K_{2ads} can be calculated from the slope and intercept, respectively.

13.4 Catalytic Properties of Oxide Nanomaterials

Catalysis is the subject which deals with the change of rate of reaction due to the presence of any substance, called the catalyst. The catalyst does not participate in the chemical reaction like other substrates. Depending on the reaction, a catalyst may take part in multiple chemical transformations. Materials that improve the rate of reaction are called positive catalysts, whereas those that slow down the rate of reaction are called inhibitors or negative catalysts. In addition, materials which increase the activity of any catalyst are called promoters, whereas materials which deactivate catalysts are called catalytic poisons. Mostly, in heterogeneous catalysis, the reaction occurs on a solid surface and involves the reaction of gases or liquids [13.240–242]. Therefore, the specific surface area of the solid plays an important role in the reaction rate, and in this respect nanotechnology plays an important role. Nanomaterials have a few times more surface area than bulk samples.

Various nanocatalysts such as doped ceria, Au nanoparticles dispersed on TiO_2 , Co_2O_3 , Fe_2O_3 , etc. have been developed to oxidize CO at lower temperatures [13.243–249]. Carbon monoxide is one of the toxic gases, and can disturb the normal functioning of hemoglobin by converting it into carboxyhemoglobin, if its level is more than 100 ppm in the atmosphere. This can be prevented by oxidation of the fatal CO into nontoxic CO_2 [13.250]. Rh, Au dispersed ceria nanoparticles also form an excellent catalyst for CO oxidation [13.251–253]. Ceria is also a vital component in three-way catalyst (TWC), which is used to remove pollutants other than CO from the environment. The

possibility of the conversion $\text{Ce}^{3+} \leftrightarrow \text{Ce}^{4+}$ assists in accepting or removing oxygen from ceria. Moreover, the fluorite structure of ceria or doped ceria has superior chemical and physical stability. Pure CeO_2 alone as a catalyst is not of much interest due to its low textural stability under high-temperature conditions, as usually encountered in exhaust gases. At high temperatures, the surface area of CeO_2 reduces drastically and it loses its redox properties and oxygen storage capacity [13.254]. It has been observed that doped ceria has superior stability towards sintering as well as its catalytic activity [13.255]. The versatility of rare-earth-doped ceria depends on the availability of the 4f shell. On substitution of trivalent rare-earth oxide, the oxygen vacancies increase, which subsequently improves the oxygen mobility and also the oxygen storage capacity.

It has been observed that ceria in nanoform is more important since nanoceria exhibits superior catalytic properties compared with bulk ceria. The homogeneity of the sample can be controlled in nanocrystalline form, which in turn can improve the catalytic properties of sintered ceria [13.256]. Nanocrystalline ceria and doped ceria have been prepared by several methods such as sol-gel, gel combustion, sonochemical, ball milling, spray hydrolysis, homogeneous precipitation, etc. [13.126, 257–262]. In a few of these synthetic procedures, the precursor needs to be heated to obtain the final product, but such thermal treatment leads to agglomeration of the powders, which is not very encouraging since the powders become difficult to disperse.

Fig. 13.7 XRD patterns of SDCN, SDCH, GDCN, and GDCH

Table 13.3 Physicochemical properties of doped ceria

	Surface area (m ² /g)	Particle size (nm)	Agglomerate size	
			Before sonication (μm)	After sonication (μm)
SDCH	135	10	19	4
GDCN	128	11	19	5
SDCN	102	16	26	9
GDCN	76	16	27	11

For catalytic purposes, it is necessary to synthesize monodisperse ceria or doped ceria nanopowders having high surface area. It has been demonstrated that addition of H₂O₂ before precipitation of cerium hydroxide leads to less agglomeration between the particles [13.263, 264].

We have demonstrated the effect of the presence of H₂O₂ on the synthesis and catalytic properties of doped ceria nanopowders. For this purpose, four sets of samples were prepared wherein two sets consisted of Ce_{0.8}M_{0.2}O_{1.90} (M = Gd³⁺, Sm³⁺) without H₂O₂ and the other two sets consisted of Ce_{0.8}M_{0.2}O_{1.90} (M : Gd³⁺, Sm³⁺) with H₂O₂ in molar ratio of 1 : 2 (metal ion : H₂O₂). The samples are referred to as GDCH for gadolinia-doped ceria and SDCH for samaria-doped ceria. The samples prepared in the absence of H₂O₂ are referred to as GDCN and SDCN, respectively. Pure ceria was also prepared by the same procedure without H₂O₂ to compare with the results. Calcination

Fig. 13.8 Oxidation of CO in presence of different catalysts

of all samples was done at 600 °C for 1 h before further characterization.

Careful analysis of the XRD patterns (Fig. 13.7) revealed that the doped samples were of fluorite type with structure similar to pure CeO₂. Also, it is clearly visible from Fig. 13.7 that the (111) diffraction peak of GDCH and SDCH were broader than that of GDCN and SDCN, which implies that the samples prepared in the presence of H₂O₂ had smaller particle size than the samples prepared without H₂O₂. Thus, H₂O₂ affects the particle size of the nanoparticles. The samples prepared in the absence of H₂O₂ form hydroxide precipitate upon addition of NaOH to the mixed nitrate solution. During the condensation process, H₂O is eliminated, thus forming a three-dimensional (3-D) network of M–O–M (M = metal ion) linkages. The samples prepared in the presence of H₂O₂ have peroxo linkages. These peroxo species would disrupt this 3-D network as it is a sideways linkage, thus reducing the number of adjacent –OH species. Upon calcination, these O–O linkages also break down, which ultimately leads to smaller crystallite size. The presence of peroxo linkages has been confirmed by Raman spectroscopy, which is described later. The crystallite size of all the as-prepared and calcined samples was determined using the Scherrer equation.

The crystallite sizes of the as-prepared material were found to be smaller than for the calcined samples, as expected (Table 13.3).

To study the efficiency of these nanopowders as catalyst as well as to investigate the effect of H₂O₂ on the

same, Sm-doped ceria powders were investigated for their catalytic activity. The catalytic property of pure CeO_2 prepared by the same route was also investigated under similar conditions for better comparison. Figure 13.8 presents the catalytic activity of CeO_2 , SDCN, and SDCH nanopowders for the CO oxidation reaction as a function of temperature. Samarium-substituted samples were found to show better activity as compared with the unsubstituted sample. Even though the onset of conversion of CO to CO_2 could be observed in pure ceria at room temperature, 100% conversion was achieved only at $\approx 500^\circ\text{C}$, suggesting a sluggish rise in activity with increasing temperature. For the Sm-doped sample prepared in the absence of H_2O_2 , 100% conversion took place at 475°C , whereas for the same composition prepared in the presence of H_2O_2 , the 100% conversion temperature dropped to 395°C , which is a marked improvement from 500°C . This observation reveals that substitution as well as particle size has profound effects

on the conversion temperature and subsequently on the catalytic activity. The decreasing order of catalytic activity as evident from Fig. 13.10 is: SDCH > SDCN > CeO_2 . The catalytic activity of ceria is attributed to factors such as ease of movement of lattice ions and the possibility of readily changing between Ce^{3+} and Ce^{4+} , together with the high oxidizing capability of the Ce^{4+} ion. The presence of a trivalent rare-earth ion introduces oxygen ion vacancies which further increases the mobility. The higher catalytic activity of SDCH as compared with SDCN could be due to the higher surface area and smaller particle size of the former as compared with the latter. In the sample having higher surface area and lower particle size, the activation barrier is easily overcome and subsequently higher conversions are observed at relatively lower temperature.

Thus, the samaria-doped nanoceria prepared in the presence of H_2O_2 showed marked improvement in catalytic properties compared with pure ceria.

13.5 Oxide Nanomaterials in Ionics

Nanocrystalline ceramics are expected to exhibit improved or unique characteristics as compared with conventional ceramic materials. Generally, ceramic nanopowders are functional materials as they have great potential for many advanced applications due to their unique characteristics, particularly related to their electrical, optical, mechanical, and thermal properties [13.265]. Among the technologically important ceramics, pyrochlores in general have received a lot of attention due to their potential for use in fuel cells as electrolytes [13.266]. In $\text{A}_2\text{B}_2\text{O}_7$ pyrochlores, the A^{3+} ions occupy the 16d sites (1/2, 1/2, 1/2), the B^{4+} ions are at the 16c sites (0, 0, 0), and the O ions occupy the 48f sites (x , 1/8, 1/8) and 8b sites (3/8, 3/8, 3/8). The 8a sites in pyrochlore remain unoccupied. Here, x is a positional parameter that indicates the extent to which the 48f oxygen ion is off-centered, and it is sensitive to the sizes of the A and B ions. Studies have shown that the ionic conduction is due to oxygen vacancy hopping along the 48f–48f pathway [13.267–269].

Riess et al. have demonstrated that the ionic conductivity strongly depends on the synthesis route used to produce the ceramics [13.270]. Soft chemical routes play an important role in the preparation of nanomaterials, on further manipulation giving rise to highly dense pellets. Among the solution chemistry routes, the combustion technique is capable of producing

nanocrystalline powders of oxide ceramics at a lower calcination temperature in a short time with improved powder characteristics [13.271]. The success of this process is attributed to the intimate mixing among the constituents using suitable fuel or complexing agents in an aqueous medium followed by an exothermic redox reaction between the fuel and an oxidizer (i.e., nitrates) [13.272]. During gel combustion, the generated heat helps in crystallization and formation of the desired phase. The evolution of gaseous products during the combustion dissipates the heat of combustion and limits the rise of temperature, thus reducing the possibility of premature local partial sintering among the primary particles, which helps to form soft agglomerates. Dense pellets can be prepared from soft agglomerated powders. To rule out electronic conduction in the samples, measurement in H_2 atmosphere was also performed. Electrolyte material to be used in solid oxide fuel cells (SOFCs) has to survive in the presence of H_2 atmosphere. Therefore, it is important to ensure the stability of pyrochlores in reducing environment also.

As an example of an ionic conductor a series of samples, namely $\text{Nd}_{2-y}\text{Gd}_y\text{Zr}_2\text{O}_7$, were investigated. These samples prepared by the solid-state route indicated that the composition near $y = 1.0$ showed the highest conductivity in the range of $350\text{--}423^\circ\text{C}$ in air only [13.273]. However, solid-state synthesized sam-

Fig. 13.9 XRD pattern of $\text{NdGdZr}_2\text{O}_7$ calcined at different temperature

ples in general do not have high sintered density. Hence, we also explored the ionic conductivity of samples (around $y = 1.0$) prepared by the rapid gel combustion route, which often results in sinter active powder.

The net oxidizing valency of gadolinium and neodymium nitrates and zirconium oxynitrate and the reducing valencies of fuel were estimated using the valencies of the individual elements [13.274]. Therefore, based on the stoichiometry concept, the ratio of oxidizing and reducing valencies should be unity, which implies that the ratio of valencies of metal nitrates/oxynitrates to citric acid should be 1 : 2.78.

Using this synthetic procedure, the obtained powders were found to be in pyrochlore structure only. The XRD pattern of the calcined powder of $\text{NdGdZr}_2\text{O}_7$ is shown as an example in Fig. 13.9 [13.275]. However, due to the presence of broad peaks and noisy background for the samples calcined at 600 °C, the superstructure peaks, characteristic of pyrochlore orderings, are difficult to visualize. The superstructure peaks start to become prominent upon further heating. The crystallite sizes were calculated using Scherrer's formula. The average crystallite size of all the samples was within the range 4–6 nm. The crystallinity improves with increase in calcination temperature, as inferred by the appearance of narrow and sharp XRD peaks (Fig. 13.9). The intensity of the superstructure peaks decreases with increase in Gd^{3+} content in the solid solution, suggesting that the disorder also increases.

The conductivity in these pyrochlore materials arises due to hopping of oxygen ions along the 48f–48f

vacancy pathway [13.267–269]. The ionic conductivity of these samples was determined from measured impedance data. A typical impedance spectrum of a polycrystalline material consists of two semicircular arcs corresponding to grains and grain boundaries, in the high- and intermediate-frequency ranges, respectively. The electrode polarization is the third part of the impedance spectrum in the low-frequency region, which becomes significant as the measuring temperature increases. While considering the electrical properties of the material, each of the individual arcs due to grains and grain boundaries is represented by a parallel resistance–capacitance (R – C) circuit having a specific time constant for relaxation [13.275]. The real–imaginary impedance spectra show a grain boundary arc with capacitance value obtained from curve fitting in the range of 10^{-8} – 10^{-9} F. As the capacitance value of the grain conductivity–relaxation process is very small, only one arc due to grain boundaries is visible in the spectrum. In this case, the high-frequency intercept with the axis of the real part of the impedance is considered as the grain resistance. The grain boundary resistance (R_{gb}) is obtained by subtracting the grain resistance (R_g) from the total resistance (R_t). It can be seen that, with increasing measuring temperature, both R_g and R_{gb} decrease significantly. At the same time, it is observed that the influence of electrode polarization processes starts to dominate the electrical conduction mechanism. With further increase in the measuring temperature, the arc due to grain boundaries disappears and the intercept with the real impedance axis represents the total resistance of the material. Thus, it is again found that, with increasing Gd doping concentration, the material becomes more resistive due to both grains and grain boundaries. One more important point is that the influence of the grain boundaries is not so significant in the measurement temperature range of 375–800 °C when the grain size is around 0.8–1.0 μm .

The activation energy and preexponential factors could be calculated based on the Arrhenius behavior. The activation energy ranges from 0.98 to 1.06 eV with increasing Gd^{3+} content in the series, which agrees with oxide ion migration [13.276]. The interesting observation is that the activation energy in air (E_a) and the preexponential factor (σ_0) increase with increasing Gd content in the solid solution (Fig. 13.10). It has been reported earlier that, with increase in the Nd content in the $\text{Nd}_{2-y}\text{Gd}_y\text{Zr}_2\text{O}_7$ series, the degree of order increases [13.277]. On the other hand, with increase in Gd content in the same series, the degree of disorder in

Fig. 13.10 Arrhenius plots of total electrical conductivity of $\text{Gd}_{0.8}\text{Nd}_{1.2}\text{Zr}_2\text{O}_7$, $\text{GdNdZr}_2\text{O}_7$, and $\text{Gd}_{1.2}\text{Nd}_{0.8}\text{Zr}_2\text{O}_7$ samples measured in air

Fig. 13.11 Room-temperature x-ray diffraction patterns of $\text{NdGdZr}_{2-x}\text{Sc}_x\text{O}_{7-\delta}$ ($0 \leq x \leq 0.20$) samples sintered at 1773 K for 12 h. Inset shows the systematic shift in the (222) peak for the $\text{NdGdZr}_{2-x}\text{Sc}_x\text{O}_{7-\delta}$ ($0 \leq x \leq 0.15$) samples

the crystal increases, which results in an increase in the activation energy. The preexponential factor is proportional to the number of mobile species (concentration of oxygen ion vacancies), which increases with increasing disorder in the system.

Since only a single activation energy is observed in the measured temperature range for all the samples,

Fig. 13.12 Raman spectra recorded on the sintered samples (1773 K for 12 h) of $\text{NdGdZr}_{2-x}\text{Sc}_x\text{O}_{7-\delta}$ ($0 \leq x \leq 0.15$). Inset shows the blue-shift of the band corresponding to E_g mode

the concentration of mobile species in the preexponential factor is temperature independent. The impedance measurement in hydrogen atmosphere reveals that the activation energy and preexponential factor do not deviate significantly from the values obtained in air. The Nd^{3+} , Gd^{3+} , and Zr^{4+} ions are very stable in reducing atmosphere. Therefore, it can be concluded that these materials possess only oxygen ionic conduction even at low $p\text{O}_2$ and no significant electronic conduction is introduced into the electrolyte, a criterion which is essential for an electrolyte material for application in electrochemical devices such as solid oxide fuel cells, oxygen sensors, etc.

Based on these results, we optimized the concentration of Nd^{3+} at the Gd^{3+} site, finding a result of 1 : 1, i.e., $\text{NdGdZr}_2\text{O}_7$. To further improve the conductivity we attempted to incorporate Sc^{3+} ions at the Zr^{4+} site in the composition with the highest ionic conductivity (i.e., $\text{NdGdZr}_2\text{O}_7$) to enhance the oxygen vacancy concentration. These would, in turn, increase the charge carrier mobility and thereby further improve the ionic conductivity of this composition. The samples were also prepared through the gel combustion route, as it resulted in very high-density products upon sintering as compared with the conventional solid-state prepared samples. The extent of Sc^{3+} solubility in $\text{NdGdZr}_2\text{O}_7$ along with the phase relation and subsequently the ionic conductivity of these compositions were studied.

Table 13.4 Corresponding activation energy and preexponential factor of $\text{NdGdZr}_{2-x}\text{Sc}_x\text{O}_{7-\delta}$ ($0 \leq x \leq 0.15$)

Sample composition	Activation energy E_a (eV)	Preexponential factor A ((S/cm)K)	σ at 923 K (S/cm)
$x = 0.00$	1.011	2.26×10^4	7.96939×10^{-5}
$x = 0.05$	1.052	9.34×10^4	1.89504×10^{-4}
$x = 0.10$	1.061	10.23×10^4	1.87601×10^{-4}
$x = 0.15$	1.126	21.70×10^4	1.72634×10^{-4}

From the XRD data (Fig. 13.11) it is clear that Sc^{3+} ions were successfully doped to substitute at Zr^{4+} sites in $\text{NdGdZr}_2\text{O}_7$ to form a homogeneous solid solution up to doping concentration of $x = 0.15 \text{ Sc}^{3+}$. A local lattice distortion in the doped pyrochlores, arising due to Zr(Sc) site distribution and additional oxygen vacancy creation, can be explained in terms of shifting of Ra-

man bands (Fig. 13.12) from their normal positions as a function of the Sc^{3+} content. Ionic conductivity measurements on the system indicate an increase in activation energy of ionic conduction as well as a significant increase in the charge carrier concentration, as given in Table 13.4. Among the whole series, the composition with $x = 0.05$ was found to have good conductivity.

13.6 Conclusions

Synthesis is an important part of any work. The preparatory routes for nanoparticles are broadly classified into two categories as mentioned below. The solid-state process is a conventional and widely used synthesis method to prepare polycrystalline ceramic materials. This method is not only common but is also most promising for scaling up of compound production. Solid-state diffusion is an inherently sluggish process. It involves the mechanical mixing of the solid constituents (oxides/carbonates) with repeated grindings and annealing at elevated temperatures, generally over a long duration. However, with solid-state routes, there are some disadvantages such as being kinetically slow, mostly needing higher temperatures, the influence of sample history and defects, that reaction progress monitoring is difficult, and that larger particles are obtained. The shortcomings of the solid-state synthesis method can be overcome by employing solution chemistry techniques which possess advantages such as fast kinetics at room or slightly elevated temperatures with no influence of sample history and defects, resulting in finer particles with the reaction being easy to monitor. Gel combustion synthesis is a facile synthesis technique used for laboratory-scale preparation of nanocrystalline ceramic powders with reproducible characteristics, being based on a redox reaction between the oxidant and fuel. Coprecipitation refers to simultaneous precipitation of more than one metal ion from the same

solution, resulting in more intimate mixing of cations as compared with that achieved by mixing oxides/salts of individual cations. Thermal decomposition of such compounds results in chemically homogeneous fine oxide powders with high surface area. The sol-gel process is a low-temperature approach for synthesizing solid-state oxide materials (usually polymeric). The template method involves fabrication of the desired material within the pores or channels of a nanoporous template. Ultrasound has become an important tool for synthesis of nanoparticles. TiO_2 has many promising applications in areas ranging from photovoltaics and photocatalysis to photo/electrochromics and sensors. The structural, thermal, electronic, and optical properties of TiO_2 nanomaterials have been reviewed extensively in the past decade. Indium oxide (In_2O_3) is an n-type semiconducting material, and its observed optical transparency arises from the relatively wide bandgap. Cerium oxide or ceria (CeO_2) is a rare-earth metal oxide with optical properties and ability to filter ultraviolet radiation. Residual surface hydroxides can also add to the rich surface chemistry exhibited by metal oxides such as MgO , CaO , SrO , BaO , Al_2O_3 , TiO_2 , Fe_2O_3 , ZnO , etc. and this chemistry is generally attributable to Lewis acid, Lewis base, and Brønsted acid sites of varying coordination. This forms the basis of the use of nanooxides as sorbents for removal of different species from aqueous streams.

Piezoelectric

14. Piezoelectric Nanoceramics

Xiaohui Wang, Shaopeng Zhang, Longtu Li

Understanding ferroelectricity in perovskite, bulk dense nanograin ceramics is a fundamental issue that has remained unsolved for decades. The novel development of an unconventional pressureless two-step sintering strategy featuring densification without grain growth is deemed particularly exciting because it is more desirable for commercial production. Using this technique, high-density pure barium titanate (BT) ceramic samples could be produced, which allowed for better understanding of the size effect in nanometer-scale BT ceramic systems and to address real industrial applications. In this chapter, we describe the methods for fabrication of highly dense piezoelectric nanoceramics followed by the systemic investigation of the size effect on the microstructures and piezoelectric behavior of $(1-x)\text{BiScO}_3-x\text{PbTiO}_3$ (BSPT) nanoceramics. BSPT ceramics with average grain size from the micrometer scale down to 10 nm have been prepared by a two-step sintering method. The microstructures and properties of these bulk dense nanocrystalline ceramics were characterized by means of x-ray diffraction (XRD), high-resolution transmission electron microscopy (HRTEM), atomic force microscopy (AFM), scanning probe microscopy

(SPM), and hysteresis-loop and dielectric measurements.

Motivated by the market demand for small-grain-size ferroelectric ceramics and the promise of enhanced properties in fine-grained ceramics, investigation of the grain size effect on microstructures and properties of ferroelectric/piezoelectric ceramics becomes significantly important.

Piezoelectric material as one kind of ferroelectric can convert electrical energy into mechanical energy and vice versa. This electromechanical property arises due to the coupling of the spontaneous polarization with the lattice strain. Many devices such as ultrasonic trans-

ducers and piezoelectric actuators make use of this property. Since the synthesis of $(1-x)\text{BiScO}_3-x\text{PbTiO}_3$ (BSPT) by Eitel and coworkers in 2001 [14.1], this new perovskite solid solution has attracted considerable attention as a promising candidate for high-temperature actuator and transducer applications due to its high Curie temperature and robust thermal stability as well as excellent piezoelectric properties. Most of the work has focused on microstructure and properties (electrical, dielectric, and ferroelectric) as a function of composition and phase.

14.1 Introduction to BSPT

BSPT $((1-x)\text{BiScO}_3\text{-}x\text{PbTiO}_3)$ solid-solution ceramics were first reported by Eitel et al. [14.1] in 2001, as new high-temperature piezoelectric materials. They investigated a series of complex perovskites with general formula $\text{Bi}(\text{Me}^{3+})\text{O}_3\text{-PbTiO}_3$ ($\text{Me}^{3+}=\text{Sc}^{3+}, \text{Fe}^{3+}, \text{In}^{3+}, \text{Yb}^{3+}$, etc.), under the guidance of a tolerance factor t proposed by Goldschmidt [14.3]. Among these solid solutions, only $\text{BiScO}_3\text{-PbTiO}_3$ (BSPT) has a tolerance factor ($t = 0.907$) less than that for $\text{Pb}(\text{Zr}, \text{Ti})\text{O}_3$ ($t = 0.96$) and can maintain stable perovskite structure under atmospheric conditions. It exhibits a significantly high T_c of 450°C near the morphotropic phase boundary (MPB), and other piezoelectric properties such as electromechanical coupling factor of $K_p = 0.57$ and piezoelectric constant of $d_{33} = 450 \text{ pC/N}$. Since then, extensive studies have been carried out on BSPT ceramics [14.1, 2, 4–13], single crystals [14.14–18], and thin films [14.19–25], revealing its high Curie temperature, excellent ferroelectric/piezoelectric properties, and robust thermal stability. BSPT solid solution is considered as a promising candidate for high-temperature sensor and actuator applications.

14.1.1 Structures and Morphotropic Phase Boundary

Since the synthesis of Rochelle salt by Seignette in 1665 and the discovery of its dielectric properties by Valasek in 1921 [14.26], the number of ferroelectrics has grown rapidly. Among them, ferroelectrics with ABO_3 -type perovskite structure are the most numerous, including BaTiO_3 and $\text{Pb}(\text{Zr}, \text{Ti})\text{O}_3$ (PZT), being extremely important for the electronic and automobile industries. BSPT solid solution has a similar structure,

Fig. 14.1 Schematic diagram of ABO_3 -type perovskite structure

with $\text{Bi}^{3+}/\text{Pb}^{2+}$ ions occupying the A sites, $\text{Sc}^{3+}/\text{Ti}^{4+}$ ions taking the B site, and O_2^{2-} taking the face-center sites (Fig. 14.1).

Similar to the $\text{Pb}(\text{Zr}_{1-x}\text{Ti}_x)\text{O}_3$ system, the structure of $(1-x)\text{BiScO}_3\text{-}x\text{PbTiO}_3$ solid solution changes with the composition x , and in their composition phase diagram there exists a specific region called the morphotropic phase boundary (MPB). The MPB was initially defined in the PZT system as a near-vertical line separating compositions with rhombohedral and tetragonal symmetries. Actually, it represents a region with a certain composition range and commonly exists in other binary system including PbTiO_3 (PT), such as $\text{PbMg}_{1/3}\text{Nb}_{2/3}\text{O}_3\text{-PbTiO}_3$ (PMN-PT), $\text{PbZn}_{1/3}\text{Nb}_{2/3}\text{O}_3\text{-PbTiO}_3$ (PZN-PT), etc. In the vicinity of the MPB region, these materials show superior piezoelectric and dielectric properties. The phase diagram of the BSPT system given by Chaigneau et al. [14.2] in 2007 is shown in Fig. 14.2.

14.1.2 Ceramic Properties and Grain Size Effects

Since the discovery of BSPT solid solution, the properties of BSPT ceramics have attracted more attention due to their excellent piezoelectric properties and robust thermal stability. Like PZT, the best piezoelectric activity is found near the MPB between the tetragonal phase and the rhombohedral phase. In a previous study [14.8], the optimum piezoelectric properties were determined to occur at $x = 0.635$, with d_{33} value up to 700 pC/N

Fig. 14.2 Composition phase diagram of BSPT solid solution (after [14.2])

($K_p = 0.632$) and Curie temperature of 446°C , both of which are much higher than commercial $\text{Pb}(\text{Zr}, \text{Ti})\text{O}_3$ (PZT).

However, motivated by the market demand for small-grain-size ferroelectric ceramics and the promise of enhanced properties in fine-grained ceramics, investigation of the grain size effects on the properties of ferroelectric/piezoelectric ceramics becomes significantly important [14.27]. In recent years, studies of grain size effects in ferroelectric ceramics have been extended to the nanoscale, and the so-called *ferroelectric critical size* has attracted much interest [14.28–40]. As a promising candidate for high-temperature applications, research on the grain size effect in BSPT ceramics has also attracted more attention [14.7, 8, 41, 42]. However, owing to the difficulties of achieving high density while maintaining the nanograin nature, the size effect in sintered bulk ceramics has rarely been reported, and there is still no consistent conclusion regarding the grain size effect on the piezoelectric properties of BSPT ceramics, especially for grain sizes less than 100 nm. One of the obstacles lies in sintering. Normal sintering generally requires a high sintering temperature (1000°C). This causes great difficulties in obtaining ceramics with

both high density and fine grain size even when using nanocrystalline powder, thus limiting the grain size to the nanometer scale.

Highly dense BSPT ceramics with average grain size from a micrometer to as small as 10 nm have been prepared separately by a two-step sintering method. The size effects on the microstructures and piezoelectric behavior of BSPT nanoceramics were investigated. The microstructures and properties of the bulk dense nanocrystalline ceramics were characterized by means of x-ray diffraction (XRD), high-resolution transmission electron microscopy (HRTEM), atomic force microscopy (AFM), scanning probe microscopy (SPM), and hysteresis-loop and dielectric measurements. The existence of the ferroelectric phase in the nanocrystalline ceramics at room temperature has been proved by the polarization-reversal characteristics according to the measurement of hysteresis loops as well as the local ferroelectric switching behavior investigated by piezoresponse force microscopy. These results provide incontestable experimental evidence for ferroelectricity and piezoelectricity in bulk dense BSPT ceramic with grain size as fine as 10 nm with high T_c of 700 K.

14.2 Synthesis of BSPT Nanopowders via Sol–Gel Method

Nanopowder is a necessary prerequisite to fabricating bulk dense nanoceramics. When the particle size of the powders reduces to the nanoscale, agglomeration increases due to the high specific surface area and energy. Thus, it is the size of the agglomerates rather than the size of the nanoparticles that determines the sintering behavior of the powder and the final microstructure of the ceramic. Therefore, low-cost production of nanopowders without agglomeration and compaction of particles to achieve homogeneous, high green density are required to fabricate nanoceramics.

The citrate sol–gel method is extensively used for synthesis of metal oxide nanopowders due to its simple setup and relatively low processing temperature. For BSPT nanopowders, Sc_2O_3 , $\text{Bi}(\text{NO}_3)_3 \cdot 5\text{H}_2\text{O}$, $\text{Pb}(\text{NO}_3)_2 \cdot 3\text{H}_2\text{O}$, and $\text{C}_{16}\text{H}_{16}\text{O}_4\text{Ti}$ are chosen as starting materials to provide Sc^{3+} , Bi^{3+} , Pb^{2+} , and Ti^{4+} . Besides, $\text{C}_6\text{H}_8\text{O}_7 \cdot \text{H}_2\text{O}$ (analytical reagent (AR)), HNO_3 (AR), $\text{NH}_3 \cdot \text{H}_2\text{O}$ (AR), and H_2O_2 (AR) are used as accessory materials [14.7]. The whole process is illustrated in the flowchart in Fig. 14.3.

The as-prepared BSPT nanopowders were observed under TEM (Fig. 14.4). The particles are well resolved with average size ≤ 10 nm. x-ray diffraction (XRD) patterns of BSPT nanopowders with different compositions and different calcination temperatures are depicted in Fig. 14.5.

It is known from the Scherrer equation that, if the particle size of the powder is very small, the XRD peaks will be significantly broadened. Consequently, the XRD patterns of BSPT nanopowders calcined at 600°C do not show their characteristic splitting and, at first glance, are like those of the pseudocubic phase. On further increase of the calcination temperature to 800°C , grain growth is induced and powders with larger particle sizes can be obtained. Then, the XRD patterns of BSPT powders exhibit peak-splitting behavior. For the rhombohedral phase ($x = 0.600$) the 111 peak splits, while for the tetragonal phase ($x = 0.680$) the 110 and 200 peaks split. However, for BSPT powders with MPB composition ($x = 0.635$), peak splitting is masked due to the coexistence of different phases.

14.3 Sintering of BSPT Nanoceramics

Due to their extremely large specific surface area, as-prepared BSPT nanopowders have very high sintering activity and are very sensitive to sintering temperature and holding time. Moreover, Pb and Bi tend to be volatile at high temperatures, making it easy for the grains to grow. Figure 14.6 displays the grain size change for different holding times at sintering temperature of 1000 °C using BSPT nanopowders prepared by the sol-gel method. When sintered at 1000 °C for 5 min, the grain size of BSPT ceramics reached ≈ 400 nm. Increasing the holding time to only 10 min, the grain size grows to ≈ 1 μm . On further prolonging the sintering time from 10 to 30 min, the rate of grain growth slows to an increase of 1 μm . So, it is obvious that the conventional sintering method cannot be used for fabricating fine-grained BSPT ceramics. Therefore, an innovative sintering method is required.

14.3.1 Two-Step Sintering

The two-step sintering method was first reported by *Chen and Wang* [14.43] in 2001 and has been proved to be an efficient method to prepare fully dense nanograin bulk ceramics of numerous kinds of oxides or even

nonoxides [14.44–49]. This technique exploits the difference in kinetics between grain boundary diffusion and migration during sintering. As shown in Fig. 14.7, first a green ceramic sample is heated up to a higher temperature T_1 to obtain a starting density $\geq 75\%$. Then, the sintering temperature is rapidly reduced to a lower temperature T_2 and held at T_2 for a long time. This unique sintering schedule guarantees that all pores in the ceramic are subcritical and unstable against shrinkage after the first step and the ceramic can fulfill densification without grain growth in the second sintering step.

Determination of Sintering Parameters

Based on the discussion above, three essential parameters should be determined: the first-step temperature T_1 , the second-step temperature T_2 , and the holding time t . Among these, the first-step temperature T_1 defines the final grain size, because grain growth mainly occurs in this stage. It also provides the required starting density of $\geq 75\%$, as suggested in [14.43]. To determine the density of the ceramic after the first-step sintering, the green pellets are heated to different T_1 temperatures at heating rate of 4 °C/min. Then, the pellets are taken out of the furnace to be rapidly cooled down to room temperature in air. The relative densities of as-sintered pellets are measured using the Archimedes method. Figure 14.8 shows the relative density change of BSPT ($x = 0.64$) ceramics with T_1 . According to Fig. 14.8, the first-step temperature T_1 should be at least 950 °C. Therefore, $T_1 = 930, 960, 1000, 1020$, and 1050 °C were chosen in this work.

Various sintering schedules with different values of T_1 and T_2 were used to explore the temperature region without grain growth while maintaining full density. Ex-

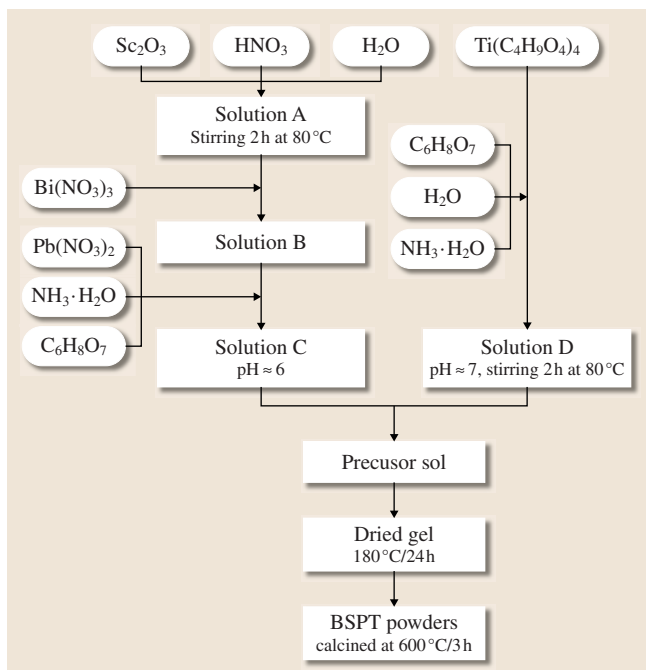

Fig. 14.3 BSPT powder process flowchart

Fig. 14.4 TEM micrograph of BSPT powder

Fig. 14.5 x-Ray diffraction patterns of BSPT nanopowders with different compositions and calcination temperatures

amples of these experiments are presented in Table 14.1. The average grain size (GS_A) was calculated by measuring Feret's diameters of more than 150 grains for each sample. The changes of relative density and the average grain size of samples obtained under different sintering conditions are listed in Table 14.1.

Based on the data in Table 14.1, the relative density and grain size changes of the ceramic samples sintered at different T_1 and the same $T_2 = 800^\circ\text{C}$ are also depicted in Fig. 14.9. Comparing the relative density curves in Figs. 14.8 and 14.9, there is a 10–20%

increase of density due to the densification occurring in the second step. Moreover, the insufficient relative density of samples A and B indicates that the first-step temperature is not high enough and T_1 should be higher than 1000°C to ensure a relative density $\geq 95\%$. Thus, $T_1 = 1000^\circ\text{C}$ and 1050°C were chosen to determine the effect of the second-step temperature T_2 , and the results are shown in Fig. 14.10. Comparing the two curves in Fig. 14.10, an increase of 50°C in T_1 leads to about 100 nm larger grain size of the samples, and an increase of T_2 from 850 to 900°C causes grain growth of 200–250 nm. This phenomenon again proves that BSPT solid solution is extremely sensitive to sintering temperature. However, when the second-step temperature T_2 is lower than 850°C , no grain growth is observed. This could be attributed to the suppression of grain boundary migration at such a low temperature.

Kinetic Window for BSPT Ceramic Sintering
Based on the above data and analysis, the kinetic window for BSPT ceramic sintering can be determined (Fig. 14.11). Solid symbols indicate sintering conditions that can obtain full densification without grain growth, while open symbols indicate those that cannot reach full density (below the lower boundary) or cause uncontrollable grain growth (above the upper boundary). Such behavior resembles that of Y_2O_3 [14.43] and $BaTiO_3$ [14.47, 48], providing a feasible approach of two-step sintering to produce high-density fine-grained **MPB** BSPT ceramic using the pressureless sintering method. Highly dense **MPB** BSPT ceramics with homogeneous fine grains could be achieved using pressureless sintering without any sintering aids at a low temperature of 800 °C with grain size as

Fig. 14.9 Relative density and grain size change with T_1 for samples A, B, C2, D, and E1 in Table 14.1 (after [14.7])

small as 200 nm [14.7]. Furthermore, the piezoelectric coefficient was found to reach 520 pC/N for the sample with grain size of 200 nm, higher than that of coarse-grained BSPT ceramics (450 pC/N), indicating a promising path for improvement of the piezoelectric coefficient.

14.3.2 Combination of Spark Plasma Sintering and Two-Step Sintering

Spark plasma sintering (SPS) has been proved as a very efficient method for fabrication of various nanomaterials [14.50]. Although the physical nature of the observed enhancement of the consolidation process is still under debate, the advantages of this sintering method, including the effect of the current, such as accelerated particle bonding, the high heating and cooling

Table 14.1 Parameters of two-step sintering for BSPT ceramics

Sample	Sintering methods		Holding time (h)	Relative density (%)	Average grain size (nm)
	T_1 (°C)	T_2 (°C)			
A	930	800	8	71.8	350
B	960		8	89.0	390

Fig. 14.10 Grain size change with T_2 for samples with $T_1 = 1000$ °C (samples C1, C2, C3, and C4 in Table 14.1) and 1050 °C (samples E1, E2, E3, and E4 in Table 14.1)

rate, and the applied pressure during sintering [14.50–52], have already been proved for numerous materials. Extensive research has been carried out on sintering of piezoelectric ceramics, most of which include lead [14.53–57]. This method has also been used for BSPT ceramic sintering. In 2009 *Algueró et al.* [14.42] prepared BSPT ceramics with average grain size of 80 nm via SPS, and in 2010 *Amorín et al.* [14.41] reported that the average grain size could be decreased to 28 nm. However, possibly due to the activation of particle surface and the high ion mobility during the SPS process, the grain size of BSPT ceramic is very sensitive to the sintering temperature and mechanical pressure, thus being difficult to control. When the sintering temperature was increased from 650 °C to 800 °C, the grain size increased almost five times, from 80 to 375 nm [14.41].

A combination of SPS and the two-step sintering technique was explored to obtain BSPT nanoceramics with grain size ≤ 100 nm. Firstly, BSPT nanopowders with $x = 0.63$ prepared by the sol–gel method are filled

Fig. 14.11 Kinetic window for reaching full density without grain growth for BSPT ceramics (after [14.7])

in a cylindrical graphite die and heated up in a SPS equipment to a certain final temperature in 4–5 min with mechanical axial pressure of 50 MPa, holding at this temperature for 3 min. Subsequently, the as-prepared SPS sample is taken out from the graphite die and sintered in an ordinary furnace using the two-step sintering method.

Appropriate sintering schedules are chosen to vary the grain sizes of the ceramic samples, as presented in Table 14.2. Since the initial density of the SPS samples is much higher, the first-step temperature T_1 can be decreased significantly. As discussed previously, the grain growth mainly happens in the first step of the two-step sintering method, and the samples can achieve densification with less or no grain growth at a relatively low T_1 temperature. Finally, the samples are held at T_2 to eliminate the residual pores that reach the critical size and are unstable. All these factors ensure minimum grain growth during sintering and full densification of the ceramic.

Figure 14.12 shows a comparison of density of the SPS samples ($x = 0.63$ close to MPB) before and after two-step sintering. Before two-step sintering, the

Table 14.2 Sintering parameters for the combination of SPS and two-step sintering

BSPT sample ($x = 0.63$)	Heating rate (°C/min)	SPS			Two-step sintering			
		T_S (°C)	Holding time t (min)	Mechanical pressure (MPa)	T_1 (°C)	T_2 (°C)	Holding time t (h)	GS _A (nm)
ST1	150	650	3	50	800	750	6	70
ST2	175	700	3	50	800	750	6	33
ST3	150	600	3	50	900	750	6	23

Fig. 14.12 Density change of SPS samples before and after two-step sintering

BSPT samples can achieve relative density of 50–60%, about 15–25% higher than pellets ordinarily prepared under uniaxial mechanical pressure. There is an increase of about 35–45% in relative density for the SPS samples sintered by the two-step sintering method.

Fig. 14.13 XRD pattern of sample ST1 with grain size of 70 nm

Since the first-step temperature T_1 is much lower than that for sintering of BSPT ceramics prepared by the ordinary method, grain growth can be suppressed further.

Fig. 14.14 TEM morphologies and grain size distributions of samples ST1, ST2, and ST3

Fig. 14.15 (a) Photo of the UHP molding apparatus. (b) Schematic diagram of the internal setup of the apparatus

The XRD pattern of sample ST1 is shown in Fig. 14.13. The pattern can be well indexed according to the pseudocubic phase with a $\approx 4 \text{ \AA}$ unit cell, demonstrating the pure perovskite single phase of the sample. From the composition phase diagram of BSPT solution [14.13, 58, 59], the actual phase of the samples ($x = 0.63$) is rhombohedral. However, since the grain size is small, the XRD peaks are so significantly broadened that the characteristic peak splitting is masked and the pattern seems like that of the cubic phase.

The micromorphology of samples ST1, ST2, and ST3 was observed by TEM (Fig. 14.14). For TEM observation, samples were first prepared by polishing ceramics down to thickness of approximately $35 \mu\text{m}$, followed by ion-beam thinning to electron transparency. The grain size distribution was obtained by measuring Feret's diameters of more than 150 grains for

each sample. Based on these statistical data, the average grain size (GS_A) was calculated and is shown in Fig. 14.14a–c. It is noteworthy that the grain boundary region in Fig. 14.14c seems very *thick* and disordered. However, when observed under higher magnification, these *thick* regions show a clear lattice image and the grain boundaries are much *thinner* (Fig. 14.14d). It can be concluded that all three samples prepared by the combination of spark plasma sintering and two-step sintering are highly dense with homogeneous nanograin microstructures as fine as 23 nm.

14.3.3 Ultrahigh-Pressure (UHP) Forming and Two-Step Sintering

With the combination of the advantages of the SPS method and the two-step sintering method, BSPT samples with average grain size ranging from 23 to 70 nm have been obtained. However, to achieve the relative density of 50–60% needed for the subsequent two-step sintering, a certain sintering temperature $T_s \geq 600^\circ\text{C}$ for SPS is required, and there is still considerable grain growth during the SPS process. Therefore, it is beyond the capability of this combined method to prepare BSPT nanoceramics with small grain size $< 20 \text{ nm}$ from starting powders of about 8–10 nm. Other strategies that can achieve higher initial green density with no grain growth are in great demand. The ultrahigh-pressure (UHP) molding method featuring extremely high pressures up to several GPa provides an opportunity.

These experiments were carried out using a cubic anvil-type apparatus. A picture and schematic diagram of the internal setup of the apparatus are shown in Fig. 14.15. BSPT nanopowders with MPB composition were encapsulated with Ag foil and then placed in the center of a solid cube made of pyrophyllite which acts as the pressure medium. The Ag foil is used to prevent

Fig. 14.16a–d TEM morphologies of sample (a) N1 (11 nm), (b) N2 (21 nm), (c) N3 (33 nm), and (d) N4 (114 nm)

Fig. 14.17a–d Grain size distribution of sample (a) N1, (b) N2, (c) N3, and (d) N4

mixing of the pyrophyllite and BSPT powder. During the pressing process, six anvils squeeze the six faces of the solid cube with the same pressure in order to make BSPT nanopowders inside the solid cube experience the same pressure from six different directions. The BSPT nanopowders are held at the highest pressure of ≈ 5.5 GPa for 15 min at room temperature. Finally, BSPT green ceramics with high relative density of about 74% can be obtained.

The as-prepared green ceramic pellets are then sintered using the two-step sintering method. The parameters of the sintering schedule are presented in Table 14.3. The densities of the fired ceramic samples are measured by the Archimedes method using distilled

water, and the relative densities calculated by dividing the measured densities by the theoretical density.

The TEM morphologies of the four samples are shown in Fig. 14.16. From the TEM images, it can be seen that the fired ceramics show very uniform microstructures. Sample N1 has the finest grain size, ranging from 6–10 nm, which is almost the same as the particle size of the starting nanopowder. It has been proved that the two-step sintering method without grain growth is powerful for fabricating 10 nm bulk dense ceramics. Similar to the micromorphologies of the samples prepared by the combination of SPS and the two-step sintering method in Fig. 14.14, samples N1, N2, and N3 seem to have *thick* grain boundaries, which

Table 14.3 Two-step sintering schedule for samples prepared by UHP molding

Sample	T_1 (°C)	T_2 (°C)	Holding time, t (h)	Relative density (%)	GS _A (nm)
N1	850	700	31	90.0	11
N2	900	700	24	90.6	21
N3	950	700	24	92.6	33
N4	950	800	12	94.0	114

Fig. 14.18 XRD patterns of samples N1–N4

could be due to different types of TEM contrasts under different magnifications. In contrast, when the grain size reaches 114 nm as in sample N4, the grain boundary region seems much *thinner* and is *normal* compared with the morphology usually observed in BSPT ceramics with grain size on the microscale [14.12]. Another noticeable phenomenon is the elongated grains shown in Fig. 14.16c, which is caused by the ultrahigh axial pressure applied during the green ceramic molding process.

The grain size distribution was obtained by measuring Feret's diameters of more than 200 grains, and the average grain size calculated for each sample is shown in Fig. 14.17. The four samples N1–N4 have average grain size of 11, 21, 33, and 114 nm,

respectively. Comparing the sintering parameters and grain sizes of samples N1–N4, the average grain size increases slightly with the first-step temperature T_1 , but is very sensitive to the second-step temperature T_2 because of the long heating time in the second step, which is consistent with the trends shown in Fig. 14.10. So, the optimal parameter of two-step sintering is strict in the BSPT system due to the volatile elements Bi and Pb. With increasing sintering temperature, the distribution of grain sizes becomes wider.

XRD patterns of samples N1, N2, N3, and N4 are shown in Fig. 14.18. Similar to the XRD pattern of sample ST1 with grain size of 70 nm shown in Fig. 14.13, the XRD peaks of samples N1, N2, and N3 do not show the splitting characteristic which is commonly observed in BSPT ceramics with coarse grains [14.13]. This is because of the peak broadening due to the small grain size effect. When the grains grow up to 114 nm or more, the peak splitting appears. With decreasing grain size, the peak position moves towards higher angles. This might be caused by the decrease of lattice parameters and lattice spacing with the reduction of the grain size. According to Bragg's equation, $2d \sin \theta = n\lambda$, when the lattice spacing decreases, the Bragg angle θ will increase, which means that the peak position moves towards higher angle. Without considering the unique characteristics of the peak profiles and positions in the BSPT nanoceramics, the perovskite structure is confirmed for all the samples. The full-pattern XRD refinement results show that even the finest, 11 nm BSPT ceramic consists of two phases, tetragonal and monoclinic, with phase fractions of 23% and 77%.

14.4 Grain Size Effect on the Properties of BSPT Ceramics

Early studies already noted that, for coarse BaTiO_3 ceramics, the relative permittivity decreases with grain size and reaches a maximum at average grain size of approximately $1 \mu\text{m}$ [14.60]. Various assumptions and models have been used to explain the observed phenomenon, including the internal stress model [14.32, 61], distribution model [14.62], domain size effect [14.60], etc. However, the dielectric properties of the piezoelectric ceramic BSPT system have rarely been reported until now, especially the dependence of the dielectric properties on grain size at the nanoscale.

14.4.1 Dielectric Properties

Figure 14.19 shows dielectric–temperature curves of MPB BSPT ceramics with different grain sizes, ranging from 11 nm to $1.5 \mu\text{m}$. The dielectric anomaly associated with the ferroelectric transition is clearly observed for all the samples, but is strongly flattened and broadened for the ceramics with smaller grain size (as shown in Fig. 14.19b). The dielectric constant peak at 100 kHz significantly decreases when the grain size reduces from $1.5 \mu\text{m}$ to 11 nm. The nanoceramics show lower di-

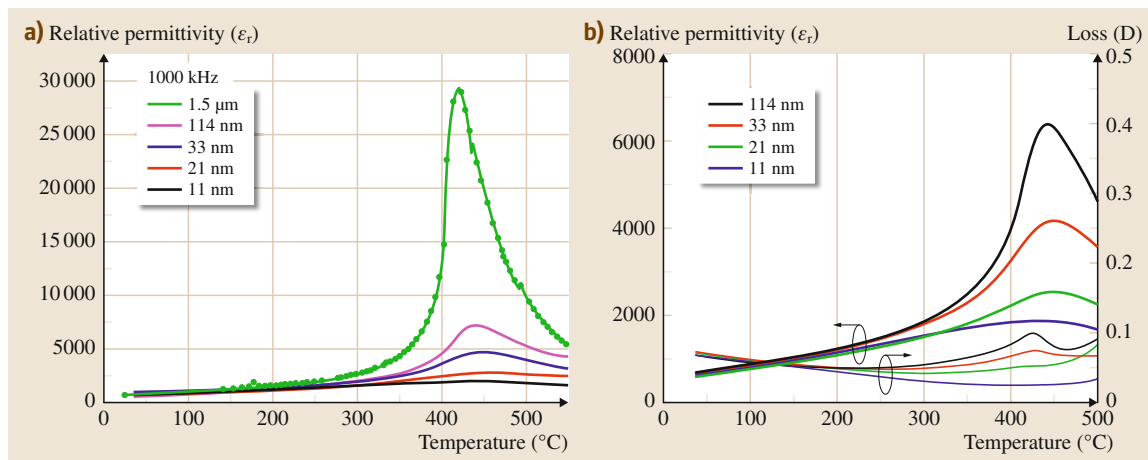

Fig. 14.19a,b Grain size effects on dielectric properties of BSPT ceramics. **(a)** Dielectric constant–temperature curves for grain size ranging from nano- to micrometer. **(b)** Dielectric constant–temperature curves for different nanoscale grain sizes

electric constant and a smeared transition as the grain size decreases. However, the Curie temperature (ferroelectric transition temperature) for the nanoceramics ($T_c = 437^\circ\text{C}$) is less sensitive to the change of grain size, almost the same as for the coarse ceramics. As suggested by Buscaglia et al. [14.39], a wide distribution of grain sizes over the volume of nanoceramics leading to different local polarizations and Curie temperatures T_c might correspond to the broadening of the dielectric–temperature peaks of nanoceramics.

14.4.2 Ferroelectric Property

The ferroelectric property is the most important characteristic of piezoelectric ceramics. Figure 14.20 shows polarization–electric field hysteresis loops for MPB BSPT ceramics with different grain sizes. In Fig. 14.20a, square loops close to saturation are obtained for BSPT ceramics with grain size $\geq 114\text{ nm}$. However, when the grain size is less than 100 nm, polarization switching is strongly suppressed and the loops become narrow. Both the remnant polarization and coercive field decrease with the reduction of grain size. Similar results were observed for MPB BSPT ceramics prepared by SPS sintering by Amorin et al. [14.8] (Fig. 14.20b). In addition, unlike the behavior of BSPT nanoceramics with average grain size of 114 nm in Fig. 14.20d, on increasing the electric field applied to the BSPT nanoceramics with grain size of 11 nm, no square loops can be achieved even at the maximum electric field of 60 kV/cm (Fig. 14.20c). This indicates

incomplete polarization switching. Two factors should be considered in such macropolarization behavior in nanoceramic BSPT. As the grain size reduces to the nanoscale, the volume of grain boundary grows rapidly. During polarization switching, most of the electric field applied to the nanoceramics is shared by the grain boundaries because of their high resistivity. The electric field applied to the grains is insufficient to switch the domain walls [14.8]. On the other hand, the domain walls are pinned by the grain boundary and defects, thus like *frozen* [14.36]. The energy needed to switch the domain walls increases, and the electric field is now inadequate. Considering all these factors, polarization switching is difficult (or even impossible) under common electric fields used for coarse ceramics. However, the existence of a ferroelectric phase in the nanocrystalline BSPT ceramics with grain size as fine as 11 nm at room temperature has been proved by the polarization-reversal characteristics according to the measurement of hysteresis loops.

14.4.3 Piezoelectric Property

To investigate the size effect on the piezoelectric property, we prepared samples of BSPT ceramics with MPB composition using nanopowders and the two-step sintering method.

Macroscopic Piezoelectric Response

The variation of the macroscopic piezoelectric coefficient (d_{33}) as a function of grain size in MPB

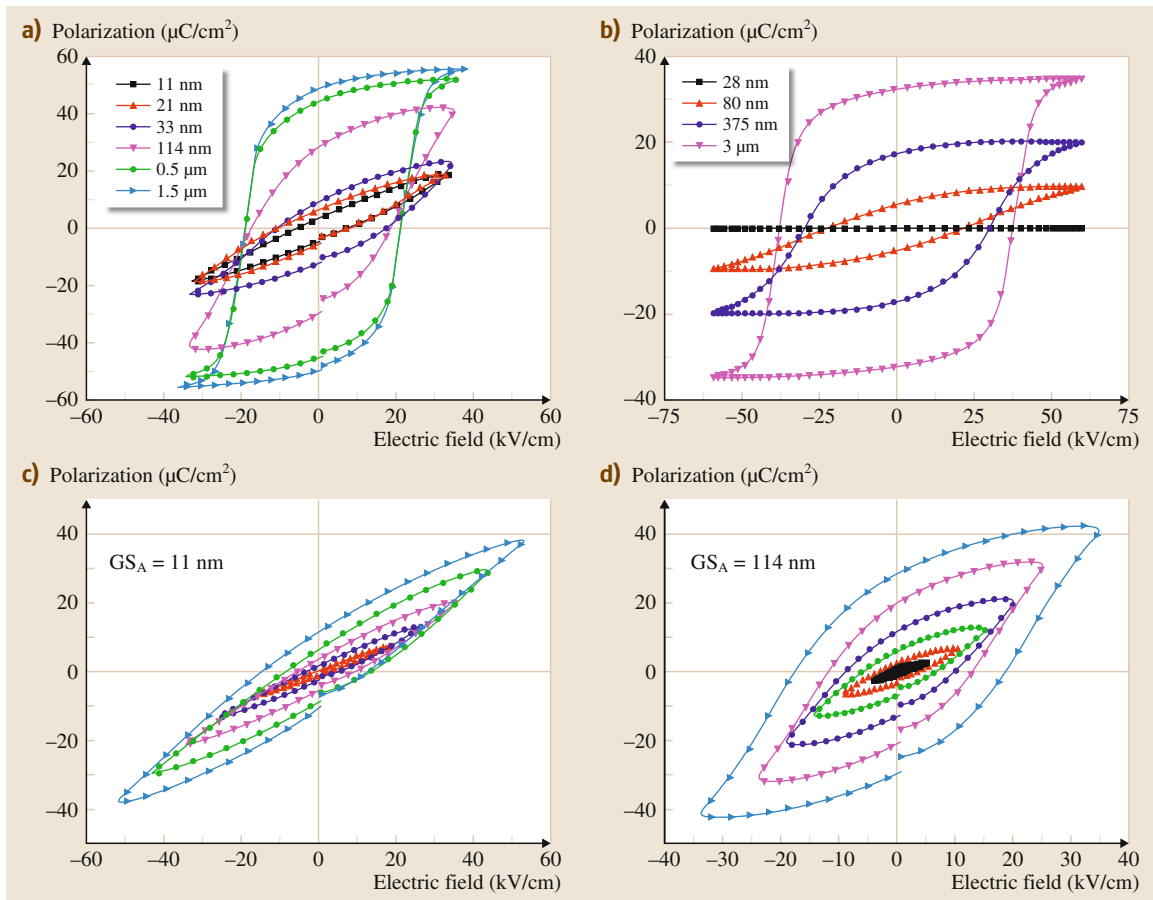

Fig. 14.20 (a) Grain size effects on the hysteresis loops for BSPT ceramics obtained by the two-step sintering method. (b) Grain size effects on the hysteresis loops for BSPT ceramics obtained by SPS (after [14.41]). (c, d) Hysteresis loops for BSPT ceramics produced by two-step sintering with grain size of 11 and 114 nm, respectively

BSPT ceramics is shown in Fig. 14.21. There is a maximum value of $d_{33} = 700$ pC/N at grain size of around $1.5 \mu\text{m}$ [14.8], which is much higher than that (450 pC/N) of coarse-grained BSPT ceramics prepared by the conventional method, and d_{33} decreases with decreasing grain size. However, in the submicrometer range of 200–1000 nm, d_{33} can maintain a very high value, with a drastic increase of d_{33} (620 pC/N) for grain size decrease from 500 to 300 nm. The enhanced piezoelectric activity at the MPB is usually explained in terms of its intermediate structure between the rhombohedral and tetragonal phases. As a result, there may be more crystallographic directions suitable for polarization, facilitating piezoelectricity. On the other hand, nanosized domains have also been suggested to contribute to enhanced

piezoelectricity [14.63–65]. In our study, the piezoelectric force microscopy (PFM) image reveals a fine domain structure, with probably 90° domains having width of 60–70 nm [14.8]. Using computer simulation, Ahluwalia et al. [14.63] investigated the domain-size dependence of the piezoelectric properties of a model ferroelectric, and their results showed that the piezoelectric coefficient is enhanced by reducing the domain size. Supporting experimental evidence was observed by Wada et al. [14.64] in barium titanate single crystals and Takahashi et al. [14.65] in microwave-sintered BaTiO₃ ceramics, correlating superior piezoelectric properties to small domain sizes. Therefore, the superior piezoelectric properties of the MPB ($x = 0.635$) ceramic could be a result of both the MPB composition and the small domain size, although further experiments

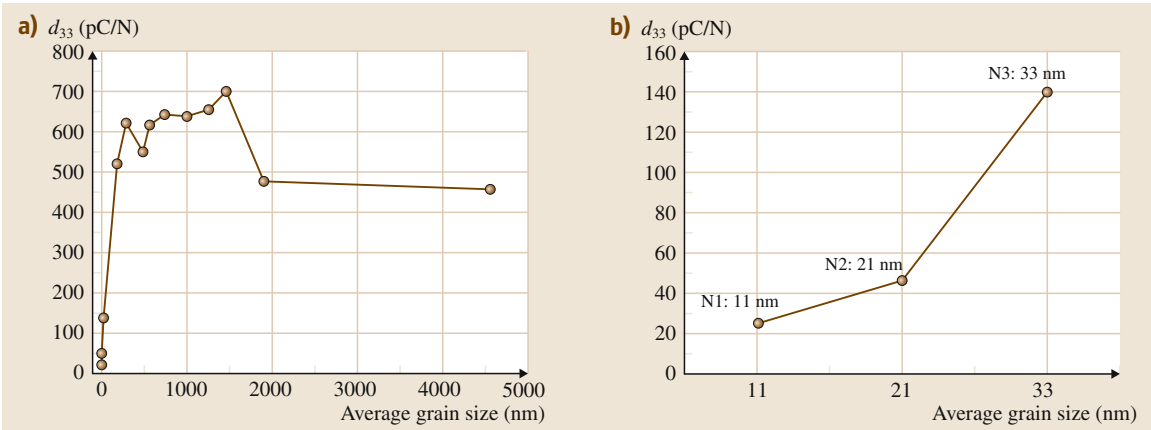

Fig. 14.21a,b Grain size effect on the macroscopic piezoelectric properties of BSPT ceramics: (a) from micro- to nanoscale; (b) nanoscale

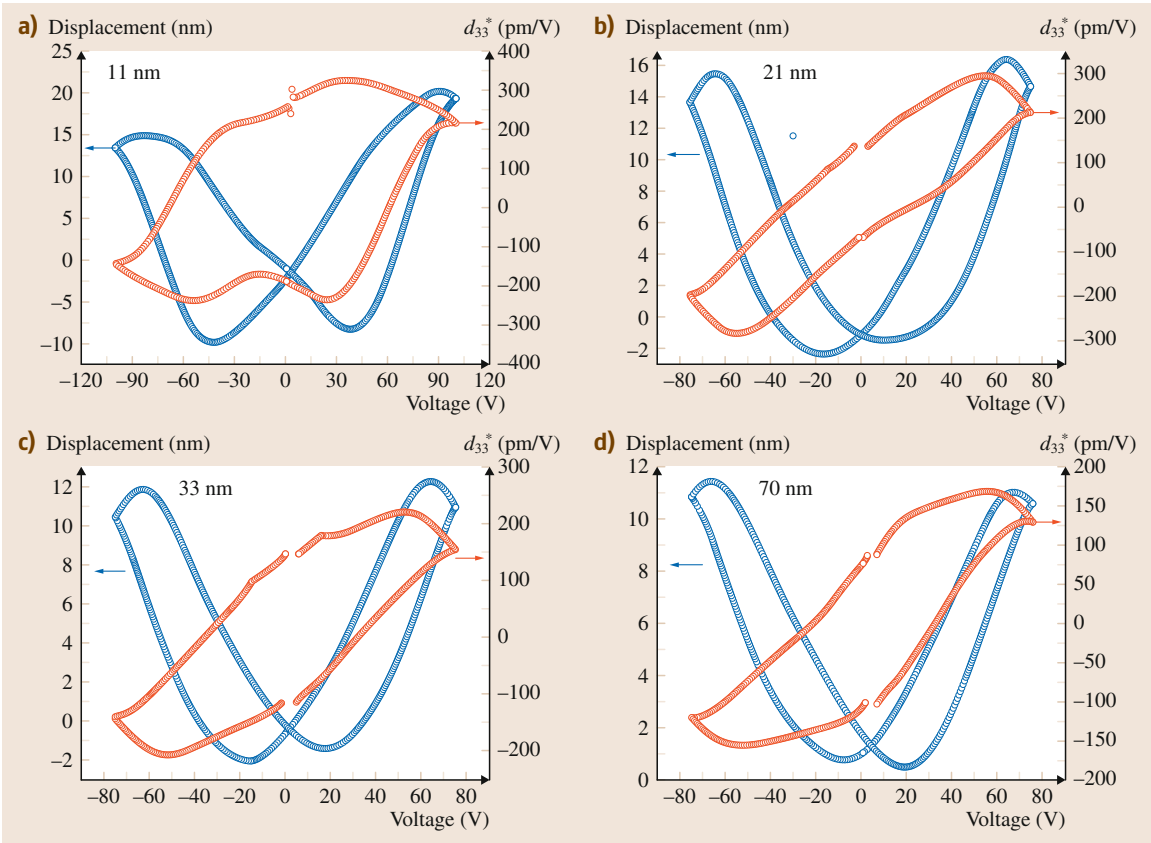

Fig. 14.22a-d Local piezoelectric response versus applied voltage for BSPT nanoceramics of various grain sizes: 11 nm (a), 21 nm (b), 33 nm (c), and 70 nm (d). Displacement–voltage ($Z - V$) loops (blue curves); piezoelectric hysteresis loops (red curves)

separating these two effects are required to verify this hypothesis.

Moreover, with the grain size reducing to the nanoscale (less than 100 nm), the fraction of the grain boundary and internal stress will increase rapidly, inhibiting realignment of the nanodomains. The grain boundary shares more voltage, leading to insufficient polarization of the grain *core*. Considering all these factors, polarization switching for nanoceramics is difficult under the same common electric field (40 kV/cm) used for coarse ceramics, so that the macroscopic piezoelectric property d_{33} measured by quasistatic piezoelectric coefficient testing shows a smaller value (Fig. 14.21b).

Local Piezoelectric Response

To investigate the local piezoelectric response for BSPT nanoceramics, scanning probe microscopy (SPM) was used in our study. Local nanoscale piezoresponse AFM and piezoelectric force microscopy (PFM) were carried out using a SPM system (AFM, SPI3800N&SPA400; Seiko, Tokyo) by inducing mechanical oscillations with an alternating-current (AC) voltage at 5.0 kHz applied to the tip of a microcantilever (SI-DF3-R, Rh coated) with spring constant of 1.9 N/m and free resonance frequency of 28 kHz. For this measurement, the sample was polished and glued to a conductive substrate serving as a bottom electrode connected to ground.

Measurements were carried out by keeping the SPM tip at fixed height above the surface of the samples and applying a bias voltage from -100 to $+100$ V over the small AC excitation voltage while recording the piezoresponse signal (displacement). Typical well-shaped *butterfly* displacement–voltage ($Z-V$) loops for BSPT nanoceramics were recorded (Fig. 14.22, blue curves). The effective piezoelectric coefficient d_{33}^* can be derived from the slope of the displacement versus voltage, exhibiting a piezoelectric hysteresis loop curve (Fig. 14.22, red curves). A ferroelectric state for BSPT nanoceramics with average grain size as small as 11 nm has been confirmed. Fifty different regions were chosen randomly on each sample, and $Z-V$ curves at these regions were measured, considering the variations

Fig. 14.23 Grain size effect on the microscopic piezoelectric properties of BSPT nanoceramics

in the local piezoelectric response among different regions which are common in BaTiO₃ [14.38]. The mean effective piezoelectric coefficient for each sample was calculated by averaging values obtained from the 50 curves.

The grain size effect on the mean values of the local effective piezoelectric coefficient d_{33}^* is shown in Fig. 14.23. In contrast to the trend of macroscopic d_{33} for nanoceramic BSPT shown in Fig. 14.21b, the local effective piezoelectric coefficient d_{33}^* was found to increase with reduction of grain size. This can be explained by the different polarization degrees caused by SPM measurement and the microscopic poling process, as suggested by Buscaglia et al. [14.39]. As discussed previously, in the macroscopic poling process, the voltage applied to the nanograin ceramic samples cannot reach the high value required for domain switching due to the pinning effect of grain boundaries and defects, or it may cause dielectric breakdown of the samples. However, during SPM measurement, the electric field could be very high in the microregion under the cantilever tip, leading to full switching of the nanodomains and resulting in the higher piezoelectric response.

14.5 Summary

Highly dense BSPT morphotropic phase boundary ceramics with average grain size from micrometer scale to 10 nm have been successfully prepared by the two-step sintering or modified two-step sintering method.

Maximal piezoelectric constant d_{33} of 700 pC/N was achieved with grain size around 1.5 μm due to the high density and fine domain size. The size effect on the microstructures and piezoelectric behavior of BSPT

nanoceramics was investigated and characterized by means of XRD, HRTEM, AFM, SPM, and hysteresis-loop and dielectric measurements. The dielectric anomaly associated with the ferroelectric transition is clearly observed for all the samples, but is strongly flattened and broadened for ceramics with smaller grain size. The existence of ferroelectrics in nanocrystalline ceramics as fine as 10 nm has been proved by the

polarization-reversal characteristics according to the measurement of hysteresis loops as well as the local ferroelectric switching behavior investigated by piezoresponse force microscopy. When the grain size reduces to less than 100 nm, polarization switching is strongly suppressed, leading to small macroscopic piezoelectric constants. However, BSPT nanoceramics present very strong local piezoelectricity as observed by SPM.

Graphite Oxide

Wei Gao

This chapter introduces a peculiar carbon compound previously named as graphitic acid, graphite oxide (GO), or more recently, graphene oxide (GO). It is basically a wrinkled two-dimensional carbon sheet with various oxygenated functional groups on its basal plane and peripheries, with thickness of around 1 nm and lateral dimensions varying from a few nanometers to several microns. It was first prepared by the British chemist B.C. Brodie in 1859, and became very popular in the scientific community during the last half decade, simply because it was believed to be an important precursor to graphene (a single atomic layer of graphite, the discovery of which won Andre Geim and Konstantin Novoselov the 2010 Nobel Prize in Physics). Several strategies have been introduced to reduce GO back to graphene; however, in this chapter we mainly focus on GO itself, and more relevantly, its synthesis, chemical structure, physical and chemical properties, and possible applications. We emphasize here that, despite its strong relevance to graphene, GO also has its own scientific significance as a basic form of oxidized carbon and technological importance as a platform for all kinds of derivatives and composites that have already demonstrated various interesting applications. The synthesis recipes include the Brodie and Staudenmaier methods (Sect. 15.1.1), the Hummers

method and its modification (Sect. 15.1.2), and the Tour method (Sect. 15.1.3). Section 15.2 covers characterization methods together with chemical structure models as well as physical properties of graphite oxide. In the application section (Sect. 15.3) several examples are given, followed by concluding remarks in Sect. 15.4.

Two-dimensional nanomaterials typically refer to flat or slightly corrugated sheets with nanometer thickness and infinite lateral dimensions, such as graphene, single-layer boron nitride (BN), molybdenum disulfide (MoS₂), etc. The quantum confinement in the thickness direction results in exotic electronic properties and highlighted surface effects that can be useful in sensing, catalysis, and energy storage applications [15.1]. They have attracted tremendous attention recently, since they are one of the major categories in nanoscience that

were predicted to be thermodynamically unstable in the free state and have not been well explored. In 2005, Geim's group first reported the experimentally observed room-temperature quantum Hall effect on a real piece of graphene, which was obtained by mechanical exfoliation of highly oriented pyrolytic graphite (HOPG) [15.2, 3]; soon after that, a storm of graphene research dominated the world of carbon nanomaterials science. The term "graphene" then became a new superstar after carbon nanotubes (CNTs) in the carbon world. One of the

biggest challenges in graphene research at that time was large-scale production of graphene, since the first method that *Geim's* group adapted was both time consuming and extremely low in yield. Different strategies have been introduced, including metal-ion intercalation [15.4], liquid-phase exfoliation of graphite [15.1, 5], chemical vapor deposition (CVD) growth [15.6], vacuum graphitization of silicon carbide (SiC) [15.7], bottom-up organic synthesis of large polycyclic aromatic hydrocarbons (PAHs) [15.8–10], and of course, chemical reduction of GO [15.11, 12]. Each strategy has its own advantages and disadvantages; nevertheless, GO was believed to be one of the most promising pathways to graphene, mainly due to its wet chemical processability and large-scale availability in monolayers.

GO is not a naturally occurring compound, and the history of GO research can be dated back to over 150 years ago. When it was first made by chemical treatments of graphite with potassium chlorate (KClO₃) and fuming nitric acid (HNO₃), British chemist *Brodie* named it graphitic acid or graphite oxide [15.13], and after graphene research emerged in 2004, people started calling it graphene oxide. From a chemistry point of view, there is barely any difference between the two. If there has to be, we would refer to a single atomic layer of graphite oxide as graphene oxide. Since most of the experiments on GO were done in wet chemical processes, and people are generally dealing with large amounts of GO flakes in solution, we believe that when GO is dispersed in certain solvents, it is at least partially exfoliated by the solvent molecules, and thus can be referred to as graphene oxide. Otherwise, in solid state, GO powder or GO film is basically graphite oxide. In the following content, we will generally abbreviate both graphite oxide and graphene oxide as GO, since there is really no big difference between them, even in the context of electronic structures and properties (the case is different for graphite and graphene).

In terms of chemistry, GO is a new type of non-stoichiometric macromolecule that is chemically labile and hygroscopic in ambient condition. However, synthesis of GO has evolved and been modified several times with different chemicals such as potassium permanganate, concentrated sulfuric acid [15.14], and even phosphoric acid [15.15], and the resulting compounds

differ slightly in their chemical composition depending on the protocol used.

Over the past 150 years, research in GO has been quite limited. Without the recent popularity of graphene, researchers would still be confused about its detailed chemical structure. In the past few years, extensive research has been done to elucidate its chemical composition [15.16, 17], which turns out to be a corrugated carbon sheet with over half of the carbon atoms functionalized with hydroxyl and epoxy groups, and edges partially occupied by hydroxyl, carboxyl, ketone, ester, and even lactol structures. Even with those clarifications, the distribution of these groups and the spatial connectivity remain obscure even today. Chemical reduction of GO to graphene is one of the hottest topics in GO research, and the most commonly accepted reagent is hydrazine, as first introduced by *Ruoff* at UT Austin [15.12]. Pristine GO is an electrical insulator, and after reduction, it becomes electrically conductive. Several orders of magnitude increase in conductivity are usually observed during reduction processes; however, so far all graphene materials derived from GO have much poorer crystallinity [15.18] and carrier mobility than their mechanically cleaved counterparts [15.2, 3]. Thus, researchers would rather name them reduced GO (RGO), chemically modified graphene (CMG), or chemically converted graphene (CCG). For convenience, we will stick to the term RGO for these materials in the following discussion. The harsh chemical oxidation environment in GO synthesis processes actually creates lots of defects and vacancies within the sp² carbon lattice, which are almost impossible to recover by subsequent chemical treatments [15.18]. Taking this into account, GO researchers have switched their interest toward GO and RGO applications. Despite its poor crystallinity, GO, RGOs, and their derivatives have shown several promising applications in energy storage, sensing, water purification, electronics, etc. We note that, in literature, some researchers tend to ignore the differences between RGOs and high-quality graphene, and announce their results as graphene properties and applications, while we think it is necessary to put GO and RGOs into different categories and summarize RGO results into a separate chapter from the graphene chapter.

15.1 Synthesis of Graphite Oxide

In this section we introduce four different recipes for GO preparation in chronological order, and discuss and

compare their chemical processes and product structures in detail.

Table 15.1 Comparison of chemical compositions of Staudenmaier and Hummers GO (after [15.14])

Method	Carbon (wt%)	Oxygen (wt%)	Water (wt%)	Ash (wt%)	C/O atomic ratio
Acid–permanganate–nitrate (Hummers)	47.06	27.92	22.99	1.98	2.25
Staudenmaier	52.11	23.99	22.22	1.90	2.89

15.1.1 Brodie and Staudenmaier Methods

Brodie prepared the first batch of GO when he was investigating the chemistry of graphite in 1859 [15.13]. When he added KClO_3 to a slurry of graphite in fuming HNO_3 , he obtained a new batch of compound which later was determined to contain carbon, oxygen, and hydrogen. He washed the batch free from the salts produced in the reaction, dried it at 100°C , and again put it under an oxidation environment. The appearance of the product changed in the following three repeated treatments, finally resulting in a substance with *light-yellow color* which would not change with any additional oxidation treatment. He emphasized that the product could not be produced by one prolonged treatment and that one had to promote the oxidation process with restoration of the original conditions each time.

According to his elemental analysis, the molecular formula for the final product was $\text{C}_{11}\text{H}_4\text{O}_5$. Weak acidity and mild dispersibility in basic solution were observed; however, reflective goniometric characterization failed due to the small size, limited thickness, and imperfect structure. He also reacted the final product with *protochloride of copper* and *protochloride of tin* to obtain GO salts, and followed up with detailed analysis of composition and thermal decomposition. Nonetheless, his observations and conclusions were limited by the theories and characterization techniques available at that time, leaving a huge space for work and improvement until today.

One of the earliest improvements on Brodie's work was carried out in 1898 by *Staudenmaier* [15.19, 20]. Two major changes were introduced:

1. Adding concentrated sulfuric acid to improve the acidity of the mixture.
2. Addition of multiple aliquots of potassium chlorate solution to the reaction mixture over the course of the reaction.

These changes led to a highly oxidized GO product (with the same composition as the final product obtained by Brodie) in a single reaction vessel, thus greatly simplifying the GO synthesis process.

However, Staudenmaier's method was both time consuming and hazardous. The addition of potassium chlorate typically lasted over 1 week, and the chlorine dioxide evolved needed to be removed by an inert gas, while explosion was a constant hazard. Therefore, further modification or development of this oxidation process was still worth investigation.

15.1.2 Hummers Method and Its Modifications

Almost 60 years after the introduction of Staudenmaier's strategy, chemists *Hummers* and *Offeman* at the Mellon Institution of Industrial Research developed a different recipe for making GO [15.14]. A water-free mixture of concentrated sulfuric acid, sodium nitrate, and potassium permanganate was prepared and maintained below 45°C for graphite oxidation. According to their description, the whole oxidation process finished within 2 h, leading to a final product with higher degree of oxidation than Staudenmaier's product (Table 15.1).

However, it was found that Hummers' product usually has an incompletely oxidized graphite core with GO shells, and a preexpansion process is helpful to achieve a higher degree of oxidation. Firstly introduced by *Kovtyukhova* in 1999 [15.21], pretreatment of graphite with an 80°C mixture of concentrated H_2SO_4 , $\text{K}_2\text{S}_2\text{O}_8$, and P_2O_5 for several hours was widely adopted thereafter. The pretreated mixture was diluted, filtered, washed, and dried before the real Hummers oxidation step took place. Other reported modifications also include increase of the amount of potassium permanganate, etc. [15.11]. Nowadays, this modified Hummers method is the most common recipe used for GO preparation (Fig. 15.1). A typical GO product made by this method consists of thin flakes of GO with 1 nm thickness (corresponding to a single layer), and around $1\ \mu\text{m}$ in lateral dimensions on average; meanwhile the chemical composition was determined to be $\text{C} : \text{O} : \text{H} = 4 : 2.95 : 2.5$ [15.21]. The oxidation degree and yield of GO have been extensively improved when compared with the very first product by Brodie. However, the separation and purification processes in the modified Hummers method are still quite complicated and time consuming.

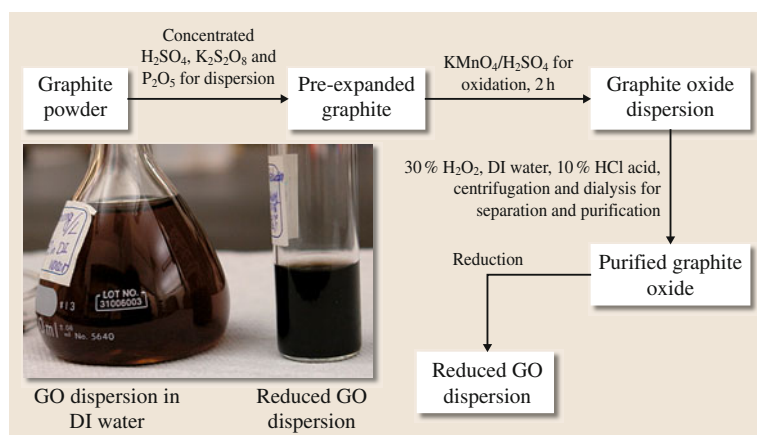

Fig. 15.1 Schematic of the recipe of the most commonly used modified Hummers method for GO preparation [15.11]. Lower left: Photograph of the final GO product in deionized (DI) water (left) and the dispersion after hydrazine reduction with ammonia (right)

15.1.3 Tour Method and Discussion

Tour Method

As the gold rush of graphene research started in 2004, GO jumped into the center of carbon nanomaterials research, and lots of publications have emerged talking about its structure, reduction, and applications. In 2010, a new recipe was introduced by Tour's group at Rice University, which avoided use of sodium nitride and increased the amount of potassium permanganate, and also introduced a new acid into the reaction vessel:

phosphoric acid [15.15]. They reported a GO product with higher degree of oxidation made by reacting graphite with six equivalents of KMnO_4 in a 9 : 1 mixture of $\text{H}_2\text{SO}_4/\text{H}_3\text{PO}_4$. One of the biggest advantages of this protocol is the absence of NaNO_3 , thus avoiding generation of toxic gases such as NO_2 , N_2O_4 , or ClO_2 in the reaction, and making it more environmentally friendly. Furthermore, phosphoric acid is believed to offer more intact graphitic basal planes and the final yield is much higher than with the Hummers method. A comparison among these protocols is shown in Fig. 15.2.

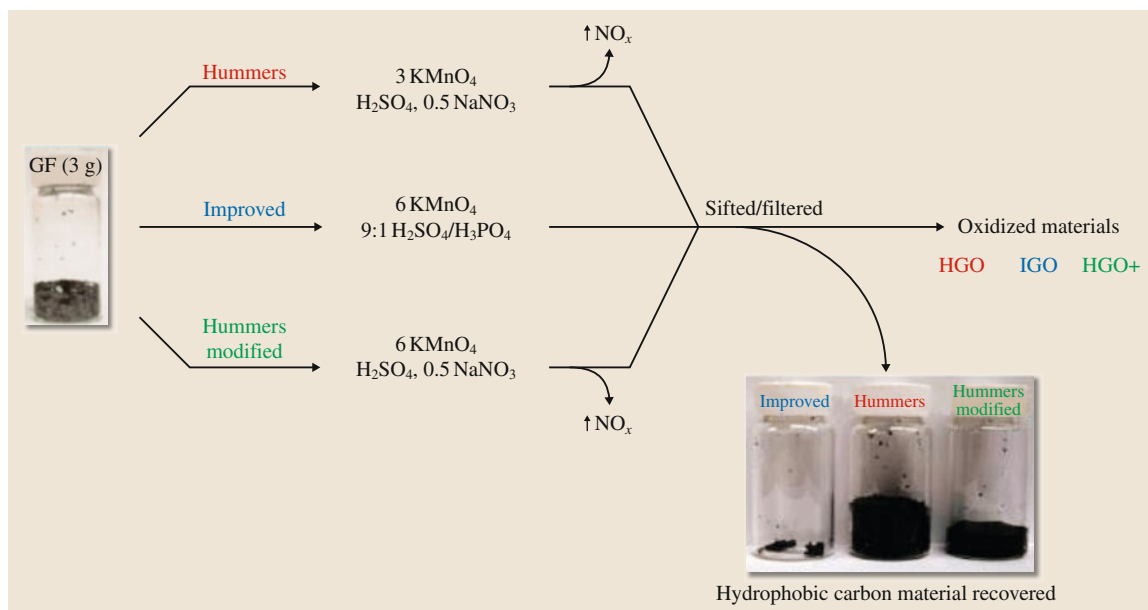

Fig. 15.2 A comparison of procedures and yields among different GO preparation recipes (after [15.15])

Fig. 15.3 Proposed mechanisms for the effect of the second acid in prevention of overoxidation of the sp^2 carbon network once they have formed the vicinal diols (after [15.22])

Discussion

The source of the graphite is also an important factor in GO fabrication. The most common source of graphite is a naturally occurring mineral which has been purified to remove heteroatomic contaminations such as sulfur and iron. As a result, there must be certain defects in the crystalline structure which could serve as starting sites for chemical oxidation. However, also due to the inherent defects and complexity of the structure, the precise oxidation mechanism in those reactions is hard to elucidate. Besides that, graphite nanofibers have also been used as starting material to make GO, and the resulting GO nanosheets are more uniform in size distribution. The coin-stacked graphene planes along the length of the fibers are believed to play an important role here, and tunability of the GO size by the oxidation time was also observed [15.23].

So far, two different combinations of oxidation reagents have been used to oxidize graphite to GO, including potassium chlorate with nitric acid, and potassium permanganate with sulfuric acid (both acids in the most concentrated state). In literature, nitric acid has been reported to react with aromatic carbon surfaces such as carbon nanotubes [15.24] and fullerenes [15.25], resulting in various oxygenated functional groups such as carboxyls, lactones, and ketones as well as release of toxic gases such as NO_2 and N_2O_4 . Similarly, potassium chlorate provides its oxidation capability by in situ generation of dioxygen, which is very reactive [15.26]. When the Brodie and Staudenmaier methods were introduced for GO synthesis, these chemicals were believed to be the strongest oxidizers available. As for the second combination ($KMnO_4$ and H_2SO_4), the permanganate ion is also a typical oxi-

dation reagent. The reactivity of MnO_4^- can only be activated in acidic solution, mainly described by the formation of dimanganese heptoxide from KMnO_4 in the presence of strong acid as follows [15.27]:

The transformation of MnO_4^- into the more reactive form Mn_2O_7 will certainly help oxidize graphite, but the bimetallic form of manganese oxide has been reported to detonate when heated to 55 °C or when reacted with organic compounds [15.27, 28].

The final acid introduced for GO synthesis is phosphoric acid, which is also believed to have the advantage of offering more intact benzene rings in the basal planes of the final product [15.22]. Figure 15.3 shows a possible explanation for this advantage [15.22]. The formation of the five-membered phosphor ring helps prevent further oxidation of the diols.

Purification is another important but tedious step in GO fabrication, since all of these protocols require long washing, filtration, centrifugation, and dialysis step. It has been reported that GO contaminated with potassium salts is highly flammable, which poses a fire hazard. The volume expansion and gelation observed during water washing of GO significantly slow down the purification process, and substitution with HCl acid and acetone was introduced by Kim et al. [15.29].

In summary, at least four different recipes have been introduced in the history of GO synthesis, and improvements in oxidation, simplicity, yield, and product qualities have been demonstrated. Today, making a batch of GO is no longer a problem, which thus has facilitated the rush of GO research; however, we still lack basic understanding of the oxidation processes and detailed mechanisms, which prevents chemically engineering and manipulation of the reaction to tackle critical technology issues, such as bandgap tuning, size distribution control, edge structure selection, etc.

15.2 Characterization, Chemical Structure and Properties

As a unique form of oxidized carbon, GO lies beyond the scope of organic compounds and large polycyclic aromatic hydrocarbons (PAHs), thus making it quite interesting and challenging to characterize the peculiar structure. In this section, we start with a variety of characterization results shown in literature on GO and then try to clarify its molecular structure, electronic states, and chemical reactivity.

15.2.1 Characterizations

Solid-State ^{13}C Nuclear Magnetic Resonance (SSNMR) Spectroscopy

GO sheets are gigantic molecules that fall into the category of colloids. GO dispersions in water are much too concentrated to be analyzed by liquid-phase NMR. In literature, the most powerful and precise technique to characterize GO is solid-state ^{13}C NMR [15.30]. Due to the low natural abundance of ^{13}C (1.1%), the signal-to-noise ratio in the measurement of regular samples is quite low, and long acquisition time is usually required for good-quality data. Therefore, in 2008, Ruoff and coworkers prepared a ^{13}C -enriched GO sample and clarified its chemical structure to a new level [15.16]. According to their analysis, cross polar-

ization/magic angle spinning (CP/MAS) experiments displayed three broad resonances at 60, 70, and 130 ppm in the ^{13}C NMR spectrum of GO. Figure 15.4 shows typical one-dimensional (1-D) and two-dimensional (2-D) ^{13}C pulse spectra from a ^{13}C -labeled sample, clearly demonstrating both the chemical structure assignments of the major peaks and the spatial proximity between the sp^2 carbon, epoxy carbon, and hydroxyl carbon atoms (as indicated by the green, blue, and red circles in Fig. 15.4b).

Interestingly, although the isotopical labeling of GO greatly improved the SSNMR analysis resolution, there still remained some unassigned peaks in this work. Later on, further reports came out with more detailed assignments of those peaks, such as a new identification of the 101 ppm peak, which had long been ignored by previous researchers. The 101 ppm peak probably comes from the five- or six-membered-ring lactol structure as shown in Fig. 15.5. Figure 15.6 shows a typical comparison of a ^1H - ^{13}C cross polarization spectrum and a direct ^{13}C pulse spectrum obtained from unlabeled GO, with quantitative data on the relative ratio of all these functionalities being 115 (hydroxyl and epoxy):3 (lactol O—C—O):63 (graphitic sp^2 carbon):10 (lactol + ester + acid carbonyl):9 (ketone carbonyl) [15.17].

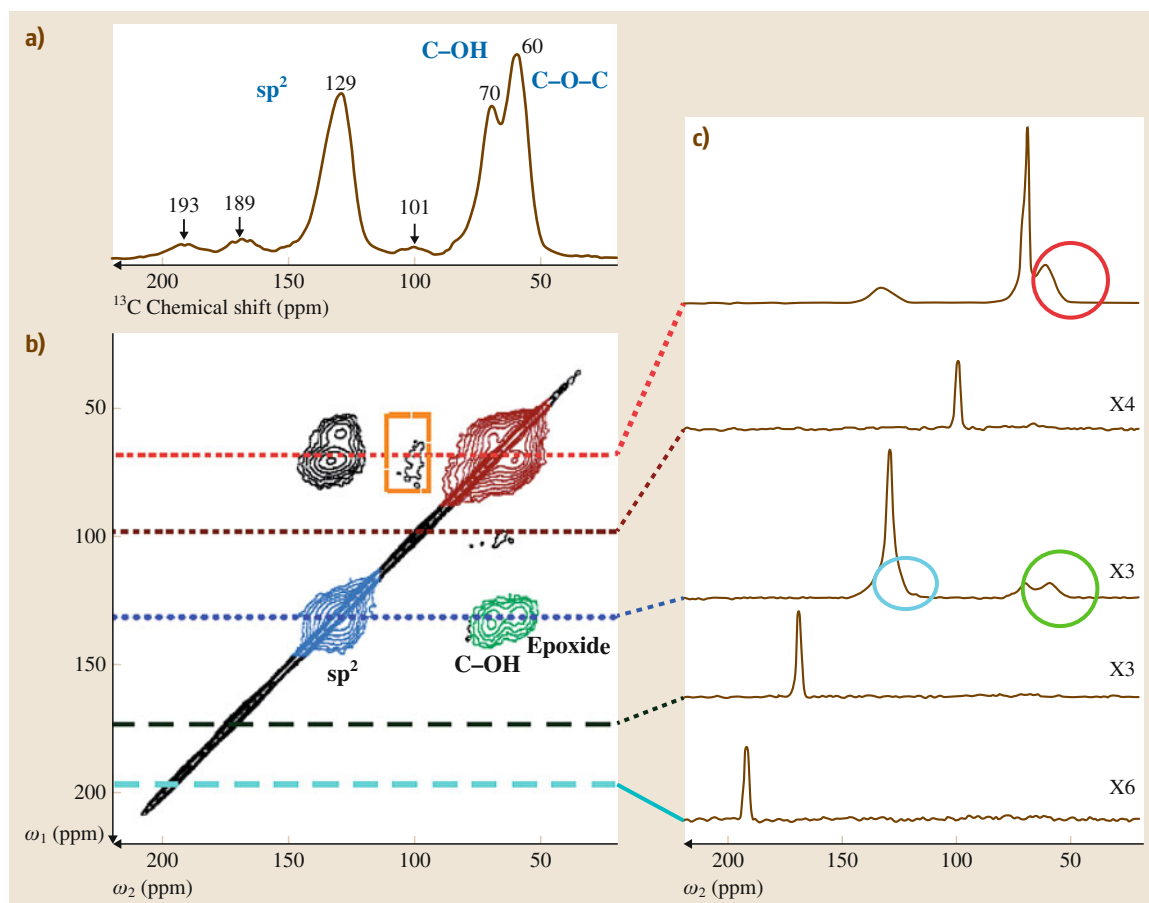

Fig. 15.4 (a) 1-D ^{13}C MAS and (b) 2-D $^{13}\text{C}/^{13}\text{C}$ chemical-shift correlation solid-state NMR (SSNMR) spectra of ^{13}C -labeled graphite oxide with (c) slices selected from the 2-D spectrum at the indicated positions (70, 101, 130, 169, and 193 ppm) in the ω_1 dimension. All the spectra were obtained at a ^{13}C NMR frequency of 100.643 MHz with 90 kHz ^1H decoupling and 20 kHz MAS for 12 mg of sample. In (a), the ^{13}C MAS spectrum was obtained with direct ^{13}C excitation by a $\frac{\pi}{2}$ pulse. The recycle delay was 180 s, and the experimental time was 96 min for 32 scans. In (b), the 2-D spectrum was obtained with cross polarization and finite-pulse radio frequency-driven dipolar recoupling (fpRFDR) ^{13}C – ^{13}C dipolar recoupling sequence. The experimental time was 12.9 h with recycle delays of 1.5 s and 64 scans for each real or imaginary t_1 point. Gaussian broadening of 150 Hz was applied. The green, red, and blue areas in (b) and circles in (c) represent cross peaks between sp^2 and C–OH/epoxide (green), those between C–OH and epoxide (red), and those within sp^2 groups (blue), respectively (after [15.16])

More advanced SSNMR techniques were later used for GO characterization, including 2-D ^{13}C double-quantum/single-quantum (2Q/SQ) correlation SSNMR, 2-D ^{13}C chemical shift anisotropy (CSA)/isotropic shift correlation SSNMR, and 2-D triple-quantum/single-quantum (3Q/SQ) correlation SSNMR [15.31]. The 2Q/SQ spectrum eliminates diagonal signals in the 2-D spectrum, offering a clearer correlation signal between

^{13}C –OH carbon and ^{13}C –O– ^{13}C carbon (Fig. 15.7). The 3Q/SQ spectrum offers coherence correlation between three different carbons, thus providing a large amount of information regarding the connectivity between differently functionalized carbon atoms as well as the distribution of those functional groups on GO surfaces. Interestingly, theoretical simulation was used simultaneously to fit these data with a simplified GO

Fig. 15.5 Structure of the five- and six-membered lactol rings. The carbons circled in red are those that give ^{13}C NMR signals at 101 ppm (after [15.17])

structural model, and satisfactory fitting was obtained by ab initio calculations with structure model A (with only 1,2-ether) shown in Fig. 15.7d.

All these analyses significantly helped to identify GO's chemical structure, leading to improved clarity in its chemical composition. However, it is also noteworthy to point out here that all those SSNMR characterizations were done on GO samples made by

the modified Hummers method, and GO products from other methods do differ in the relative ratio of these functionalities [15.15].

Diffuse Reflectance Infrared Fourier-Transform (DRIFT) Spectroscopy

Besides SSNMR, DRIFT is another powerful tool to detect chemical functionalities in oxidized carbons [15.32]. For samples of GO, since it is hygroscopic, the large amounts of water molecules adsorbed in the structure have become the biggest obstacle to FTIR analysis. Therefore, in 2005, Dekany and coworkers reported a detailed DRIFT analysis of deuterated GO samples prepared with the Brodie method, and they were able to assign most of the peaks observed in the spectra and distinguish the signals of hydroxyl groups from that of others, thus providing a strong clarification of all the previous debated assignments in GO FTIR spectrum (Fig. 15.8; Table 15.2). Deuterium exchange of GO imposes red-shifts of all hydroxyl-related bands, thus one can easily distinguish between C–OH and COOH stretching vibrations, and a new band was also uncovered around 1384 cm^{-1} , which was hidden in the spectrum of air-dry GO and was attributed to organic carbonates. The possible functional moieties in GO include carboxyl, lactone, phenol, lactol, chromene, ketone, etheric rings, and organic carbonate, but definitely no pyrones [15.32].

Other Characterizations

As a pseudo-ordered structure, the surface of GO is covered nonuniformly with oxygenated groups, leaving approximately $2\text{--}3\text{ nm}^2$ carbon clusters isolated within the sp^3 carbon matrix, as can be easily verified by Raman spectroscopy [15.18, 33], scanning tunneling microscopy (STM) [15.34, 35], high-resolution transmission electron microscopy (HR-TEM) [15.36, 37], and transport studies [15.38, 39].

The Raman spectrum of GO basically consists of a broad D peak ($\approx 1350\text{ cm}^{-1}$) and G peak ($\approx 1594\text{ cm}^{-1}$), with a wide weak bump extending from 2681 to 3050 cm^{-1} . The D/G ratio is around 0.95, indicating a large amount of defects within the crystal lattice. However, upon chemical reduction, an increase in the D/G ratio is usually observed, the explanation for which remains ambiguous.

The UV-Vis spectrum of GO in water has two featured peaks around 233 nm due to $\pi\text{--}\pi^*$ transition of C=C bonds, and a broad shoulder between 290 and $\approx 300\text{ nm}$ assigned to n-to- π^* transition of C=O bonds [15.40]. Upon reduction, a red-shift of the first

Fig. 15.6a,b $^1\text{H}\text{--}^{13}\text{C}$ cross polarization (CP) spectrum of GO obtained with 7.6 kHz MAS and contact time of 1 ms (67 000 scans, (a)), and a direct ^{13}C pulse spectrum obtained with 12 kHz MAS and a 90° ^{13}C pulse (10 000 scans, (b)). The peak at 101 ppm is caused by the carbons of five- and six-membered-ring lactols (after [15.17])

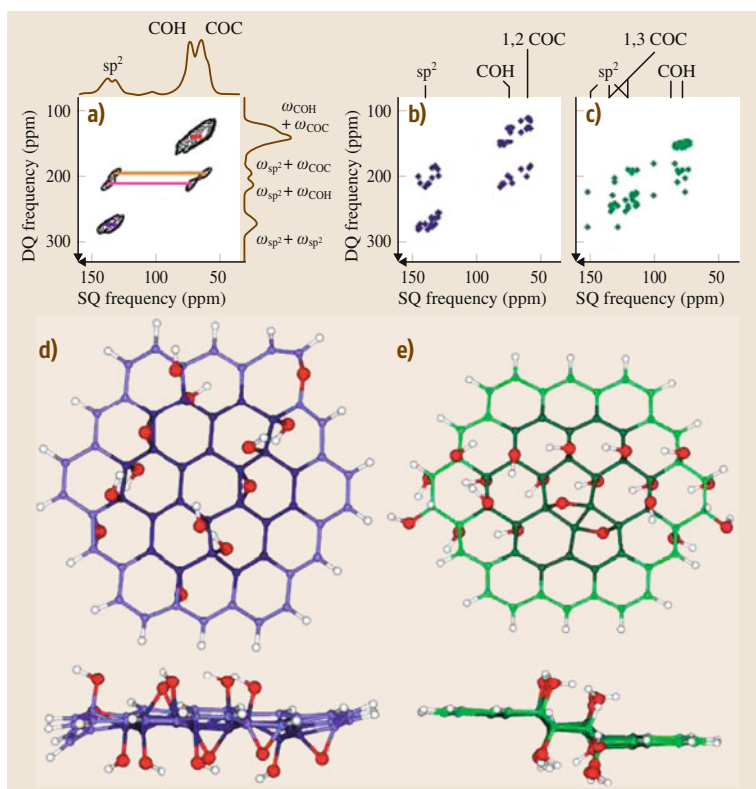

Fig. 15.7 (a) Experimental 2-D ^{13}C DQ/SQ correlation SSNMR spectrum of uniformly ^{13}C -labeled GO using ^{13}C - ^{13}C J coherence transfer. Fast recycling with short recycle delays of 0.3 s and low-power (7 kHz) decoupling was used. Signal assignments in (a) are those made in [15.10] and confirmed here. The carrier frequency was set at 211.17 ppm. (b,c) Predicted DQ/SQ correlation spectra based on isotropic chemical shifts calculated for (b) model A and (c) model B. (d,e) Structural models for (d) model A and (e) model B from the (top) top and (bottom) side views. Carbons in (d,e) are color coded to match the spectra in (b,c). Red and white spheres denote O and H, respectively. ^{13}C at the edge of the models (light blue or green) were not included in (b,c). The calculated spectrum (b) based on model A well reproduced the experimental spectrum (a) (after [15.31])

Fig. 15.8a-c DRIFT spectra of graphite oxide (GO) samples. Spectrum of deuterated GO is offset by 0.12 Kubelka–Munk units. The inset shows the enlarged 1900–1500 cm^{-1} region of (a) air-dry GO, (b) deuterated GO, and (c) anhydrous GO spectra (after [15.32])

Table 15.2 IR peak positions of air-dry GO (GO/H₂O) and deuterated GO (GO/D₂O) and their assignments. Asterisks (in the same row) designate isotopomer peak pairs. Band intensities and widths are classified as: w (weak), m (medium), s (strong), and vs (very strong) and sh (shoulder), vsp (very sharp), sp (sharp), and br (broad), respectively (after [15.32])

peak and the disappearance of the second one were usually observed.

x-Ray diffraction (XRD) analysis of GO powder shows a prominent but somewhat broad peak around 11°, the position of which can be easily influenced by the degree of oxidation and hydration of the GO sample, and of course, the humidity level of the atmosphere during the measurement. The reported interlayer distance of GO samples varies from 5.97 Å [15.32] to 9.5 Å [15.15].

x-Ray photoelectron spectroscopy (XPS) analysis of GO powder also offers two broadened and overlapped peaks centered around 284 and 286 eV, corresponding

to sp² carbon and oxidized carbon, respectively. Some studies try to deconvolute these peaks into different oxidation functionalities, while we think XPS is at most a semiquantitative analysis technique, and this kind of analysis is going beyond the resolution limit of the instrument.

Atomic force microscopy (AFM) and TEM could easily confirm the 2-D nature of GO sheets when they are spin-coated onto a pretreated silicon wafer. The thickness of a GO sheet is typically around 1–2 nm, and the lateral dimensions vary between several hundred nanometers and micrometers. Based on AFM studies, it is believed that sonication results in near-complete

Fig. 15.10 Proposed structure models for GO

exfoliation of GO [15.41]. The wrinkled surface and occasionally holes can be observed in both AFM and TEM images of GO (Fig. 15.9).

Thermal gravimetric analysis (TGA) offers information on the thermal stability of GO. Unfortunately, GO is thermally unstable. When heated in Ar, GO starts decomposing slowly above 60–80 °C, and loses up to 60% of its total weight when heated up to 950 °C. The loss of adsorbed water will also occur during this process. It is important to mention that, for GO TGA analysis, the temperature ramping rate is usually set to be very low (around 1 K/min), in case the rapidly evolved gases explode and cause problems.

15.2.2 Chemical Structure

Based on the characterizations listed above (mainly SSNMR and DRIFT analysis data), at least six different structural models for GO have been suggested [15.42], and the precise chemical structure of GO remains controversial (Fig. 15.10).

The earliest model by Hofmann and Holst presented in 1939 consists of epoxy groups spreading

across the basal planes of graphene, with C/O ratio of two [15.43]. The model was modified by Ruess in 1946 with the introduction of hydroxyl groups into the lattice and also the corrugation of the basal plane [15.44]. Different from the Hofmann model, the Ruess model prefers 1,3-ether on a cyclohexane ring with the 4-position hydroxylated, also being stoichiometrically regular. Ruess's suggestion was supported by the observed structure of poly(carbon monofluoride), (CF)_n [15.45], later by Mermoux in 1991. The existence of hydroxyl groups in this model accounted for the hydrogen content in GO for the first time; in 1957, Clauss and Boehm supplemented this contribution with C=C bonds, ketone and enolic groups, as well as carboxylic groups around the edges [15.46]. More than a decade later, Scholz and Boehm reconsidered the stereochemistry of this model, and modified it into a corrugated carbon layer consisting of alternately linked ribbons of quinoidal structure and opened cyclohexane rings in chair conformation [15.47]. They completely removed epoxy and ether structures from this model, and put hydroxyl groups at the 4-position of 1,2-oxidized cyclohexane rings. On the other hand, the Ruess model

Fig. 15.11 Schematics of phenol–quinone exchange, favoring the forward direction due to the aromaticity of the phenol structure

was still a possibility; in 1988, *Nakajima* and *Matsuo* proposed a stage 2 type model $(C_2F)_n$ in fluorinated graphite product, and tried to make the oxide analog for GO [15.48].

Most of these models have now been supplanted by the two most recent models, named after *Lerf* and *Klinowski* [15.30, 49, 50] and *Dekany* [15.42], respectively. In the Lerf–Klinowski model, the periodicity in the structure was rejected, being substituted by a non-stoichiometric amorphous alternative. In their studies, the SSNMR technique was used for the first time for GO structural characterization, while all previous reports were simply based on elemental analysis, reactivity observations, and XRD data. Obviously this is an important milestone in the GO structure debate, and as discussed in the previous section, the assignments of all those CP/MAS signals in SSNMR spectra soon helped to clarify the basic structural information for GO.

Lerf and coworkers have presented many detailed discussions and analyses of the GO structure, based on not only SSNMR analysis, but also GO reactivity with a variety of compounds and infrared spectroscopic data. First of all, they attempted Diels–Alder-type cycloaddition reactions ($4+2$) on GO (conjugated double bonds should react) with maleic anhydride; however, no reaction was observed [15.49]. In the context of the distribution of the alkenes on the GO basal plane, this result is definitely inconclusive, since the lack of reactivity of GO with dienophile could be due to the complexity of the GO local environment such as the steric effect of epoxy and hydroxyl groups. Later, they suggested that alkenes ($C=C$) in GO are probably either aromatic or conjugated, based on the logic that isolated double bonds could not survive the harsh oxidation environment applied when making GO [15.30]. Secondly, in combination with the interpretation of FTIR data earlier, they proposed that keto groups are more favored at the periphery of GO than carboxylic

acids [15.51]. The acidity of GO was further explained by them through a keto–enol tautomerization and proton exchange on the enol site. The keto form is supposed to be thermodynamically more favored; however, α,β -unsaturated ketones that are present in aromatic regions would favor phenoxide product and allow proton exchange (also known as phenol–quinone exchange, shown in Fig. 15.11). Thirdly, they observed strong hydrogen bonding between GO flakes themselves and water molecules, as indicated by the constant full-width at half-maximum of the water peak in the 1H NMR spectrum [15.50].

The Dekany model was another well-recognized structure for GO, which adopted the logic of the Ruess and Scholz–Boehm models, and stuck to the corrugating nature of the carbon network. It followed the basic framework of the Scholz–Boehm model, while adding 1,3-ethers into the structure and extending the *trans*-linked cyclohexyl networks [15.42]. In 2008, *Cai* et al. prepared a ^{13}C -labeled GO sample, and conducted 1-D and 2-D SSNMR analysis on it. According to their conclusion, only the Lerf–Klinowski model and the Dekany model are possible [15.16].

Later on, *ab initio* chemical shift calculations were used to simulate the SSNMR signals in GO by *Ruoff*'s group [15.31], and an experimental 2-D ^{13}C double-quantum/single-quantum correlation SSNMR spectrum of ^{13}C -labeled GO was compared with spectra simulated for different structural models using *ab initio* geometry optimization and chemical shift calculations. According to their conclusion, only the Lerf–Klinowski model fits best with the experimental data; furthermore, all the previous proposed models were excluded. This is definitely another big step forward in the clarification of the GO structure; however, we need to point out that, due to the size limitation in the theoretical modeling, the Lerf–Klinowski model used to simulate the NMR spectrum in this paper is quite simplified, and thus trivial details of the structure on the edges as well as the precise distributions of those functional groups are still unclear.

Unfortunately, to date, the precise structure of GO remains elusive. Major reasons include sample-to-sample variability due to different synthesis methods and degrees of oxidation, the amorphous, nonstoichiometric nature of GO, and the limited resolution of the major characterization techniques such as SSNMR and FTIR. In this case, the term “graphite oxide” may refer to a family of different compounds with certain discrepancies in the functional group distribution and relative content.

15.2.3 Reactivity and Physical Properties

Dispersibility

The most common reaction medium for GO is water, and there are different ways to disperse GO into water, including sonication and mechanical stirring. Sonication has been reported to create defects and decrease the sheet size of GO from several microns to 100 nm, and also widen the size distributions, thus being less favorable than mechanical stirring in many applications [15.41, 52, 53]. The dispersibility of GO in water is typically on the order of 1–4 mg/ml [15.54]. On the other hand, GO can also be dispersed in organic solvents such as dimethylformamide (DMF), *N*-methylpyrrolidone (NMP), tetrahydrofuran (THF), etc. [15.55, 56], thus is also believed to be amphiphilic with the core more hydrophobic and edges more hydrophilic [15.55, 56], acting just like a surfactant [15.57]. As a giant molecule with amphiphilicity, GO can be assembled into continuous single-layer films by the Langmuir–Blodgett method [15.58–60].

Toxicity

GO and RGOs were reported to be toxic to bacteria (*Escherichia* and *Staphylococcus*) due to cell membrane damage to the bacteria in contact with the sharp edges of GO and RGO by Akhavan et al., and hydrazine-reduced GO was more toxic than pristine GO [15.61]; inhibition of bacterial growth with minimal toxicity to human alveolar epithelial A549 cells was also shown by Hu et al. [15.62]. Wang et al. demonstrated that GO has dose-dependent toxicity to human fibroblast cells, with obvious toxicity being observed at doses above 50 µg/ml [15.63]. GO toxicity and blood compatibility were also reported to be dependent on dose, extent of exfoliation, and sheet size [15.64–66]. RGO was demonstrated to be less toxic than carbon nanotubes to PC12 cells at high concentrations by Zhang et al. [15.67]. PEGylated nanosized GO only exhibited mild toxicity toward Raji cells at concentrations as high as 100 mg/l [15.68]. Paradoxically, other recent reports showed high biocompatibility of GO or RGO [15.69–73]. To address these discrepancies, Ruiz et al. reported the nonspecific enhancement of cellular growth by GO, thus verifying that GO is nontoxic to both bacteria and mammalian cells, and attributing the previous reported toxicity as effects from carry-on impurities in GO [15.74]. However, incorporating Ag nanoparticles onto the GO matrix significantly activated its antibacterial activity [15.75, 76].

Hygroscopicity

The hydroxyl, epoxy, and carboxyl groups on GO make it very hydrophilic, and adsorbed water molecules tend to present in the interlayer voids even after prolonged drying [15.77]. Therefore, GO turns out to be quite hygroscopic, with water content strongly depending on the humidity of the environment [15.78]. When a large amount of interlamellar water is present in stacked GO films, a network of hydrogen bonds (H-bonds) forms between water molecules and those oxygenated groups on GO, thus significantly influencing its structural, mechanical, and electronic properties [15.77–80]. For example, as the humidity level rises, GO film swells in volume [15.78, 80] and its tensile modulus decreases [15.77]. Some theoretical simulations have predicted that the interlayer distance between GO flakes rises from 5.1 to 9.0 Å when the water content increases from nearly 0 to 26 wt %, and that when the water content exceeds 15 wt %, the H-bond network is dominated by water–water H-bonds while the functional groups are connected indirectly via a chain of water molecules [15.81]. The dynamics of the interlamellar water has also been studied by neutron scattering, and a *two-site* jump motion mechanism has been proposed [15.78]. Interestingly, when water is replaced by D₂O, a lower interlayer distance was always observed, probably due to the lower solubility, lower reactivity, and stronger bonding of D₂O compared with H₂O [15.78]. The presence of water has also been used to account for the carbonyl formation and hole formation during GO reduction processes [15.78].

Reactivity

Independent of the dispersion medium, a stable colloidal dispersion of GO is readily reactive with a variety of chemicals, most of which have been reducing reagents. The first example would be the hydrogen sulfide reduction introduced by Hofmann in 1934 [15.82]. No report on lithium aluminium hydride (LiAlH₄) reduction has emerged, probably due to the strong reactivity of LiAlH₄ with the common dispersion medium of water. Although NaBH₄ is slowly reactive with water, the reaction is kinetically slow enough to allow GO reduction to occur. Meanwhile, the most popular reductant so far has been hydrazine [15.12]. The reduction mechanism has been proposed, at least for one of the major functional groups on GO, as shown in Fig. 15.12 [15.12]. Besides these, GO was believed to be one of the most important precursors to graphene; thus in literature, lots of chemical reduction protocols have been demonstrated, and to compare their effectiveness,

characterizations of products with electrical measurement, elemental analysis, ^{13}C SSNMR, XPS, FTIR, Raman, XRD, TEM, near-edge x-ray absorption fine structure (NEXAFS) spectroscopy, etc. have been widely reported. These chemical or thermal treatments and their product characterizations are summarized in Table 15.3.

The restoration of π conjugation can be verified by changes between GO and RGO in UV-Vis spectra, XPS data, and electrical conductivities. The red-shifts of UV adsorption peaks suggested the extension of π - π conjugation according to Hückel's rule. The appearance of the π - π satellite peak in XPS was also a good indication. Electrical conductivity would be another good criterion to judge the degree of restoration. As shown in Table 15.3, more than 20 chemicals have been reported as reducing reagents for GO, and so far the product with highest electrical conductivity is produced by hydriodic acid with acetic acid treatment [15.89]. As mentioned above, it must be emphasized that all these chemical treatments worked as reduction protocols to GO, but their products were far from HOPG graphene in terms of crystallinity, since the carrier mobility in these products is at least three orders of magnitude lower than that of graphene. In this case, we conclude that GO as a chemically active compound is prone to be reduced

very easily, but the defects and disorder structure in GO are very hard to remove. This can also be verified by the Raman data in Table 15.3. All of the Raman spectra reported on RGOs have prominent D peaks, and most of them have higher D/G ratio than that of GO, indicating highly defected structures.

On the other hand, the reduction processes are usually accompanied by heteroatom incorporation into the final product, further complicating the structure and pushing RGOs further from pristine graphene. As shown in Table 15.3, both elemental analysis and XPS data show the existence of heteroatoms in the final product, including oxygen, nitrogen, sulfur, boron, hydrogen, etc. Thus, researchers have also tried to compare the purity of their products by comparing the ratios of C/O, C/(O+N), etc. These heteroatoms influence the electrical conductivity as well, such as residual C-N groups that can act as n-type dopants [15.134].

To elucidate the reduction mechanism as far as possible, how the functional groups on GO react with various chemicals is summarized in Table 15.4. Most of these reactions are explained based on fundamental organic chemistry in terms of the reactivity of the individual functional groups. As one can see from this table, even the most popular reagent (hydrazine) would still

leave some functional groups intact. Therefore, though the sp^2 carbon lattice structure is thermodynamically favorable over GO, complete restoration of π conjugation is very hard, let alone the carbon vacancies created in the oxidation process.

Electronic Structure and Fluorescence

If we recall the chemical structure of GO, it is basically composed of 2–3 nm sp^2 carbon clusters surrounded by a heterogeneous sp^3 carbon matrix. In a carbon material with a mixture of sp^2 and sp^3 carbon atoms, the photoluminescence behavior is determined by the π states of the sp^2 clusters [15.136]. This is simply because the π and π^* electronic levels lie within the bandgap of the σ and σ^* states (typically around 6 eV [15.136]) of the sp^3 domains [15.137, 138]. π -Electrons are highly localized in sp^2 domains, and radiative recombination of electron-hole pairs in those sp^2 clusters can give rise to fluorescence [15.138–140]. Therefore, the size, the shape, and even the interface structure of sp^2 carbon clusters can determine the local bandgap and thus the energy of the fluorescence.

Since the oxygenated functional groups are randomly distributed on the GO surface, the corresponding sp^2 carbon clusters have a wide size distribution; hence, no signature features can be assigned in the electronic structure. The size-dependent bandgap of sp^2 carbon clusters has been calculated, as shown in Fig. 15.13 [15.135]. Just as expected, larger clusters have lower-energy bandgaps, varying from ≈ 7 eV for a single benzene ring to ≈ 2 eV for about 40 fused rings, though it is necessary to point out that the structural model adapted in this simulation was quite simplified (with only zigzag edges and ordered hexagonal shapes) and that it did not take into account of the electronegativity effect of the nearby connected sp^3 carbons. When only cluster size is taken into account, the ensemble band diagram corollary is shown in Fig. 15.14 [15.135]. Interestingly, in Fig. 15.14, the authors also depicted a photoluminescence process from a finite-sized sp^2 cluster (composed of several conjugated repeating alkene units that were populated at the initial stage of the vapor hydrazine reduction), corresponding to the enhanced blue luminescence (≈ 390 nm, 3.18 eV) that they observed in the first 3 min of reduction.

On the other hand, some researchers have suggested that edge structures can also account for the optoelectronic properties of GO/RGO, or preferably GO/RGO quantum dots [15.141]. When the size of GO/RGO sheets decrease to the nanometer scale, the peripheries start to play a major role in the electronic structure.

As for GO, the periphery is partially occupied by oxygenated groups; however, these groups are excluded as the origin of observed luminescence, because the luminescence was reported to be enhanced with reduction [15.135]. As proposed earlier [15.142], instead of the commonly assumed H-termination or σ -type dangling bonds, the armchair edges are actually of carbyne (*o*-benzyne) type, whereas the zigzag edges are of carbene type (Fig. 15.15). This means that the nonbonding electron on the edge carbon is no longer in its free state, but couples with another electron on the adjacent carbon (the armchair case), or interacts with the π electron on the same carbon atom (the zigzag case). Therefore, the activity of an unsaturated valence has not been seen in this case, and stabilization is achieved by localization of the itinerant π electrons through σ - π coupling in the zigzag case [15.143]. Based on both theoretical calculations and experimental data, Radovic et al. strongly suggested that this type of edge structure tends to be stable in ambient conditions, and the stability increases when the number of conjugated aromatic rings increases. Carbenes have two electronic configurations

in the ground state, the triplet ($\sigma^1\pi^1$) and singlet (σ^2) state, with the triplet configuration typically lower in energy [15.142]. In the case of carbyne, the situation is exactly the opposite. Regardless of its detailed configurations, the strong blue luminescence observed in RGO quantum dots has been assigned to the highest occupied molecular orbital (HOMO)–lowest unoccupied molecular orbital (LUMO) transition in the triplet state of carbenes at zigzag edges [15.141].

Although the exact mechanism for the observed visible and ultraviolet fluorescence in GO remains to be reconciled, GO as a unique carbon platform, together with its chemical activity, tunability, and solution processability, has already shown its technological significance. The photoluminescence from GO derivatives varies from the near-infrared to the ultraviolet region [15.16, 117, 135, 141, 144–147], and further demonstrations of its application have been widely reported, such as in drug delivery, live cell imaging [15.16, 145], fluorescence quenching [15.148–153], biosensing [15.154, 155], and nonlinear optics [15.156–158].

15.3 Applications

At the beginning of this section, we distinguish the applications of RGOs from those of GO. There are numerous reports in literature suggesting possible applications for RGOs and their derivatives (such as metal oxide–RGO and polymer–RGO composites), as vital components in conductive polymer composites [15.86], transparent conductors [15.41, 159–162], molecular, electrochemical, or biochemical sensors [15.11, 93, 110, 155, 163–185], electrochemical or photocatalysts [15.63, 108, 171, 172, 186–206], lithium storage materials [15.5, 6, 64, 207–222], electron field-emission electrodes [15.223], supercapacitor electrodes [15.152, 174, 224–239], electronic transistors [15.240], artificial muscles [15.207], electroluminescence electrodes [15.109, 241], solid-phase microextraction materials [15.242], water purification adsorbents [15.239, 243–250], organic photovoltaic components [15.150, 251–255], electromechanical actuators [15.256], etc. RGO here acts as either major functioning components themselves or as matrix supports for active nanoparticles and/or metal oxides in the composites. However, as stated above, direct use of unreduced GO is relatively rare. The applications of GO can be summarized into three different categories:

1. As an important platform for RGO and GO derivatives/composites (Sect. 15.3.1)
2. As an anisotropic proton conductor (Sect. 15.3.2)
3. Others, such as a catalyst and an electron-transparent window (Sect. 15.3.3).

15.3.1 Platform for RGOs and GO Derivatives/Composites

RGOs

We have discussed and compared reduction of GO in previous sections (Table 15.3). RGOs derived from GO differ in their electrical conductivities, micromorphologies, Brunauer–Emmett–Teller (BET) surface areas, optical activities, etc., thus leading to a variety of applications as mentioned above. Despite being referred to as graphene or RGO applications, these results actually take advantage of the large scale, wet chemical processability, high surface area, and tunable conductivity [15.257] of GO. In order to focus on GO itself, we just skip this RGO part here.

GO Derivatives

The addition of other functional groups directly onto GO, to form either covalent or noncovalent attachments,

Fig. 15.16 Nucleophilic attack of hydroxyl groups on GO to 2-bromo-2-methylpropanoyl bromide, offering an initiator for ATRP

falls into another big category of GO chemistry. According to the widely accepted *Lerf–Klinowski* model, reactive functional groups on GO are epoxy, hydroxyl, carbonyl, carboxyl, and ester moieties. It would be useful if one could selectively react with one of these groups while keeping the others intact; however, so far such orthogonal reactions have not been demonstrated. Most functionalization occurs on more than one type of oxygenated group and results in very complicated products with separation and purification being almost impossible. Regardless of their vague chemical characterization, most of these products have shown interesting applications in various fields.

For instance, carboxyl acid groups, after being activated by thionyl chloride (SOCl_2) [15.258–260], 1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide (EDC) [15.145], *N,N'*-dicyclohexylcarbodiimide (DCC) [15.261], or 2-(7-aza-1*H*-benzotriazole-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HATU) [15.262], are attacked by nucleophiles such as amines or hydroxyl groups, forming covalent attachments. The resulted amides have shown possible applications in optoelectronics [15.258, 260, 263], biodevices [15.262], drug-delivery vehicles [15.145], and polymer composites [15.261, 264]. A more complicated case involves the attachment of diamine, further covalent bind-

ing with bromide-terminated initiators, and subsequent polymerization on the GO surface [15.265, 266]. The resulting GO–polymer composites usually offer better dispersibility in many solvents. Besides that, isocyanate derivatives have also been shown to react with carboxyl and hydroxyl groups, leading to amide and carbamate esters [15.267]. These products can be well dispersed in polar aprotic organic solvents. Chitosan chains also reacted with the carboxyl groups on GO, forming amino bonds with only microwave assistance, offering possible biomedical applications [15.268].

Epoxy group is another major functionality on GO. The epoxy rings can be easily opened under acidic conditions or by nucleophilic attack; For example, octadecylamine was used to react with GO and offered a colloidal dispersion of functionalized GO (FGO) in organic solvents [15.269]. Hexylamine was also used to attack the epoxy rings on GO to form alkylated GO, which can further be reduced into alkylated conductive graphene paper [15.270]. Ethylenediamino- β -cyclodextrin was also introduced to attach cyclodextrin onto the GO surface via amine–epoxy reaction [15.145]. An ionic liquid [1-(3-aminopropyl)-3-methylimidazolium bromide, RNH_2^+] was attached to GO via the end amine group in a nucleophilic attack of the epoxy groups [15.271]. Another example involved 3-aminopropyltriethoxysilane (APTS) attachment onto

epoxy via a S_N2 reaction and of course ring-opening of epoxy groups, while reinforcement in the mechanical properties of the resulting silica composite was demonstrated [15.272]. Interestingly, inspired by the synthetic polymer chemistry or biochemical systems, cross-linking of GO with poly(allylamine) or sodium borate, via epoxy and hydroxyl groups, has also been investigated [15.118, 273], and mechanical enhancement of the resulting GO film was observed in both cases. Unfortunately, these cross-linking strategies cannot stabilize GO in solvents, especially in water; unlike the case for polymers, cross-linked GO paper still breaks down when in contact with water, hence other chemical methodologies to tackle this problem are of interest to GO chemists.

Hydroxyl groups on GO can act as nucleophiles to attack ketones; For instance, 2-bromo-2-methylpropanoyl bromide was used to react with hydroxyl groups on GO to form an initiator for atom-transfer radical polymerization (ATRP), offering GO-poly-methyl methacrylate (GO-PMMA) as the final product (Fig. 15.16) [15.274].

It is also worthwhile to mention the covalent functionalization of RGOs with diazonium salts [15.54, 131, 275]. The aryl diazonium salt was believed to react with the sp^2 carbon domain in RGOs [15.276] to yield highly functionalized RGOs with superior dispersibility. Direct reaction of diazonium salts with GO was also reported by Gao [15.243], rendering thiophenol-functionalized GO with high mercuric ion adsorption capability. All the reactions mentioned above lead to strong covalent bonding between GO and the other chemical, and most of them happen with more than one functionality on GO, proving GO to be a very active compound.

Additionally, noncovalent functionalization of GO has also been demonstrated. Noncovalent interactions such as $\pi-\pi$ stacking, cation- π , or van der Waals interactions mainly happen on sp^2 carbon domains; For instance, a GO-based biosensor has been demonstrated utilizing GO-protein/DNA $\pi-\pi$ interactions [15.155]. Doxorubicin hydrochloride was also reported to form a hybrid with GO via noncovalent interactions [15.277].

15.3.2 An Anisotropic Proton Conductor

As we revisit the chemical structure of GO, we find that over half of the carbon atoms in GO are sp^3 hybridized, attached with oxygenated groups including hydroxyl, epoxy, and carboxyl moieties. These oxygen-containing functionalizations allow GO to be used as a unique sub-

strate for a hydrogen-bonding network on its surface, and lead to its hygroscopicity, just as in the very first polymer electrolyte, Nafion.

Protons in the H-bond network can hop from one to another, thus ionic conductivity was observed in GO [15.225]. It is not hard to understand that this ionic conductivity observed in GO is humidity dependent: as the humidity goes down, the conductivity also decreases. Also, the two-dimensional structure renders it anisotropic, since the proton hopping should be facilitated in the lateral direction rather than the vertical direction. Around two orders of magnitude difference in vertical and in-plane conductivity was observed. Taking advantage of this attribute, both sandwich and in-plane supercapacitor devices, employing GO as the solid electrolyte and RGO as electrodes, have been reported to be important complementary devices to the existing thin-film ultracapacitors [15.225].

Such ionic (protonic) conductivity was also noticed by Cao et al., and by incorporating only 5 wt % GO into a poly(ethylene oxide) matrix, they were able to develop a solid electrolyte membrane for low-temperature polymer fuel cells [15.278]. The authors attributed the observed ionic conductivity mainly to the carboxyl acid groups on GO edges, whereas we suggest that other oxygenated groups also play important roles. The composite film offered temperature-dependent conductivity from 0.089 S/cm at 25 °C to 0.134 S/cm at 60 °C and 100% relative humidity, leading to a maximum powder density of 53 mW/cm² without optimizing the catalyst layer composition.

Interestingly, a relevant application of *unreduced* GO as a hole transport layer, substituting PEDOT:PSS (poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate)) in polymer solar cells, has also been demonstrated [15.279, 280]. Li et al. claimed that the sp^2 domain hopping at the Fermi level does not contribute to the blocking of electron transport, and observed that the injection of holes into the valence band of GO is much more favorable [15.279]. Murray et al. also showed that GO is an effective replacement for PEDOT:PSS in organic photovoltaics, and that it enhances the device durability by 20 times in humid ambient condition [15.280].

15.3.3 Catalyst and an Electron Transparent Window

Due to its extraordinary hygroscopicity, GO has been demonstrated as a dehydrative polymerization catalyst [15.281]. During the polymerization process, GO

was substantially reduced by the thermal effect and further acted as a conductive carbon additive in the polymer matrix. The elastic modulus was increased from 40 to 320 MPa with only 0.1 wt % GO loading. GO has also been used as a catalyst in Friedel–Crafts addition of indoles to α,β -unsaturated ketones, with recyclable activity up to five cycles [15.282].

On the other hand, GO turns out to be transparent enough to photoelectrons (energy higher than 450 eV) that are captured and analyzed in XPS, Auger

electron spectroscopy (AES), and electron energy-loss spectroscopy (EELS), but not permeable to molecules [15.283]. Kolmakov et al. demonstrated the application of 100–1000 μm^2 GO sheets as transparent windows for an in situ environmental cell in XPS analysis. They obtained good-quality XPS data from aqueous solutions and nanoparticles deposited on the back side of GO films [15.283]. Krueger et al. also applied self-assembled GO for SEM environmental cell membranes [15.284].

15.4 Concluding Remarks

GO, a group of gigantic organic molecules first discovered over one and a half centuries ago, has reemerged as an important precursor to graphene since the last decade, yet now has written its own history independent of its relationship with graphene.

In this chapter, we summarize and discuss its synthesis, characterizations, structures, chemical activities, and physical features based on the fundamental understanding in chemistry and material science. The applications of GO and its derivatives have also been introduced and categorized. Starting from natural graphitic material, GO can be prepared in a large amount by strong chemical oxidation. Various characterizations have proved GO to be an oxidized carbon compound with two-dimensional structure, in other words a sheet of fused hexagonal rings with lots of oxygenated groups attached on both sides. The mixture of sp^2 and sp^3 carbon atoms in GO makes it corrugated, amphiphilic, and fluorescent, while the oxygen-containing functionalization renders it hygroscopic, dispersible, and chemically reactive. Its two-

dimensional nature leads to large-scale availability of atomically thin, transparent GO films, which can be further reduced to form transparent, conductive membranes. Wide applications extending into more than ten different categories have been demonstrated, and GO has become an important material in both fundamental science and contemporary technologies.

The salient features of GO have made it hard to identify its precise chemical structure. Although many researchers have tried to tailor its molecular structure using various chemicals, well-resolved control or manipulation of its sp^2/sp^3 domain, the location, density, and type of chemical functionalizations, and of course, the size, shape, and edge structure of GO itself remain far from realization. The development of better chemical processes to eliminate the oxygenated groups and to restore π conjugation is also of interest for technological applications. Water-stable cross-linking strategies would also be intriguing in terms of enhanced mechanical properties and wider technological applications.

Compound C

16. Compound Crystals

Roi Levi, Maya Bar-Sadan, Reshef Tenne

Graphite nanoparticles are known to be unstable due to the abundance of rim atoms with dangling bonds, closing into fullerenes and nanotubes under appropriate conditions. It was proposed in 1992 that this property is common also to nanoparticles of inorganic layered materials rather than being limited to carbon. Indeed, inorganic fullerene-like nanoparticles (IF) and inorganic nanotubes (INT) were produced initially from the layered materials WS_2 and MoS_2 , and subsequently from numerous other layered compounds. The state of the art in this field is described briefly in this review.

This chapter reviews the main methods used for IF and INT synthesis and discusses the relations between the different mechanisms and the resulting morphologies. Emphasis is placed on methods reported recently. The main differences between the morphologies are presented using WS_2 and MoS_2 as representatives of the inorganic IF/INT family. The measured properties of $W(Mo)S_2$ IF and INT are further examined and compared with theoretical calculations.

16.1 Nanostructures	605
16.2 Synthetic Methods	608
16.2.1 IF Synthesis	608
16.2.2 INT Synthesis	614
16.3 Physical Properties	618
16.3.1 Synthesis and Structural Properties	618
16.3.2 Mechanical Properties	622
16.3.3 Electronic and Optical Properties	625
16.3.4 Calculations and Simulations	627
16.4 Applications	628
16.4.1 Tribological Applications	629
16.4.2 Composites	629
16.4.3 Hydrogen and Lithium Adsorption/Desorption in INT	630
16.4.4 Miscellaneous	630
16.5 Conclusions	630
References	631

Finally, current applications of WS_2 and MoS_2 IF and INT are reviewed, highlighting recent advances in the fields of tribology and nanocomposite materials.

16.1 Nanostructures

Zero- and one-dimensional nanostructures such as nanoparticles, fullerenes, nanorods, nanobelts, nanowires, and nanotubes often possess unique properties with respect to the single-crystal bulk material. Thus, intensive attention is focused on their various applications in materials sciences and nanoscale devices, where commercial applications are being explored [16.1,2].

Nanostructures possess a relatively small number of atoms in their smallest dimension and exhibit an extremely high surface-to-volume ratio. Therefore, their properties may be significantly influenced by their

shape, interfaces, and structure down to the level of a single atom [16.3]; for example, the electrical properties of a particle may depend strongly on the interfaces between different phases or compositions inside the particle as well as the atomic configurations of the different areas [16.2]. Moreover, these configurations may yield new insights into the growth mechanisms of these nanoparticles [16.2]. Thus, deep understanding of the composition and structure at the atomic level is key to understanding the relations between the unique properties of nanomaterials when compared with the bulk phase [16.3].

Fig. 16.1 Schematic drawing of a nanotube roll-up vector $(n, m) = 1, 4$

Closed-cage structures, namely nanotubes and fullerenes, are an important subgroup of nanostructures. The discovery of carbon nanotubes [16.4] immediately brought to mind the question of whether nanotubular structures can be produced exclusively from carbon. The synthesis of noncarbon nanotubes based on molybdenum and tungsten disulfides in 1992 proved that hollow one-dimensional (1-D) nanostructures are not unique to carbon [16.5]. These hollow nanoparticles were termed inorganic nanotubes (INT) and inorganic fullerene-like (IF) nanoparticles. In contrast to carbon nanotubes (CNT) and fullerenes (e.g., C_{60}), these nanostructures are made of inorganic compounds with layered structure, and more recently from nonlayered compounds. Today, it is well established that numerous materials form closed-cage structures, and that carbon fullerenes and nanotubes are only a special case [16.6]. The last 20 years of research into nanomaterials have seen the discovery of nanotubulenes composed of dozens of inorganic compounds. Some of them were even found in rocks from Earth and space, as was the case with carbon nanostructures [16.7, 8].

Closed-cage structures are generally constructed from folded two-dimensional (2-D) layers. In analogy to graphite, nanoplatelets of many layered inorganic compounds are unstable towards folding and can form closed-cage structures, i.e., INT and IF [16.9]. The two most relevant interactions in 2-D (layered) compounds are the strong chemical (mostly covalent) bonds within the molecular sheet, and the weak van der Waals (vdW) interactions responsible for stacking the layers with the vdW gap between them.

A monolayer of a 2-D compound can be defined as a 2-D lattice which is constructed by the lengths of two translation vectors (a_1 and a_2) and the angle between them (φ); for example, the cylindrical surfaces of a CNT are composed of carbon atoms arranged in a hexagonal structure, which is essentially a rolled-up 2-D lattice of hexagonal graphene [16.10]. Similarly, many of the inorganic compounds which form tubular structures possess a hexagonal (trigonal) atomic arrangement within the layer. Furthermore, the structure of INT may be classified in the same manner as for CNT, i.e., as (n, m) . Using the basis vectors of the 2-D lattice (a_1, a_2), the roll-up vector is defined as $c = na_1 + ma_2$ (Fig. 16.1). For a 2-D hexagonal lattice ($|a_1| = |a_2| \equiv |a|$), the radius R of the corresponding tube is then given by $R = c/2\pi = a/2\pi \cdot \sqrt{3(n^2 + m^2 + mn)}$.

INT and IF differ significantly from many of the other zero-dimensional (0-D) and 1-D nanostructures (e.g., quantum dots and nanowires, respectively). Here, the surface and bulk atoms of the former experience an almost identical chemical and physical environment. Thus, the properties of many known 0-D and 1-D nanostructures are negatively affected by surface oxidation and reconstruction. Various examples include the luminescence of quantum dots, the magnetic behavior of spintronic devices, and the superconducting behavior of 1-D nanowires, all of which are overshadowed by surface effects. INT and IF are therefore relatively immune to these effects, since in general the chemical bonding of the surface atoms is the same as those situated in the inner layers [16.1].

An additional subgroup of nanostructures with hollow structures are those obtained from compounds with a three-dimensional (3-D) crystal lattice such as GaN [16.11], MgO [16.12], and spinel ($ZnAl_2O_4$) [16.13]. Another recent example is polycrystalline arrays of nanotubes from TiO_2 and similar materials via electrochemical anodization of Ti foils in fluoride and other acidic solutions [16.14, 15]. As these topics will not be covered here, the reader is referred to [16.16] for further information.

There has been a significant increase of scientific interest in INT and IF over the last decade. The first INT and IF synthesized belong to the transition-metal dichalcogenides (MX_2 , $M = W, Mo$). These were polyhedra and cylinders of WS_2 which were produced by heating thin tungsten (molybdenum) films in a reducing H_2S atmosphere [16.17]. Since then, multiple MX_2 chalcogenide nanostructures have been synthesized from a variety of materials such as $M = Mo$,

Fig. 16.2 (a) Schematic drawing of monoatomic graphite layers. (b) Schematic drawing of MoS₂ triatomic layers

Nb, Ta, Zr, Hf, and Re, and X = S, Se [16.18–24]. Various approaches to nanotubes of other materials, such as NiCl₂ [16.25], VS₂ [16.26], TiS₂ [16.27], and InS [16.28], have also been reported. Furthermore, **INT** of several materials such as binary oxides, nitrides, and halides, as well as metals and nonmetallic elemental materials, have been prepared and characterized [16.29–32]. In addition to the **INT** from binary compounds, **INT** of complex materials such as perovskite titanates have also been reported, as well as composites involving nanotubes, nanowires, and nanoparticles.

In contrast with **INT**, **IF** nanoparticles are known only for a few families of materials, such as WS₂ [16.5], MoS₂ [16.18, 33], TaS₂ [16.34], TiS₂ [16.35], **BN** [16.36, 37], TiO_x [16.38], Cs₂O [16.39], V₂O₅ [16.40], CdCl₂ [16.41], CdI₂ [16.42], and NiBr₂ [16.43]. All the above indicate that, under suitable conditions, many 2-D inorganic compounds may form **INT** or **IF**. Therefore, research in this area has focused on synthesis of new **INT** and **IF** materials and understanding their different properties. However, scaling up the synthetic process for semi-industrial applications has been achieved so far in a limited number of cases only.

Molybdenum and tungsten disulfides (MS₂, M = Mo, W) are typical representative compounds of the rather extensive family of layered binary and ternary metal chalcogenides. Typically, the lattice of metal disulfides consists of triple atomic layers (S–M–S) stacked in a hexagonal order. The metal atoms are sixfold coordinated and are hexagonally packed between two trigonal atomic layers of S atoms. Therefore, **INT** and **IF** possess a more complex structure when compared with **CNT** and C₆₀ (Fig. 16.2). Furthermore, nanotubes with the same radius formed from thicker 2-D monolayers experience larger internal strains and are thus less stable [16.44]; for example, the strain energies of single-walled **CNT** (**SW-CNT**) are lower when compared with the those of TiS₂ and GaSe tubes

formed with three and four atomic monolayers, respectively [16.45, 46]. To compensate for the larger strain, **INT** and **IF** accommodate a larger radius and also gain stability by forming multi-walled structures. Therefore, **INT** and **IF** are relatively more energetic than their organic counterparts, frequently resulting in a very challenging synthetic procedure to overcome these obstacles.

In recent years, **INT** and **IF** have been produced by various synthetic routes and experimental techniques, resulting in a large variety of nanostructured materials with different properties. Several routes to **INT** of Mo and W sulfides and selenides have been reported in the last decade [16.29, 30]. Among the synthetic routes used are electron beam irradiation in a transmission electron microscope (**TEM**) [16.47], electrical pulse in a scanning tunneling microscope (**SEM**) [16.48], sono-electrochemical bath reaction [16.17], and electrochemical deposition from ethylene glycol solution [16.49]. However, to date, only in the case of **INT** and **IF** of W(Mo)S₂ could production be scaled up to the pilot stage of several kg per day in the case of the **IF** and a few hundred grams of **INT**-WS₂. Currently, the most efficient methods for producing W(Mo)S₂ **INT** and **IF** are based on sulfurization of W(Mo)O_x nanoparticles (**NP**) in a fluidized bed reactor using a stream of H₂S gas [16.50, 51].

The present chapter reviews the main synthetic routes to obtain **INT** and **IF** with a focus on those of W(Mo)S₂ as model compounds for the layered chalcogenide family. The different mechanisms that affect the various morphologies of the final products will be discussed. Furthermore, these nanostructures will be examined in light of recent advances in calculations and theoretical modeling of the stability and properties of nanostructures. These well-studied materials allow for some generalizations relating the synthetic process with their emergent properties by ultimately understanding their structure.

16.2 Synthetic Methods

Following the first **INT** and **IF** nanostructures reported in 1992 by *Tenne et al.* [16.5], numerous synthetic routes have been utilized to produce these structures. The synthetic methodologies can be divided into two main categories: chemical and physical synthesis. The first includes synthetic routes in which a chemical reaction is applied. The second group consists of routes in which the starting material undergoes a structural change into a closed hollow nanostructure following an energy stroke.

16.2.1 IF Synthesis

The most common chemical synthetic methods rely on sulfurization of the appropriate metal oxide. Additional methods have been developed which rely on decomposition, rolling up of sheets, and crystallization of the appropriate amorphous metal sulfide. However, as the next sections will show, the morphology and exact composition of the precursor have a significant influence on the final shape, size, and structure of the products.

Formation of **IF** by chemical synthesis generally takes place by two different mechanisms: the first from the outside inwards, i.e., starting from the nanoparticle surface, and the second in the opposite direction, i.e., starting from a small nucleus and growing outwards to become a nanocrystal. The outside-in approach was the first method to be used in the production of large amounts of **IF**. Here, solid metal oxide nanoparticles are sulfurized to the appropriate metal sulfide nanoparticles with closed-cage structure (**IF**). Therefore, the rate of formation of the **IF NP** strongly depends on the diffusion rate of the sulfurizing agent within the nanoparticle lattice, while the

initial diameter of the precursor **NP** dictates the final **IF** size.

The syntheses of **IF-WS₂** and **IF-MoS₂** differ in some important details, but the main features are common to both. Within the first few seconds of the reaction, the outer surface of the oxide **NP** precursor reacts with the H₂S gas and a completely closed MS₂ layer, or two, are formed. This sulfide layer is an inert surface and protects the **NP** against aggregation, which would otherwise lead to the formation of the bulk 2H-MS₂ phase. Fast hydrogen diffusion into the **NP** reduces the oxide core to MoO_{3-x} or W₁₈O₄₉ within 1–2 min [16.53]. The oxide core is then converted to the respective sulfide (**IF**) through a slow diffusion-controlled reaction ending after ca. 30 min. Deep understanding of the outside-in growth mechanism for this synthesis (Fig. 16.3) for both **IF-WS₂** and **IF-MoS₂** made it possible to control the resulting product.

The final **IF** size is determined by the size of the precursor oxide **NP**. The produced **IF** possesses a hollow core (5–10 vol. %). This is due to the density difference between the oxide precursor and the sulfide product (5%), and the fact that the initial volume of the oxide **NP** is preserved during the chemical transformation. This means that, prior to the **IF-WS₂** synthesis, the precursor oxide **NP** of a desirable size and shape must be prepared.

The first two completely closed MS₂ layers serve a second purpose of protecting the metal oxide core from being completely reduced to the respective metal [16.18]. The driving forces for hydrogen propagation into the core of the oxide **NP** are the uniform hydrostatic pressure and the chemical reactivity of the

Fig. 16.3 Schematic depiction of the growth mechanism of **IF-WS₂**, using **WO₃ NP** as a precursor in a solid-phase reaction: (a) initial **WO₃ NP**; (b) partly reduced oxide (**W₂₀O₅₈**) **NP**, encapsulated with several (1–2) layers of tungsten disulfide; (c) the suboxide (**W₁₈O₄₉**) core within the envelope of a few (3–5) disulfide layers; (d) the final quasispherical closed-cage **IF-WS₂ NP** (after [16.52])

oxide core towards hydrogen. Thus, the hydrogen radial diffusion into the core of the NP is also uniform. However, if H₂S is not provided in sufficient amounts, the oxide core is rapidly reduced. Since the metal is appreciably denser than its oxide, subsequent diffusion and reaction of the sulfur atoms in the core is blocked, as the H₂S is unable to penetrate the dense core. Therefore, in the case of complete reduction of the oxide NP into the respective metal, sulfurization of the metallic NP is truncated after only two closed layers of MS₂ enfoldng the metallic core are formed [16.18].

The last stage of the reaction is controlled by the slow inward diffusion of sulfur or H₂S through the outer layers of MS₂ and outward diffusion of O or OH moieties from the core. The sulfurization of the reduced tungsten oxide core is a slow process, as the large sulfur atoms are unable to diffuse through the closed outer

layers. However, sporadically occurring defects in the curved WS₂ layers allow diffusion of the sulfur atoms inwards. The probability of this event is rather low, providing an upper limit on the rate of this process. Once hopping into an inner layer has occurred, fast diffusion of the sulfur atom in the van der Waals (vdW) gap between the layers follows until the sulfur atom encounters another defect in the inner MS₂ layer and another hop to the next gap occurs, and so on. Eventually, the diffusing sulfur atom reaches the lateral growth front of the innermost layer as it forms, allowing it to rapidly react with the suboxide core. This process results in a single growth front, which progresses inwards in a quasi-epitaxial fashion. This stage is thus controlled by the diffusion of sulfur to the single growth front and may take several hours depending on the NP precursor size and reaction temperature.

anism for the
formation of
INT and IF-
WS₂ from WCl_n
(after [16.57])

Preprepared oxide precursors allow a degree of control over the final IF size but require an additional synthetic step. This preparation step may be performed in situ as reported for IF-MoS₂ [16.55]. Here, the synthetic process consists of two additional steps: evaporation of MoO₃ powder at $T \geq 700^\circ\text{C}$ and reduction and condensation of the oxide vapor to give MoO_{3-x} NP in the gas phase. The parameters influencing the formation of the IF are the temperature, flow rates, and concentrations of gases (H₂ and H₂S). Furthermore, the reactor design has a large influence on the reaction products [16.55]. The size of the IF-MoS₂ particles produced in this study varied between 10 and 250 nm. However, in situ production of the precursor NP by random agglomeration in the gas phase may result in a nonsymmetric size distribution with respect to the average final size of the product, shifting it towards smaller sizes (left-skewed) [16.56]. Also interestingly, the shape of the IF-MoS₂ nanoparticles is not fully spherical but somewhat squashed. This could be associated with the shape of the in situ formed molybdenum suboxide nanoparticles and requires further investigation.

The outside-in process for IF-WS₂ NP was also shown to occur in the case of crystallization of an amorphous metal sulfide precursor [16.58]. This process is

initiated on the surface, resulting in the formation of WS₂ layers around the amorphous core and progressing inwards. Due to a larger density of crystalline WS₂, a hollow core is eventually formed. Here, the mass transfer is driven by a concentration gradient of WS₂ due to the compactization.

This mechanism was also shown to create giant IF-MoS₂ bubbles (Fig. 16.4) when an amorphous NP containing a mixture of MoS₂ : I₂ was used as the precursor [16.54]. The formation of the exceptionally large voids during the annealing was attributed to entrapment of iodine released by the thermal decomposition inside the NP. The simultaneous formation of patches of 2-D layers is enhanced by the isothermal chemical transport reaction of the iodine. Eventually, the increasing amounts of iodine being released inflate the NP due to rising internal vapor pressure until the NP ruptures. Subsequently, the IF-MoS₂ NP is formed by stitching the 2-D patches, thus healing the ruptured NP.

The sulfurizing reagent is commonly gaseous H₂S, which is hazardous, therefore complicating the process. Most of the alternatives to this problem involve in situ production of H₂S [16.59–61]. IF-WS₂ and MoS₂ have been synthesized using only solid precursors by reacting the metal oxide nanopowder, sulfur, and a hydrogen-releasing agent (NaBH₄ or LiAlH₄)

in a conventional furnace operated at 900 °C [16.59]. Another solid reagent used to release sulfur in situ is thiourea [16.60,61].

In contrast to the outside-in mechanism, the opposite mechanism, i.e., inside-out growth, is usually initiated by the formation of a small fragment of layers which serve as a nucleus and template for growth of additional layers (Fig. 16.5). Therefore, this mechanism is controlled by gas-phase diffusion rather than by a solid-phase diffusion process. Indeed, outside-in synthesis of **INT** and **IF** from oxide **NP** is a slow, diffusion-controlled process. Furthermore, it is limited to reactive oxides such as WO_3 and cannot be readily applied to obtain **IF-MS₂** **NP** from less reactive oxides such as TiO_x and NbO_x . To circumvent these inherent difficulties, a new strategy was developed using volatile metal halides or carbonyls as precursors [16.21]. These highly reactive compounds have high vapor pressure at low temperatures ($T < 300^\circ\text{C}$). Moreover, their vapor reacts promptly with H_2X ($\text{X} = \text{S}, \text{Se}, \text{Te}$) gas to produce **IF** nanoparticles.

The formation of **IF NP** from the reaction of volatile metal halides with H_2S is driven by nucleation and subsequent layer-by-layer growth of the small nucleus outwards [16.35,57,62,63]. While the growth process is diffusion controlled here as well, it is the diffusion of the reagents through the gas phase that dictates the overall growth rate, thus making it a faster process when compared with solid-state diffusion. This mechanism also allows for in situ **IF** doping, where the dopant is present in the gas phase, as opposed to ex situ doping, which is harder to carry out [16.64,65]. Furthermore, it has been indicated that the products of this reaction have the advantage of being much less agglomerated than those obtained from the oxide **NP** [16.57]. Interestingly, the growth of the **IF** is self-limiting (arrested growth) with the **NP** not growing beyond, say, 150 nm.

IF-NbS₂ [16.21] were the first **IF NP** to be synthesized via this mechanism, followed by a large number of nanostructures including **INT-TiS₂** [16.27], **IF-TiS₂** [16.35], **IF-WS₂** [16.66], and **IF-MoS₂** [16.63]. Unlike the outside-in mechanism, which influences the outer radius of the **IF** product, the small size of the incipient **NP** strongly influences the inner radius; for example, in the case of **IF-TiS₂** synthesis [16.35], only tiny hollow cores were obtained in the center of the **NP** (Fig. 16.6a). Furthermore, this reaction pathway was shown to result in **IF** with many layers with an almost perfectly spherical contour and relatively smooth curvature (Fig. 16.6b). In a similar approach, **IF-MoS₂** were produced using $\text{Mo}(\text{CO})_6$ and elemental sulfur or se-

Fig. 16.6 (a) **IF-TiS₂** and (b) **IF-WS₂** (after [16.62] and [16.57], respectively)

lenium as precursors in a metalorganic chemical vapor deposition (**MOCVD**) approach [16.67]. In conclusion, therefore, the inside-out mechanism may be applied to produce different chemical species by choosing the correct vapor-phase precursor.

Formation of **IF-WS₂** nanobuds was also shown to take place in locally confined conditions as reported in [16.68], where longitudinal surface corrugations act as diffusion paths for tungsten atoms feeding the growth of **WS₂** nanobuds on the **INT** surface (Fig. 16.7). The nanobuds are thought to nucleate in corrugations in the forming **INT** surface which create favorable regions for their growth. The nanobuds may then be described in the same terms used in the inside-out mechanism (Fig. 16.5). The main difference with **IF** is the asymmetric (planar) environment imposed on the incipient **NP**, which in the case of the nanobuds, are forced to

Fig. 16.7 **IF-WS₂** nanobuds (after [16.9])

Fig. 16.8 (a,b) View of the elemental trigonal prism of the 2H-MoS₂ lattice. Open circles: sulfur, closed circles: molybdenum. (c) 3-D drawing of a conical apex around a triangle joining three hexagons. (d) 3-D drawing of a conical apex around a rhombus joining four hexagons (after [16.5])

grow only in one direction, i. e., outwards from the INT surface, resulting in the bud-like appearance.

An additional mechanism which usually results in INT but occasionally results in IF is that of rolling up of 2-D sheets [16.70]. This is the result of the fact that rolling up of a 2-D sheet into a 0-D sphere (IF) as opposed to a 1-D cylinder (INT) entails folding along two directions as opposed to one direction in the latter case. Folding along two axes necessitates the introduction of defects with symmetry lower than six; such defects are rhombi (four-membered rings), triangles, or simply point defects (dislocation) with ill-

defined structure and chemical composition. In fact, scrolls and fullerene-like structures of 2-D materials were reported even before INT and IF were recognized as a universal phenomenon. Among the earliest cases were nanoscrolls of MoS₂ obtained by reacting MoCl₄ with LiS₂ in tetrahydrofuran (THF) solution which were annealed at 400 °C [16.71]. Additional reports include core-shell nanostructures of MoS₂ layers enfolding NiS NP [16.72, 73]. The roll-up process was also observed to occur during irradiation by a TEM electron beam [16.74].

This rolling-up mechanism was the first used by sulfurizing ultrathin WO₃ (MoO₃) films in a reducing atmosphere at $T = 850\text{ }^{\circ}\text{C}$ to produce INT and IF-WS₂ [16.5]. Various apex angles could be observed in these structures [16.5], some of which may be deduced by careful inspection of the structure of the MoS₂ layers. Figure 16.8 shows the original schematic visualization of an apex created by forming dislocations in the 2-D layer and subsequent folding and joining either three or four hexagons around a triangle or rhombus, respectively [16.5]. Surprisingly, this process was found to occur naturally. Samples containing substantial amount of amorphous W-S material (probably WS₃) kept in ambient conditions for several years gradually lost excess sulfur and spontaneously crystallized into small WS₂ hollow closed structures. Some of these nanostructures were shaped like a tetrahedron or octahedron [16.73, 75]. This indicated that IF-WS₂ are a genuine phase which is formed through a slow, diffusion-controlled process. It nucleates on the phase boundary between amorphous WS₃ and crystalline WS₂ in sulfur-deficient atmosphere.

Formation of IF-MoS₂ *nanopods* inside INT-MoS₂, i. e., so-called *Mama-tubes*, was reported during the sulfurization of Mo₆S₂I₈ nanowires (Fig. 16.9) [16.69]. They appear to originate from a rolling-up process of curved MoS₂ flakes. It was theorized that first a MoS₂

Fig. 16.9 (a) Overview of INT-MoS₂ *Mama tubes* with encapsulated IF-MoS₂; (b) single IF-MoS₂ inside a thin-walled INT-MoS₂ *Mama tube* (after [16.69])

envelope is formed on the surface of the $\text{Mo}_6\text{S}_2\text{I}_8$ and almost simultaneously the volume of the core is significantly decreased due to iodine release. The remaining material is then sulfurized further to form IF-MoS_2 by diffusion of molecules along the inner INT surface. The formation of these *flakes* may have been initiated by defects of the inner INT surface. The appearance of IF localizes the diffusion even more until the IF-MoS_2 nanopods are complete.

The physical synthesis methods rely on a rapid, high-energy stroke by means of a laser, arc discharge, etc. and in general do not involve a net chemical reaction. This drives the precursors and reaction medium very far from thermodynamic equilibrium, which enables sampling of local energetic minima which may be otherwise unattainable. These conditions may result in the formation of high-energy structures such as INT , IF , and even nanooctahedra, which will be elaborated upon later in this section. In fact, C_{60} was first produced by laser ablation of graphite [16.76], and arc discharge was the first method to be utilized in the production of large quantities of C_{60} and CNT [16.4]. Various physical methods have been used in the synthesis of nanostructures including laser ablation [16.25, 39, 77–80], arc discharge [16.81], resistive heating of graphite targets [16.82], and e-beam irradiation [16.37, 42, 83–85], as well as short electrical pulses from the tip of an STM [16.86]. Most of these methods entail the creation of a plasma or vapor phase in which the nanostructures are formed.

The main advantage of these high-energy experimental setups is their nonspecificity, i.e., their ability to accommodate many different precursor materials. Among them are BN [16.37], transition-metal sulfides (MoS_2 [16.87], SnS_2 [16.79], Hf_2S [16.88]), transition-metal halides (NiCl_2 [16.25, 80], NiBr_2 [16.43], CdI_2 [16.89], CdCl_2 [16.85]), transition-metal oxides (V_2O_5 [16.40]), and alkali-metal oxides (Cs_2O [16.39, 90]).

Fig. 16.10 TEM image of a MoS_2 nanooctahedron

Another important advantage of the physical routes is that the characteristic time and length scales are generally such that diffusion plays only a minor part. This situation leads to the formation of nanostructures which represent a local energetic minimum for a small number of atoms such as C_{60} and MoS_2 nanooctahedra. This is due to the local conditions consisting of a low concentration of atoms in a confined volume (a few nm wide) and large energy of the constituents, which allows adequate sampling of the energy landscape including the local minimum. The rapid nature of the physical routes confines the process in space and time as the energy is removed from the structure, preventing further coarsening of the nanoparticles. Thus, the physical techniques are unlike the chemical outside-in or inside-out mechanisms (Figs. 16.3 and 16.5, respectively) where the final IF dimensions are largely defined by the size of the precursor NP . Here, the formation of the small closed polyhedral structures by energetic techniques is distinctly different and is more conducive to the formation of nanooctahedra (Fig. 16.10) and smaller IF [16.39, 43, 55, 79, 80, 89, 91, 92].

The common characteristics of the physical mechanisms may be illustrated with the pulsed laser ablation

Fig. 16.11 Laser ablation setup

(PLA) process depicted in Fig. 16.11. Here, a pulsed laser beam hits a solid target, thereby ablating it. During the ablation process the incident light is absorbed by the electronic modes, leading to rupture of chemical bonds in the solid and surface evaporation of atomic and molecular moieties. Depending on the duration of the pulse and other parameters [16.92–94], this may be followed by a process of thermalization and conversion of the excess energy to vibrational excitations. Generally speaking, the thermalization process leads to evaporation of larger moieties from the solid surface than the short-lived electronic excitations. These processes can result in liquefaction, evaporation, ionization, and surface rupture due to pressure buildup of gases inside the solid.

An important phenomenon in PLA is the formation of a recoiling plume, which is largely attributed to the high pressure of the gases formed inside the cavities and subsequent surface rupture. The PLA processes generally occur on very short time scales of less than a few nanoseconds. The temperature of the plume may be in excess of 2000 °C [16.93, 95] in certain regions and consist of plasma, vapors, liquid droplets, and solid ejecta mixtures. This plume may also partially shield the target while being continuously irradiated by the incoming beam. This plume then undergoes rapid quenching ($> 10^9$ K/s) due to the large temperature gradient with respect to the plume environment. The temperature of this environment may be controlled by adding a furnace which anneals the products of the PLA process. The annealing process is intended to supply the gas-phase condensate with sufficient additional energy to form stable nanostructures.

The processes taking place in the physical synthesis techniques that result in the formation of IF and nanooctahedra are not yet well understood, as opposed to the chemical techniques. This is mainly due to the rapid nature of the processes, which do not allow for isolation of intermediates. In fact, despite the fact that C₆₀ was discovered more than 25 years ago, current understanding of its formation mechanism by either laser ablation or arc-discharge techniques is still rather limited [16.96–98]. Some indications were given by arc-discharge experiments with targets made of a mixture of ¹²C and ¹³C, which resulted in complete mixing of the isotopes in the C₆₀ fullerene product [16.99]. This indicates that the formation of C₆₀ in physical techniques is unlikely to take place by initial formation of 2-D graphene sheets followed by their direct folding into closed-cage structures. In contrast to the relatively simple carbon nanoclusters, the inorganic systems are much more

complex, with triatomic layers, the number of atoms in even the smallest inorganic nanostructure being orders of magnitude larger. Given this level of complexity, it is hardly surprising that the exact mechanisms of IF and INT formation in the physical techniques are still only partially understood at best [16.2].

A synthesis method which has been showing increasingly promising results in recent years is irradiation with concentrated sunlight, also known as solar ablation (SA) [16.90, 100, 101]. The solar ablation method incorporates aspects of both the chemical and the traditional physical synthesis approaches. Using this method, INT- and IF-MoS₂ have been produced, with some nanostructures achieving a fundamental minimum size as predicted by molecular structural theory [16.100]. These nanostructures are indicative of the high-temperature conditions inside the SA reactor, where small polyhedral shapes with a few layers imply hotter annealing that favors curling and closing due to defects.

The main advantage of solar ablation as opposed to laser ablation is that it encompasses a much larger active area [16.101]. However, the differences between PLA and SA are not clear cut. Relative to PLA systems, SA provides higher vapor pressure of reactants with peak reactor temperatures in excess of 2700 K [16.102]. Thermal radiation from the heated precursor powder provides a natural, extensive, and hot annealing environment. On the other hand, PLA systems drive the reaction volume much further from equilibrium due to the temporal confinement of the high-energy stroke. This suggests that a truly hybrid system incorporating laser/arc ablation and solar ablation on the same spot may reveal even more interesting structures.

16.2.2 INT Synthesis

Nanotubes are of great interest from both the scientific and application points of view, as manifested by the thousands of studies devoted to their synthesis, characterization, and applications. As mentioned previously, it was suggested [16.5] that the propensity of graphite to form polyhedral structures is not singular, and hence INT of WS₂ were indeed first observed [16.5]. Since then, a great variety of nanotubes of 2-D, and more recently 3-D, compounds have been reported. Among the 2-D compounds, transition-metal chalcogenide NT make up the largest group, including WS₂ [16.5] MoS₂ [16.33], NbS₂ [16.20], TaS₂ [16.20], HfS₂ [16.23], ZrS₂ [16.23], TiS₂ [16.23], and SnS₂ [16.79, 103]. BN nanotubes [16.104] were

Fig. 16.12a–c Schematic illustration of the growth process of the encapsulated sulfide/oxide nanowhisker in a horizontal reactor: **(a)** initialization of the sulfurization process of the asymmetric oxide nanoparticle; **(b)** growth of a long sulfide/oxide encapsulated nanowhisker; and **(c)** enlargement of the {001}R crystallographic shear planes exhibiting within one crystallographic shear plane regions of edge sharing octahedra (after [16.106])

reported as well as NiCl_2 nanotubes [16.25], which belong to the metal halide group, and VO_x -alkylamine composite NT [16.105] of the metal oxide group.

As in the case of IF synthesis, it is possible to divide the synthetic methods into chemical and physical approaches. While physical methods are much less likely to produce INT, the chemical synthesis methods may also be divided into the same categories used for the IF. Furthermore, the influence of the synthetic technique on the nanotube morphology will be demonstrated by discussing the various synthetic approaches for the formation of INT- WS_2 .

The growth of WS_2 nanotubes has advanced in four stages, and understanding of the growth mechanism has evolved accordingly. In the first stage [16.5], nanotubes were produced sporadically by reaction of H_2S gas with thin tungsten (or oxidized tungsten) film [16.5]. In the second stage, a methodological approach to nanotubes synthesis was undertaken [16.106–109]. Here, the asymmetric tungsten oxide rods (whiskers) were preprepared and fired in a horizontal oven in H_2S and forming gas atmosphere. The yield in this case approaches 100%, but the process is tedious and the typical amounts of the nanotubes were in the range of 50–200 mg. In the third stage, the small vertical fluidized bed reactor (FBR) was established [16.107]. Here, very thin (20–25 nm diameter) WS_2 nanotubes made of 4–10 layers were formed spontaneously and

very rapidly. In this case, the previous growth model of outside-in became irrelevant and a new model had to be invoked. The major drawback of this reaction was that, although the overall quantities of the nanoparticles were in the range of 20 g, the production yield of nanotubes never exceeded 5–10%. The remaining content of the product in these reactions was mostly IF- WS_2 nanoparticles and a few percent of WS_2 platelets. In the fourth stage, the larger FBR was erected and used for the synthesis of the nanotubes [16.51]. Here, the nanotube synthesis followed the path described in the second step, but now in a single reaction. This progress has led to large-scale synthesis for a variety of applications.

The conceived growth mechanisms of the nanotubes can now be recounted in an orderly fashion. The following mechanism has been proposed for the nanotubes produced in the second stage [16.106–109]. Similar to IF, one of the most common methods for INT synthesis involves an outside-in reaction (Fig. 16.3). Here, WO_{3-x} nanoparticles elongate under the reducing atmosphere (1% H_2 /99% N_2) to tungsten suboxide nanorods (nanowhiskers), which are subsequently converted to INT- WS_2 by sulfurizing the needle-like WO_{3-x} precursors [16.52, 106, 108, 109]. Thus, the reaction pathway involved a reduced tungsten oxide precursor with asymmetric unit cell. Depending on the synthesis conditions (total flow rate, flow rate of hydrogen, etc.), two kinds of morphologies were observed:

short nanotubes of approximately the same length as their precursors (50 nm) or long ones (several micrometers). Roughly 80–90% of the long nanotubes were *thin* (20–30 nm diameter), and the remainder were rather *thick* (ca. 100 nm diameter) [16.108].

While this conversion takes place in an outside-in mechanism similar to IF, an additional aspect is observed here for the *thin* INT, which are believed to grow in two steps (Fig. 16.12). In the rapid first step, three processes occur simultaneously: elongation of the needles' oxide tip, reduction, and sulfurization. As the sulfurization is unable to *catch up* with the elongation rate, the needles grow into whiskers similar to those formed by reducing tungsten oxide. During this step the tungsten oxide is amorphous and thus forms a cylinder in order to minimize the surface energy. When the whiskers reach a length of a few micrometers, the sulfurization closes the cap, thus forming the first few protective layers which serve a similar role to those in the IF formation. The process then proceeds to the second step in a similar manner to that of IF [16.92] and forms cylindrical INT.

On the other hand, when the oxide growth is sufficiently fast to prevent the sulfurization from transforming the nanowhisker into INT, the oxide characteristics dictate the final shape. Thus, the nanowhisker is reduced and crystallizes into a cuboid. The sulfurization may be sufficiently slow that the outer surface is not completely covered along the circumference, resulting in oxide thickening and subsequently forming nonregular cross-sections. Furthermore, it has been pointed out that the nanowhisker precursors may be fabricated in a separate step, although in this case the INT are far from perfectly cylindrical with their caps often open [16.109, 110]. This may be the mechanism responsible for the formation of rhombohedral INT-MoS₂ [16.61] obtained by the reaction of MoO₃ with thiourea, which serves as a sulfur source. This is supported by the presence of the oxide core observed in some of the INT.

A similar formation mechanism was used in a scaled-up production of INT-WS₂ (stage 4) reported by Zak et al. [16.51]. Here, however, the reaction was one pot; i.e., self-controlled temporal separation between the reduction/elongation step of the tungsten suboxide and the sulfurization step was achieved. The first step consisted of fast growth of long (tens of micrometers) suboxide (W₁₈O₄₉) nanowhiskers through oxide reduction, sublimation, and condensation, excluding the sulfurization process.

The starting material was shown to contain WO₃, W₂₅O₇₃ (WO_{2.92}), W₂₀O₅₈ (WO_{2.9}), and W₂₄O₆₈

(WO_{2.83}) nanoparticles. The elongated nanowhiskers were found to consist of the reduced nonvolatile W₁₈O₄₉ (WO_{2.72}) phase (Fig. 16.12). This phase consists of an ordered 2-D lattice of edge-sharing WO₆ octahedra forming a network of pentagonal columns (PC) interspersed with hexagonal channels (HC), which stabilize the highly asymmetric nanowhisker structure. This phase is known as the most stable reduced suboxide, indicating that a volatile oxide intermediate is likely involved in the rapid growth of the oxide nanowhisker. Thus, once the oxide is reduced to the nonvolatile phase, further growth of the nanowhiskers is inhibited and the sulfurization reaction is started.

In the second step, the sulfurization proceeds similarly to the reaction of IF [16.91, 109–111], where the oxide is gradually converted to the sulfide by an outside-in, diffusion-controlled reaction. The INT empty core is the result of the difference between the oxide and sulfide densities. The slower oxide to sulfide conversion in the case of the INT may be attributed to topological effects. The INT are folded along one axis, in contrast to IF, which fold along two axes and thus, in general, contain a higher defect density. As this density determines the rate of sulfur diffusion towards the core of the nanostructure, the rate of oxide to sulfide conversion is subsequently lower for the synthesis of INT.

An entirely different mechanism was invoked in the case of INT-WS₂ formed as a small fraction during the synthesis of IF-WS₂ from agglomerated tungsten oxide NP (step 3) [16.52] (Fig. 16.13). These INT were distinctly different from previously synthesized INT, being

Fig. 16.13a–f Schematic INT-WS₂ vapor–solid (VS) growth mechanism (third stage). (a) Starting oxide NP. (b) The volatile oxide phase encapsulated in the NP. (c) Breakthrough (dimple) of the volatile phase through the encapsulating surface. (d) Formation of the root of the WS₂ nanotube on the top surface of the WO_{3–x} nanoparticle. (e) Further growth of the nanotube: the volatile oxide that is emitted from the nanotube's hollow core. Reacting with H₂S it forms WS₂ at the tip of the tube. (f) Completed WS₂ nanotube (after [16.52])

Fig. 16.14 Schematic illustration of an inside-out mechanism for fabricating INT-WS₂ by thermal decomposition of (NH₄)₂WS₄ (after [16.112]).

perfectly cylindrical, crystalline, open ended, and slender (length $\approx 2\text{--}500\ \mu\text{m}$, diameter $\approx 15\text{--}20\ \text{nm}$), with the most distinctive feature being the thin walls (5–8 layers) and the large hollow core (up to 70 vol. %). These INT were typically found on the surface of the large agglomerates (20–100 μm in size) of IF-WS₂ and generally constituted 10% of the product. It was concluded that the specific conditions in the reactor induced the formation of a volatile phase inside the oxide NP. The pressure of this phase results in a cylindrical protrusion, which is subsequently sulfurized, forming an incipient INT which serves as a conduit for the release of the volatile phase. At the tip of the INT, the volatile tungsten oxide phase is sulfurized and the WS₂ molecules land on the tip of the INT, resulting in a continuous growth process of the INT. Once the tube has grown to a few micrometers in size, the fast spinning of the agglomerate can lead to its detachment from the NP agglomerate.

The fact that the INT-WS₂ were helical with a helicity angle preserved along the entire length of the nanotube lent credence to this mechanism. The chiral growth mode is energetically and kinetically favorable, because it provides a continuous growth front. In the case of nonhelical nanotubes, the growth process is interrupted each time a ring is completed and another ring must start to form. Since the growth process is continuous, the helicity angle is preserved during the growth.

The mechanism described above which entails the continuous growth of INT may be defined as a vapor–solid (VS) mechanism. It is similar to the well-known vapor–solid–liquid (VLS) mechanism which has been used extensively in the growth of nanowires and carbon nanotubes. However, to date, the VLS mechanism has been invoked only in the case of INT-NiCl₂ [16.80] and INT-SnS₂ [16.103]. The limited variety of INT grown via the VLS mechanism is most likely due to the stringent requirements of this process. For the VLS mechanism to be applicable, a eutectic point in the phase diagram of the catalyst and INT material [16.80] and a congruent melting point for these compounds are required.

The inside-out (nucleation and growth) mechanism is not encountered often in INT synthesis. Synthesis

of INT (in low yields) has been observed by reacting volatile metal halides with H₂S (or S vapors) [16.63]. Here, the incipient seed should roll up into a cylindrical morphology in order to serve as a template for incoming reactant molecules which end up in INT.

A similar mechanism is a hybrid between the inside-out mechanism and rolling up in which a single-walled INT-WS₂ rolls up and then serves as a seed for subsequent sheets rolling up around it. This mechanism is observed in the case of thermally decomposed (NH₄)₂WS₂. Here, the synthesis is based on a catalytic gas–solid mechanism [16.112]. The (NH₄)₂WS₂ particles were heated under a flow of H₂ and thiophene, which strongly catalyzes the transformation of (NH₄)₂WS₂ to WS₂ at low temperatures [16.113]. First, a single-walled INT-WS₂ is formed that serves as a template for subsequent WS₂ shells, which grow on top of the first one as shown schematically in Fig. 16.14. During the second step, the rolling up of the WS₂ sheets is induced by the escape of the NH₃ and H₂S vapors.

The rolling-up process is in fact common and may be induced by chemical methods such as heating up layered fragments [16.5] and asymmetric reduction [16.60] or physical methods such as electron beam irradiation [16.74]. As mentioned previously, rolling up forms INT more readily than it would IF, due to the nature of the defects that must be inserted in order to stabilize the structure.

A related mechanism is the solution-based use of structure-directing molecules, such as alkylamines. Here, hydrothermal reaction of the cationic (structure-directing) surfactant cetyl-triamine cation (CTA⁺) with dissolved WS₄[−] ions produces nanotubular structures. Upon further annealing the nanotubes lose the intercalated surfactant moieties and excess sulfur, converting into regular multi-walled WS₂ nanotubes [16.114]. This reduces the interlayer interactions at the edges during the heating process and supplies sufficient energy for the layers to start rolling up [16.92]. The rolling-up mechanism may also be responsible for the reduction of nanoribbons to nanotubes [16.60], where sulfidization of metal oxide sheets might result in compressive stress on the exposed side, thus inducing rolling of the nanoribbons into tubular structures or nanotubes.

INT-MoS₂ were also shown to be produced by physical methods such as solar ablation [16.100], albeit not in large quantities. Furthermore, some single-walled INT-MoS₂ with diameter of 7 nm and length of 60 nm were observed. The diameter of these INT conformed to the minimum diameter stability limit (6–7 nm) predicted for INT-MoS₂ [16.115, 116]. These results may suggest that the formation mechanism here is that of rolling induced by heating as opposed to the previous mechanisms which included a chemical component as well.

While the synthetic methods mentioned above were among the first to be used, the field of INT synthesis has grown explosively in recent years, with a large variety of inorganic compounds being synthesized by various methods. Among these, chemical vapor transport [16.9, 68, 69, 117–119] has been used for synthesis of nanotubes. This technique was used extensively in the past for growth of high-quality single crystals of layered metal dichalcogenide (MX₂) compounds.

Various methods of guided growth have been utilized, chief among them being the use of external

templates such as anodized alumina membranes (AAM) and templates fabricated by soft chemistry (*chimie douce*) methods [16.105, 120–123]; for example, synthesis of INT-MoS₂ nanotubes using a solid AAM template was reported [16.124]. Various metal oxide NT were synthesized via *chimie douce* processes, such as hydrothermal, sol–gel, intercalation-exfoliation, sonochemical reactions, etc. One extensively studied example, the composite VO_x-alkylamine NT, were used as a template for INT-VS₂ synthesis [16.26]. The outstanding feature of this study is that, so far, the layered bulk phase of VS₂ does not exist, thus showcasing the inherent stability of the nanotubular phases [16.26].

The examples above demonstrate that different synthetic routes may be employed to control the morphology of the various INT. Furthermore, the present discussion highlights the fact that understanding the mechanism and the reaction details during the synthesis is of utmost significance for controlling the morphology and properties of the resultant INT.

16.3 Physical Properties

Use of a synthetic method which allows placement of atoms at desired locations in the required morphology of the nanostructure is obviously intimately tied to the resulting properties. Thus, understanding the relationship between the synthetic method of choice and the characteristic structures produced is crucial to achieving the desirable functionality of the nanotubes. Although this is easier for the chemical methods than the physical ones, the current methods do not offer complete control over the resultant structures and, thus, their properties. Of further interest is the fact that INT can be synthesized free of defects, allowing quantitative comparisons with first-principle theoretical calculations.

This section will examine the known relationship between the different synthetic methods and the structural properties such as defect concentration and strain, and their effect on the physical properties of the IF/INT. This kind of study was lately made possible by the advent of a new generation of high-resolution/performance nanotools for the manipulation of single nanostructures. While a relatively large amount of work has been done lately on the mechanical properties of INT, the number of studies on the electronic, optical, and magnetic properties of such

nanotubes is rather limited as yet. Moreover, there are only a small number of reports linking the different synthetic methods with the resulting structures.

16.3.1 Synthesis and Structural Properties

To discuss the effects of a given synthetic method, it is useful to consider the characteristics of the three different polytypes found for the layered bulk of W(Mo)S₂, whose structure will be detailed later on. The most common polytype (2H) is stable in ambient conditions, the second (3R) is usually stable only above pressure of 4 GPa [16.125], and the third (1T) is generally unstable as a pristine material.

These phases may be used to probe the differences between the different synthetic methods; for example, it is believed that IF (INT) nanostructures which are produced by chemical synthesis routes are more thermodynamically stable compared with those synthesized by physical methods, which are more energy intensive and hence far from equilibrium. This assumption is supported by a recent report showing that the generally unstable phase (1T-MoS₂), i. e., trigonal symmetry with one layer as a repeat unit [16.101], is produced to some minor extent by solar ablation [16.101].

There are a few reports which indicate that the **INT/IF** nanostructures formed by the outside-in mechanism suffer from high internal stress. Contrarily, similar nanostructures produced by reactions involving the inside-out (nucleation and growth) synthetic methods seem to be mechanically more relaxed. One example is provided by the work of Remskar et al. on **IF-MoS₂ peapods** and the **IF-WS₂ nanobuds** mentioned in the previous section [16.68, 69]. The structure of the **IF-MoS₂ peapods** was determined to be 3R (high-pressure phase) as opposed to the **IF-WS₂ nanobuds** that exhibited the 2H structure. It should be noted that the structure was inferred from the electron diffraction as well as the number of initial layers formed. **IF-MoS₂ peapods** are obtained by firing Mo₆S₂I₈ nanowires in forming gas atmosphere. Release of iodine and rearrangement of the Mo–S bonds produces **IF-MoS₂ nanoparticles** in the cavity of the MoS₂ nanotubes. The formation mechanism of the closed-cage (polyhedral) **IF-MoS₂ NP** is characterized by rolling up of 2-D layers [16.69]. This process occurs in a confined environment (the cavity of the **INT**), in analogy to the outside-in mechanism for **IF NP**. These **IF-MoS₂ peapod** nanostructures are highly strained as reflected by their tendency to adopt the 3R polytype of MoS₂. In contrast, the **IF-WS₂ nanobuds** grow in an unconfined inside-out mechanism and exhibit the low-pressure phase of 2H composition.

However, the situation is much more complex due to the large kinetic differences in the two reactions. The outside-in method is characterized by an overall slow diffusion of the reactants to and from the growth front. A typical time for the full conversion of tungsten oxide nanoparticle into **IF-WS₂** is a few hours, in this growth mode. Also, the kinetics of the reaction is much faster at the leading edges of the layer, where atoms with unsaturated chemical bonds are present, relative to the formation of the next (inner) layer. Thus, complete single layers are formed and only then are the subsequent WS₂ layers initialized, resulting in a low number of defects in the layers. The inner layers have a smaller amount of freedom to shear with respect to each other and expand/contract according to the local stress. Furthermore, they are forced to accommodate curvature according to the contour of the top layer and are further limited by the inner oxide core [16.125]. The inside-out growth mode allows for more relaxed accretion of the layers in an unconfined environment. However, the very high growth rate leaves little time for relaxation of the nanostructures; for example, the reaction of TiCl₄ and H₂S to produce **IF-TiS₂ nanoparticles** may last a few

seconds only [16.62]. Dislocations which are trapped in the structure during the growth can nevertheless be annealed out afterwards.

In the inside-out growth mechanism, the seed may exert some measure of guidance on the subsequent layers. In contrast, the rolling-up method for the synthesis of **INT** [16.114] enables the formation of subsequent shells whose chirality may be unrelated to the previous ones.

Knowledge of the structure at the atomic level may also lead to a better understanding of the synthetic process. A remarkable example, made possible by high-resolution **TEM (HRTEM)** and high-angle annular dark-field (**HAADF**) **STEM** in conjunction with imaging simulation, is the consistent observation of a single chiral shell [16.2] in **INT-WS₂** produced by fast spontaneous reaction without WO_{3-x} nanowiskers as an intermediate phase. Previous studies could only detect chiral WS₂ nanotubes with chiral angle of $7 \pm 3^\circ$. With one exception, each of the measured tubes consisted of only one chiral shell while the other shells were achiral (zigzag or armchair) [16.107]. It was assumed that the growth of a chiral layer was energetically and kinetically favorable, because it provided a continuous growth front. Consequently, the chiral layer may serve as scaffolding for subsequent inner and outer armchair and/or zigzag layers to form [16.52, 107]. This insight also sheds light on the mechanical and electrical properties which will be detailed in the relevant sections.

When the chemical processes are close to equilibrium, the reaction time and temperature play an important role. In particular, longer annealing times and higher temperatures favor annealing of dislocations, resulting in more perfect structures. An additional role in the chemical processes is attributed to diffusion. The diffusion rates of reactants and reagents may play a decisive role in the final structure of the product; for example, the outward diffusion rate of the iodine used as a chemical transport agent from the interior of Mo_xS_yI_z nanowires determines the amount of iodine interstitials in the final product [16.17].

The physical methods are typified by highly energetic structures, which grow very fast and generally at low yields. Not surprisingly, therefore, these nanostructures incorporate point defects and dislocations, which are much less likely to occur close to equilibrium conditions. Notable in this regard are the square-like point defects which decorate the apexes of MoS₂ nanooctahedra [16.2, 126, 127] (Fig. 16.15). Deeper investigation of the laser ablation products has shown that imperfect structures of nanooctahedra – distorted octahedra and

Fig. 16.15a–e Atomic-resolution image of a MoS_2 nanooctahedron taken in an image-side aberration-corrected FEI Titan 80 300 (under negative Cs imaging conditions). Full structure (a). A magnified part of the tip of the octahedron revealing the sulfur atoms is shown in (b) and (d), with a superposition of the models presented in (c) and (e). The models in (c) and (e) correspond to 2 of the 15 hypothetical structures proposed for MoS_2 nanooctahedra in [16.127]. Mo atoms are displayed in red; S atoms are displayed in yellow. In (b), one of the most stable structures [16.127] coincides with (c), whereas the less stable structure depicted in (e) fails to match (in (d)) (after [16.2])

seashell structures with meander-like cross sections – are formed as well [16.128], as seen in Fig. 16.16. These structures appear to contain the square-like defects connecting two or more facets of different sizes. This may inhibit the facets from closing to form a perfect closed-cage structure, like nanooctahedra, and produce a scroll

structure, resembling a spiral seashell. In contrast to the symmetric and closed-cage structure of the MoS_2 nanooctahedra, the external edge of the scroll structure is capable of continuous growth.

As was pointed out in the previous section, the physical techniques such as laser ablation and arc

The pattern of diagonal lines indicates the 1T phase with MoS₆ octahedral coordination (after [16.101])

discharge are characterized by their operation in far-from-equilibrium conditions, i.e., high temperatures and short reaction times. Thus, it is often quite challenging to isolate the unstable intermediates and investigate the formation mechanisms of the products. Consequently, the exact reaction mechanism that leads to the formation of the nanooctahedra remains an open issue. While this aspect does pose problems in scaling up production using physical techniques, it is nevertheless useful in highlighting worthwhile goals for the chemical techniques. An example for this process is solar ablation [16.90], which allows production of larger amounts of nanostructures which are either scarce or totally absent otherwise.

As mentioned previously, the solar ablation technique is somewhat of a hybrid between the chemical and physical techniques. The relatively large diameter of the beam (1 mm²) produces substantially denser vaporized atoms than most laser ablation setups used for this purpose. Furthermore, the large and continuous irradiation field creates an extensive hot zone with temperatures in the range of a few thousand degrees Celsius. This annealing zone allows for thermalization and stabilization of the incipient nanoclusters. This thermalization is not available in the pulsed laser ablation setup. Obviously, such nanoclusters cannot be obtained by the pure chemical method, which uses substantially lower temperatures. One such product observed in solar ablation is single-walled INT-MoS₂ [16.100]. The hybrid

nature of the solar ablation process is exemplified in the recently reported hybrid nanooctahedra-IF-MoS₂ (NO-IF) shown in Fig. 16.17 [16.101]. These nanostructures likely start growing from the inside out in a growth mode typical for a nucleation and growth mechanism from the vapor phase. The size of the hollow core is determined by the maximum strain the nanooctahedra can accommodate, which correlates with their theoretical minimum size (\approx 3 nm) [16.126, 127]. Furthermore, the nanooctahedra may be formed initially and then serve as a nucleus for an outer IF shell formation in the extended annealing zone. Most importantly, aberration-corrected TEM revealed first-ever octahedral (1T) coordination of the MoS₂ layers embedded within nanoparticles (Fig. 16.17).

To understand the significance of this finding, it is necessary to study the structure of the three phases mentioned at the beginning of this section. The coordination of the sulfur atoms with respect to the tungsten atoms and the stacking of the layers give rise to three polytypes: a hexagonal polytype 2Hb with two molecular layers as a repeat unit (*P63/mmc*), a rhombohedral polytype 3R with three molecular layers per unit cell (*R3m*), which is stable in plane geometry at pressures above 4 GPa [16.125], and the less common trigonal polytype 1T with one molecular layer (Fig. 16.17c). It should be emphasized that full commensuration is not possible between the layers of the INT and/or IF. Therefore, the layers are slightly shifted with respect to each

other and the stacking cannot be accurately described as pure 2H, 3R, or 1T phase. As seen in Fig. 16.17, the S–M–S configurations produce a diagonal pattern for 1T and chevrons for 2H and 3R, being parallel and antiparallel, respectively. These alignments are observed in INT-WS₂ and IF-MoS₂. Due to the lack of complete commensuration between the layers, the stacking is better described as prismatic parallel, prismatic antiparallel, or octahedral diagonal. However, the terms 2H, 3R, and 1T will be used here in order to adhere to the terms used previously for bulk materials in the literature.

However, there is an ongoing debate in the literature on which phases are prevalent in INT and IF of MS₂. The techniques generally utilized in studying the structure, morphology, and defects of INT and IF are TEM, HRTEM, x-ray diffraction (XRD), and Raman spectroscopy. XRD line broadening is a standard technique to quantify the effective crystallite sizes by applying the Debye–Scherrer equation. Raman spectroscopy has been also applied to detect and quantify the morphological and structural properties as well as defects in IF and INT [16.49, 70, 129, 130].

As the 1T phase is metallic, incorporation of a single 1T layer might have dramatic effects on the mechanical and electronic properties of the whole particle due to inner metal–semiconductor junctions. Furthermore, the presence of the 1T phase in MoS₂ nanostructures was overlooked until recently. This fact could be attributed to the small number of layers arranged in this phase within the nanostructure. Another factor was the absence, until recent years, of a credible ultrahigh-resolution (aberration-corrected) TEM which could analyze such small domains in nanostructures. Obviously, the sensitivity of *bulk* techniques such as XRD and Raman was not sufficient to analyze such tiny domains. Another factor could be the unstable nature of the 1T phase, preventing the formation of multiple 1T shells.

Some generalities may also be drawn from recent reports on IF of 2-D materials with relatively high ionic character, such as CdCl₂, or NiBr₂. These allowed connections to be made between the properties of the layered bulk and the resulting nanostructures [16.40, 43, 90, 131]. It was suggested that highly ionic bonds, encountered in the 2-D metal dihalides, resulted in a faceted nanostructure and that the amount of commensuration between the layers is related to the shear modulus. Most importantly, it was suggested that the complexity of the unit cell influences the ability to seam facets and the overall stability of the nanostructure: if the lattice is not symmetric in both in-layer directions, there are more boundary conditions to satisfy in order

to produce a stable and seamless closed-cage structure [16.40].

These insights all point to one conclusion: The benefits arising from thorough understanding of the structure down to the atomic level, intimate knowledge of the synthetic mechanism, and most importantly, the interrelations between them allow for better selection of the desired properties. This is most evident in the amount of structural defects of IF and INT and their nature, which directly influence their mechanical, electrical, and optical properties.

16.3.2 Mechanical Properties

In analogy to the case of CNT, the mechanical properties of individual INT and IF have been shown to be superior to those of the bulk material. Unlike CNT, INT-WS₂ or MoS₂ do not undergo a pressure-induced phase change. In fact, under high pressure they eventually collapse, making INT and IF nanoparticles very robust under compression. While the Young's and shear moduli of CNT are appreciably higher than those of most INT, their application in ultrahigh-strength nanocomposites suffers from the pressure-induced transformation of the C–C bond into the sp³ (diamond) bond. The goal of these studies is to elucidate the structure–function relationship in INT and IF nanoparticles and eventually enhance the mechanical properties of various matrices.

While measurements of the mechanical properties of individual INT and IF nanostructures are very challenging, quite a few works have been reported on this subject in recent years. These studies will be reviewed briefly, and then the influence of the structure and defects on these properties will be examined too. It should be noted that this section focuses on the mechanical properties of single IF and INT. Nonetheless, the mechanical properties of composites will be briefly touched upon in the applications section.

The experimentally Young's modulus of INT-WS₂ agrees very well with the bulk WS₂ value [16.132]. However, in the case of the bulk material, the measurements were carried out in the *a*–*b* (basal) plane. In contrast, the mechanical properties of the bulk material along the *c*-axis are substantially inferior. They are influenced by the weakness of the van der Waals interactions and are further exacerbated by intercalation of impurities in the van der Waals galleries. The mechanical properties of individual INT and more recently of individual IF nanoparticles were systematically studied using high-resolution SEM, scanning probe microscopy (SPM) [16.132–134], and lately also TEM [16.135]. For

INT-WS₂ the Young's modulus (E) was found to be 150 GPa; the elongation to failure was 12%, and the tensile strength was 16 GPa ($\approx 11\%$ of E), as shown in Fig. 16.18. The latter value is significant, since it is much higher (for INT) than for bulk materials, whose values are commonly around 2–5% E [16.134].

These measurements are supported by first-principle calculations for zigzag (22,0) and armchair (14,14) single-walled INT-MoS₂, which are generally in agreement with the experimental findings [16.132]. The calculated Young's modulus was found to be in agreement with the bulk value (230 GPa) with elongation to failure and tensile strength of 17%, 40 GPa and 19%, 34 GPa, respectively. These values are equivalent to 17.4% and 14.7% of E . Both cases show good agreement between the experimentally observed and calculated values of the Young's modulus, as well as very high ratio of the tensile strength to the Young's modulus.

The anisotropic behavior of nanostructures under shear in different directions reflects the 2-D layered structure; i.e., the intralayer shear modulus is much higher than the interlayer shear (sliding) modulus. This was shown to be the case for INT-WS₂, where the interlayer shear modulus was measured by three-point bending as 2 GPa [16.133]. Recent measurements of the radial modulus gave similar results (3–6 GPa). This indicates that the interlayer shear may play a key role in the mechanical response to radial compression [16.136], similar to the importance of interlayer shear in the response of INT-WS₂ to torsion [16.137]. These values also concur relatively well with atomistic density-functional tight-binding calculations (DFTB) giving values of 4 and 12 GPa [16.133,136] for the shear and radial compression moduli, respectively. Considering MoS₂ as an example, similar values were found for the interlayer shear modulus of 2H-MoS₂ (15 GPa) by neutron and x-ray scattering of the linear compressibility [16.138]. These values are in contrast with the shear modulus obtained for a solid, filled beam which assumes an isotropic nature (57 GPa) [16.10]. They also contrast with the intralayer shear modulus calculated by DFTB for single-walled, armchair and zigzag INT-MoS₂ (53 and 82 GPa, respectively) [16.139]. This discussion once again highlights the anisotropy of INT properties.

It is significantly more challenging to measure the mechanical properties of single IF NP, sometimes simply due to technical issues. In addition, folding up the layers into the IF NP nested, closed-cage structure creates larger amounts of defects when compared

Fig. 16.18a–c Typical mechanical test of WS₂ nanotubes. Under tension before (a) and after (b) fracture. (c) Buckling under compression (after [16.134])

to INT. The elastic behavior and compression failure strength of individual IF-WS₂ (IF-MoS₂) nanoparticles were measured in situ with an AFM tip fixed inside a high-resolution scanning electron microscope (HRSEM) [16.140] as shown in Fig. 16.19. It was found that the compression failure strength of these nanoparticles is as high as 1–2.5 GPa. IF-MoS₂ nanoparticles were found to collapse only under 2.5–3.5 GPa. A similar in situ experiment was carried out in the TEM and was used to characterize the exfoliation of IF NP under shearing force [16.135].

The mechanical properties are directly related to the crystal structure, but are also strongly affected by structural imperfections or defects, which are the weakest

Fig. 16.19a–d Typical mechanical HRSEM images of the axial nanocompression test. (a) IF-WS₂; (b) AFM tip pressing the IF-WS₂; (c) compressive failure; (d) collapsed IF-WS₂. The arrows in (c) and (d) indicate the fragments (after [16.140])

link in the structure and first to fail. This is especially true in the case of INT-WS₂ and INT-MoS₂, which have been shown to have a very small amount of critical structural defects. This is evident from the narrow scattering of the experimental data [16.132, 134, 141]. It can therefore be concluded that the INT exhibit excellent mechanical characteristics that are commensurate with the calculated values [16.133, 134]. The lack of defects is further highlighted by the ratio of the tensile strength to the Young's modulus in INT-WS₂, which is 11%. This is an exceedingly high value in comparison with other high-strength materials [16.134]. This value is very close to the theoretical maximum emerging from the calculation for excessive distortion of a chemical bond [16.134].

As explained above, for a given diameter, INT and IF of layered materials are under higher strain compared with CNT due to the triple-layer structure [16.142]. It was also shown theoretically that line defects such as dislocations, and more extended defects such as grain boundaries and stacking faults, are intrinsic features of IF, once the thickness exceeds a certain number of layers [16.142]. The occasional formation of edges or apexes (Fig. 16.17) in IF releases some of the stress in a similar way to grain boundaries.

The effect of the morphology on the mechanical properties was observed in compression experiments of IF-MoS₂ [16.140]. It was found that the faceted nature of the IF-MoS₂ NP led to stress concentration under

uniaxial compression. Therefore, faceted IF can withstand lower loads and lower stiffness when compared with spherical, nonfaceted IF.

While the failure mechanisms of macroscopic objects are often attributed to dislocation diffusion and propagation of cracks along grain boundaries, the failure of INT under stress is in general the result of the excessive distortion of the chemical bonds. The ultimate strength and elongation of INT is believed to be limited by the breaking of a single chemical bond in the middle of the INT. This causes stress transfer to the adjacent chemical bonds, which become overstrained and consequently fail, resulting in almost instantaneous tear of the INT [16.134]. Furthermore, tensile tests of multi-walled INT-WS₂ in the TEM revealed a telescopic failure mode, supporting the idea that the strain is taken by the outermost layer of the INT [16.143].

The crystalline perfection, which is dictated by the synthetic method, strongly affects the mechanical properties of INT and IF. The likely origin of the INT-WS₂ failure mode [16.2] is supported by the good agreement between the experimental and calculated data for such nanotubes [16.134]. The correspondence of experimental and theoretical data is explained by atomic-resolution TEM study showing the outer shells of the nanotubes to be mostly achiral (armchair or zigzag) [16.2]. Due to limited computation resources and complexity, calculations are generally carried out on achiral INT. The good correlation between the theo-

retical and experimental results may be attributed to the outermost shell taking up most of the strain, which is in most cases an achiral one and defect free.

In fact, the tensile failure mode of the **INT** can vary quite dramatically between chiral and achiral **INT**. In chiral tubes, the failure mode of the tube does not require the immediate failure of a chemical bond. Instead, it may involve a mechanism whereby the pitch is elongated under tensile strain with the collapse of the hollow core of the **INT**. This failure mode is analogous to the lengthening mode of a spring under tensile stress [16.2]. Indeed, the failure mode of **INT-WS₂** strongly suggests that the chemical bonds are broken at once with seemingly little variation in the tube diameter [16.134], supporting the conclusion that the outermost layer of the nanotube is indeed achiral. This shows once more the intimate relationship between the structure and functionality of the nanotubes.

16.3.3 Electronic and Optical Properties

Controllable electronic properties are of great importance for fabrication of nanoscale devices and multifunctional materials. In comparison with the substantial work done on the mechanical properties of **INT** and **IF**, the number of experimental studies on the electronic, optical, and magnetic properties of such **INT** and **IF** is still very small. Moreover, many of the measurements were performed on large amounts of nanoparticles, with only a few studies dedicated to the study of individual nanotubes. The absence of such data does not reflect a lack of interest in this field, but rather the great difficulties in fabricating such devices in a reproducible fashion. One such problem that plagues electronic properties on the nanoscale in general is that of contacting the nanostructure in question. In particular, the issue of contacting **CNT** still involves a large amount of ongoing research with a focus on matching the contact material workfunction with that of the measured material [16.144], as well as matching the Fermi surface in order to reduce electron scattering at the interface [16.145].

The physical properties of inorganic nanostructures are variable and largely depend on the properties of the bulk compound from which they are derived; for example, **INT-MoS₂** [16.116] are semiconductors, while **INT-NbSe₂** [16.146] are low-temperature superconductors. However, in contrast to compact semiconductor nanoparticles and nanorods, which exhibit a blue-shift of the band gap due to the quantum size effect [16.109], the band gap of **INT** and **IF** undergoes

a red-shift with decreasing size [16.147], probably due to strain.

This opposite effect is attributed to the more complex nature of **2-D** layered compounds. Unlike **CNT**, the inorganic nanotube band structure cannot be estimated from a simple zone-folding scheme of the corresponding band structure of the bulk material. The rolled inorganic **2-D** layer undergoes a significant structural relaxation. The innermost atomic layer of sulfur undergoes compression, while the outermost one is under tension. This results in a less than perfect hybridization of the atomic orbitals. Thus, the valence band of **INT-W(Mo)S₂** is composed of three bands, i. e., quasi-core sulfur 3s-states, hybridized S3p-Mo4d(W5d)-states, and Mo4d(W5d)-states. The lower edge of the conduction band is composed of metal d-states [16.44].

The semiconducting character of **INT** and **IF NP** was also confirmed by optical measurements of the UV-Vis spectrum of **IF-W(Mo)S₂**, which are in agreement with the theoretical calculations [16.116,148]. The excitonic absorption agrees with the semiconducting nature of the material [16.149]. A clear red-shift in the exciton energy, which increased with the number of the closed layers in the **IF** nanoparticles, was observed. The fact that the temperature dependence of the exciton energy was similar to that of the exciton in the bulk indicated that the red-shift cannot be attributed to defects or dislocations in the **IF** material, and is a genuine property of **INT** and **IF**. Thus, the red-shift of the exciton energy in the absorption measurements was attributed to the strain in the bent layers [16.149].

Another aspect in which **INT-W(Mo)S₂** nanostructure differs significantly from **CNT** is that the former were found to be semiconductors irrespective of their chirality as shown by **DFTB** calculations [16.116,148]. However, while armchair **INT-MoS₂** were found to exhibit an indirect ($\Delta-\Gamma$) electronic transition, the zigzag **INT** possess a direct ($\Gamma-\Gamma$) transition. This observation suggests a possible luminescence of zigzag **INT-MoS₂** following optical or electrical excitation [16.150]. Furthermore, recent results for **INT-MoS₂** indicate that a high density of defects in the nanostructure may result in a metallic behavior [16.9]. Thus, the band gap of semiconducting **INT** and **IF** may be tuned, using the whole spectrum all the way from the **UV** down to the infrared, by varying the diameter of the nanotubes and also the number of layers.

An important correlation between the Raman spectra and the structure of **INT** has recently been reported [16.130]. The optical properties of **INT** and **IF-W(Mo)S₂** have been studied in detail by resonance

Raman spectroscopy in a number of studies over the last decade [16.49, 70, 129, 130, 151, 152]. The strongest peaks at 417 and 351 cm^{-1} of IF-MoS₂ correspond to the A_{1g} and E_{2g} modes, respectively. The intensity of the low-energy component of the A_{1g} mode range is enhanced in INT and IF, creating a mode labeled D-A_{1g}. It was found that the ratio of intensities between the D-A_{1g} mode and the A_{1g} mode correlates with the amount of disorder in the nanostructure. Thus, this ratio increases with decreasing diameter of the nanotube, most likely due to increased strain and larger amount of defects. Furthermore, this ratio is larger for IF than INT [16.130], which further illustrates the larger number of defects in a 2-D layer folded into a quasispherical structure as opposed to a cylinder.

The polarizability of INT-WS₂ further demonstrates the anisotropic character of the nanotube [16.151]. Raman spectroscopy measurements showed that the A_{1g} and E_{2g} modes have the same polarization behavior with a strong signal along the tube axis (ZZ) only and almost none for light polarized perpendicular to the tube axis (X-polarized light). Similar polarization effects were observed for incident and scattered light. The ratio of the perpendicular to parallel polarizabilities ($\alpha_{XX}/\alpha_{ZZ} = 0.16$) is estimated from the orientation dependence of the INT resonant Raman intensity, demonstrating the strong polarization along the INT axis. It was concluded that this effect arises both from the anisotropy due to the 2-D layered structure, as well as from the antenna effect caused by the large aspect ratio of the tubular morphology.

The Raman spectra of agglomerated INT-WS₂ nanotubes were measured under hydrostatic pressure. The two main Raman modes shift linearly to higher energies with normalized pressure coefficients of $\omega_0^{-1} d\omega/dp \approx 4.5 \text{ TPa}^{-1}$. The two-dimensional (in-plane) Grüneisen parameter value of INT-WS₂ nanotubes is 0.45, as compared with the value of 2 for CNT, which shows the softness of the INT-WS₂.

In contrast to the semiconducting IF and INT, the calculated electronic properties of MoS₂ nanooctahedra were found to be radically different from those of the bulk solid [16.126]. These properties were elucidated theoretically by density-functional tight-binding calculations (DFTB) accompanied with molecular dynamics (MD) annealing. Irrespective of their size and exact stoichiometry, all hollow octahedral molybdenum sulfide fullerenes exhibit a practically vanishing band gap between the highest occupied molecular orbital (HOMO) and the lowest occupied molecular orbital (LUMO), which are mainly of Mo 4d character. Thus, these cal-

culations suggest that the nanooctahedra should exhibit a metallic-like character. According to the DFTB-MD calculations, the occurrence of metallic-like d-band conductivity correlates sensitively with the square-like defects at the apexes and the seams between the triangular facets [16.2]. Experimental verification of these calculations is rather challenging due to the difficulties in isolation of the nanooctahedra and subsequent measurement of such small (3–7 nm) objects.

The influence of the nanooctahedra morphology on its electronic structure was studied by calculating the density of states (DOS) for particular cases of distorted nanooctahedron (MoS₂)₃₈₉, symmetric nanooctahedron (MoS₂)₄₀₀, and nanoseashell (MoS₂)₄₀₈, with roughly the same size [16.128] (see Figs. 16.15 and 16.16 for models of the nanooctahedra and nanoseashells). The calculations of all three nanostructures gave similar results and were characterized by a metal-like character of the DOS, independent of the exact morphology of the particles. The HOMO–LUMO gap did not exceed 0.01 eV, with the states around the HOMO–LUMO gap dominated by Mo 4d states. Thus, distorted nanooctahedra and nanoseashells demonstrate similar features of their electronic structure to the symmetric nanooctahedra, with the metallic character attributed to the square-like defects at the apexes and the seams.

The transport properties of WS₂ nanotubes are rather disappointing at this time. It is difficult to explain the dichotomy between the very good mechanical behavior of INT and their poor transport properties. Nonetheless, the low conductivity of INT with respect to the bulk material [16.153] may be attributed to the growth of achiral shells within and on top of the chiral shell [16.2], resulting in different electron mobility in each shell. This may further result in the formation of scattering centers that negatively affect the overall INT conductivity.

The electronic properties of INT and IF may be modified further by intercalation or doping, which is thus a subject of current interest. The large van der Waals gap typical of layered metal dichalcogenides renders them good host matrices for intercalation. Therefore, their electronic properties may also be modified not only by defects and substitutional dopant atoms, but also by the introduction of various impurities into the cavities between the layers [16.44, 65, 154].

Doping of INT and IF may pave the way for their application in semiconducting nanoelectronic devices or as a conductive phase in nanocomposites, thus offering numerous potential applications; for example, the INT-MoS₂ saturated surfaces are much more resistant

towards oxidation and humidity when compared with silicon or other semiconductors of groups IV, III–V, and II–VI while possessing a similar band gap to that of silicon (0.89–1.07 versus 1.17 eV, respectively) [16.155]. Therefore, there is great interest in n- or p-type doping of INT and IF by substitutional dopants such as Re and Nb, respectively [16.64, 155].

Another advantage that substitutional doping has over intercalations is that, unlike intercalated atoms, dopants are assumed to be less mobile under applied potential, pH, etc., and thus much effort has been put into synthesis of doped INT and IF. Doped INT have been reported for specific cases, such as Ti-doped INT-MoS₂, Nb-doped INT-WS₂, and Mo- and C-doped INT-WS₂ [16.156–159]. This is in addition to alloying in the case of INT-(W/Mo)S₂ [16.160]. Doping of IF has also been reported for Nb-doped IF-MoS₂ [16.21], Re-doped IF-MoS₂ [16.155], and recently for alloyed IF-(W/Mo)S₂ [16.161].

Incorporation of substitutional dopants in nanostructures is relatively easier in gas-phase synthesis, which allows for easy incorporation of dopant atoms in the lattice achieved by thorough mixing of the constituent atoms. This has been demonstrated for Nb- and Re-doped IF-MoS₂ [16.64, 155], which were synthesized by the inside-out (nucleation and growth) method from volatile metal chloride precursors. However, doping of the foreign atoms with 5% Re and 30% Nb resulted in segregation of secondary phases and nonuniformity of the sample. The driving force for this segregation is the large differences in crystal structure of MoS₂ (2H or 3R) as opposed to the ReS₂ structure (distorted C6) [16.162].

The electronic properties of Nb-doped INT-MoS₂ were investigated theoretically using the density-functional tight-binding method (DFTB) [16.163, 164]. The doping resulted in metallic behavior which correlates with the experimental results for Nb-doped IF-MoS₂ [16.64]. This work predicted that INT-Mo_{1-x}Nb_xS₂ should exhibit a metallic character, irrespective of their chirality, diameter, and ordering type of dopant atoms after a certain Nb threshold level is surpassed. Thus, the density of states close to the Fermi level of Nb-doped INT-MoS₂ may be tuned over a wide range by the degree of Nb doping.

Another area, where progress is slow and much further work is needed, is the coupling between the mechanical and electrical, thermal, or optical effects in a single nanotube or fullerene. In this respect, there is some promise in recent advancements in TEM, SEM, Raman, and optical in situ measurements of coupled

properties such as the optoelectronic or electromechanical properties of nanostructures.

16.3.4 Calculations and Simulations

Quantum-chemical calculations using density-functional approaches in conjunction with molecular dynamics (MD) are extremely important for predicting the stable structures and their physiochemical characteristics. The unit cells of inorganic nanotubes contain considerably more atoms than carbon nanotubes. Moreover, the atoms involved are usually heavier and contain many more electrons, increasing the computational resources needed for calculations of inorganic nanotubes significantly. Thus, an accommodation widely utilized is simulations of smaller structures with subsequent use of semi-empirical models to extrapolate to larger structures. These extrapolations are then compared with the measured values, if available.

In addition to these general considerations, atomistic simulations of the structure and stability for a series of existing and hypothetical inorganic nanotubes have been carried out. An overview on theoretical investigations of INT and IF is presented in [16.44, 165], respectively. These calculations were performed with empirical force fields, semi-empirical quantum-mechanical methods, and particularly with density-functional-based methods (DF), mainly using pseudopotentials and plane-wave (PW) basis expansions or within a tight-binding approach (DFTB). The calculations for INT are usually more straightforward compared with IF as their structure is more perfect and allows for the use of periodic boundary conditions along the tube direction. Therefore, a narrow ring may represent the structure for the calculations of, e.g., zigzag nanotubes. This is opposed to IF, which invariably necessitate construction of full structures with thousands of atoms, containing edges and defects. These defects may vary greatly between individual IF and may even render the simulations inaccurate. In general INT with a simple roll-up vector, such as armchair or zigzag, are easier to handle with ab initio calculations. Chiral nanotubes with large pitch have larger unit cell and cannot be easily calculated using accurate quantum-chemical methods. Thus, a few studies which use line-group symmetries have also been published [16.166], allowing for analysis of rather large tubes of various chiralities.

The first quantum-mechanical calculations of metal sulfide nanotubes were performed by DFTB for INT-MoS₂ and WS₂ nanotubes [16.116, 167]. As anticipated, the strain energy is clearly larger than that of CNT

due to the triple atomic layer structure of the former. Moreover, the strain energy of the INT is inversely proportional to the radius squared of the nanotube. Thus, the nanotube becomes less stable than the corresponding strip below diameter of 6 nm. This is consistent with the experimental finding that the smallest observed (inner) diameter of INT-W(Mo)S₂ is around 6–7 nm. Moreover, the interlayer van der Waals interactions in the strips and INT contribute to stabilization of nanotubes of larger inner diameters. This may account for the difficulties in the synthesis of single-walled INT-W(Mo)S₂ [16.115].

Recent simulations of INT-MoS₂ under radial mechanical compressive deformation revealed several remarkable trends [16.168]. As expected, the strain–stress correlation slope is steeper for smaller nanotubes, i. e., nanotubes with smaller diameter are stiffer, which nicely correlates with the reduced stability of INT with decreasing diameter [16.115, 116]. Furthermore, the strain–stress relation is essentially independent of the tube’s chirality, as the slope (normalized by the INT diameter) is nearly identical for different chiralities [16.168]. Another trend is that, in contrast to tensile strain–stress curves, the radial compression deviates from linearity toward higher stress values; i. e., the more the system is deformed, the harder it is to deform them further.

The calculations show that nanotubes with small diameter possess lower strength. This implies that the innermost shell determines the failure point of the multi-walled INT as they break from the inside out. When loaded, the innermost tube wall is under the highest strain energy, and it bursts and unbends. Subsequently, the strain is transferred to the next largest tube, which collapses beyond a given strain as well, and so forth. These calculations indicate that it might be possible to tune the mechanical properties of INT-MoS₂ by controlling the structural properties of the innermost shell [16.168].

The quantum chemical calculations of nanooctahedra represent the upper limit of full DFTB exact calculations. This allowed a comparison between detailed

investigations of synthesized nanooctahedra by electron microscopy and the calculated structures [16.126]. Full quantum-mechanical calculations for IF-MoS₂ NP consisting of several thousand atoms are beyond the limit of presently available technology. A phenomenological model for the energetics and stability of the nanoparticles was therefore developed. This model circumnavigated the computational obstacles in the full quantum-mechanical calculations of such large nanoclusters. Furthermore, by using several approximations, the calculations were extended to larger multi-walled IF-MoS₂. This development enabled a comparison between the calculated phase diagram of hollow MoS₂ nanoparticles with the experimentally observed structures. The validity of the model and the approximations was supported by the good agreement between the calculated results and the published experimental data [16.5, 18, 87]. Thus, the stability of nanooctahedra increases proportionally with the number of layers, while single-walled MoS₂ nanooctahedra were found to be less stable than nanoplatelets over the whole size range. Furthermore, the calculations show that multi-walled octahedral MoS₂ fullerenes with more than 10⁴ atoms are more stable than the corresponding nanoplatelets. This exemplifies the general underlying principle of fullerene formation of forming the structure with the lowest energy possible.

Knowledge of the structure at the atomic level is also needed for interpreting high-resolution electron microscopy data. The calculated lattice is then used to calculate the exit wave for comparison with HRTEM results. Therefore, it is easily seen that modeling and simulation is crucial to thorough investigation of the structure. Ultimately, modeling and simulation is a very powerful tool for elucidation of the structure and properties at the nanolevel. Moreover, its predictive power has been illustrated in a number of important cases, such as the transition from nanooctahedra to quasispherical (IF) MoS₂ nanoparticles. Here, the theoretical calculations predicted that such transitions would occur when the size of the nanocluster exceeds about 10⁵ atoms, which was confirmed experimentally [16.101].

16.4 Applications

The extensive advancements in the synthesis and structural elucidation of these nanostructures has been paralleled by the major progress achieved in scaling up the production and applications of W(Mo)S₂ IF and INT. One such example is the commercial engine oil

NanoLub utilizing the superior tribological behavior of IF. The large number of potential applications in the fields of lubrication, high-performance nanocomposites, energy storage, as well as others is briefly reviewed in this section.

16.4.1 Tribological Applications

MoS₂ has been used as a solid lubricant or as an additive in oil or grease for more than 60 years. The weak interlayer interactions (van der Waals forces) between the 2-D layers results in a low interlayer shear modulus which allows for easy shearing in a vacuum environment. However, the application of MoS₂ platelets in tribological applications is limited to oxygen- or moisture-free atmosphere. In the presence of such vapors, tribologically induced reactions with the rim atoms of the platelets lead to fast deterioration of the solid lubricant. Therefore, it was assumed that the IF and INT stability in lubricating conditions would be enhanced with respect to platelets due to their closed-cage structure which exposes only the vdW surfaces and (almost) no dangling bonds. Moreover, it was hypothesized that spherical IF-MS₂ would behave like nano ball-bearings, giving rise to rolling and thus providing superior solid lubrication over the platelets. Further work suggested that, under mechanical stress, the IF would slowly deform and exfoliate, transferring MS₂ nanosheets onto the underlying surfaces (third-body effect). These sheet fragments coating the moving surfaces asperities provide effective lubrication until they are completely gone, or oxidize. Finally, the IF NP have been proposed as environmentally friendly lubricant additives as alternatives to the classical phosphorus- and/or sulfur-based lubricants due to their small sizes and morphology [16.161].

The beneficial tribological effects of IF powder additives in lubricants have been studied in quite some detail, as summarized in [16.169–171]. Work in progress indicates that this effect is particularly important when the clearance (gap) between the two mating surfaces and the surface roughness are approximately of the same order of magnitude as the nanoparticles themselves, i. e., 30–300 nm. Additionally, IF aggregation was found to be an important parameter in these applications [16.172]. Thus, there is great interest in preventing aggregation and mass production of nonagglomerated IF.

Recent years have seen an increase in the attention given to self-lubricating coatings, which have numerous potential applications in machining, aerospace, sport, medical, and various other industries. Unlike fluid lubricants, IF embedded in a coating cannot lubricate by acting as ball-bearings unless a gradual release from the coating is invoked. Thus, under heavy load/shear conditions, the IF NP are gradually exfoliated, trans-

ferring nanosheets onto the moving mating surfaces, which provide the lubrication and a reduction in the friction coefficient within a few run-in cycles. Another advantage of the IF is that they inhibit oxidation of the metal surface dramatically, thereby preventing decomposition of the brittle oxide and scratching of the metal surface. Recent work showed improved performance of orthodontic implements and endodontic files coated with such self-lubricating films [16.173, 174]. Moreover, toxicological tests indicated that the product is benign [16.175, 176], though further work is needed to confirm this important point. Finally, such coatings may be highly suitable for harsh environments such as outer space, where regular lubricants would either freeze or boil, or deep-sea thermal vents, where lubricants have to withstand high compressive pressures and high temperatures.

16.4.2 Composites

The mechanical properties of INT and IF indicate an abundance of applications in composite materials such as the shielding of vehicles or as additives in high-strength construction materials. Among these promising properties are the mechanical robustness of INT- and IF-W(Mo)S₂ [16.132–134], high-pressure resilience to degradation under hydrostatic pressures of up to 20 GPa [16.177], and the ability to withstand shockwaves of up to 30 GPa with local temperatures rising up to 1000 °C [16.178]. These works led to a surge of interest in fabricating nanocomposites with enhanced mechanical properties incorporating INT- and IF-W(Mo)S₂.

The aforementioned findings stimulated numerous studies which were devoted to the study of nanocomposites of INT and IF embedded in polymer matrices. Thus, *Naffakh* et al. [16.179] found that addition of small amounts of IF to isotactic polypropylene (iPP) increased the thermal stability of the polymer with a remarkable effect on the polymer's crystallization rate. The increased rate of crystallization of polymer matrices by IF nanoparticles was found to be common to a variety of other polymer matrices such as Nylon 6 [16.180]. Furthermore, the storage moduli of IF-iPP nanocomposites were appreciably higher than those of pristine iPP. Recent work on IF and INT embedded in epoxy resin demonstrated a substantial increase in their mechanical properties, including shear strength and moduli, as well as peel strength and fracture toughness [16.181, 182].

16.4.3 Hydrogen and Lithium Adsorption/Desorption in INT

As mentioned above, layered dichalcogenides are good host matrices for intercalation due to their large van der Waals gap. Thus, INT are attractive substrates for hydrogen and lithium intercalation storage in energy applications; for example, adsorption and desorption of hydrogen in INT-MoS₂ was investigated at room temperature [16.183] with adsorption kinetics that was nearly linear and with a saturation after ≈ 30 min allowing for fast and steady hydrogen buildup. Comparison of the gas adsorption (1.2 wt %) and electrochemical storage (0.97 wt %) indicates that the gas adsorption process is the result of physisorption of hydrogen in the INT-MoS₂ nanotubes. Similarly, Li insertion into INT-MoS₂I_{0.3} bundles prepared by chemical vapor transport was investigated [16.184], with a significant increase in the amount of inserted lithium and a decrease of ≈ 0.7 V in the insertion potential for the electrodes when compared with bulk 2H-MoS₂ powder. Furthermore, electron paramagnetic resonance (EPR) measurements showed that the lithiated INT bundles were less sensitive to air than the bulk material.

16.4.4 Miscellaneous

As the preceding sections demonstrate, the applications of IF and INT are numerous and are steadily expanding. Recent work in the area of functionalization is promising to expand these areas even more [16.58]. This is especially promising in the context of catalysis, where nanostructured materials have long been heralded as the next leap in heterogeneous and homogeneous catalysis. Thus, one of the most important potential applications of INT-MoS₂ is their use as catalysts for hydrodesulfurization of thiophene and dibenzothiophene and desulfurization of petroleum and gasoline [16.64, 68, 69, 155, 185, 186].

The optical properties of INT and IF have also revealed potential for practical applications; for example, black metallic coatings containing IF showing less than 1.7% reflectivity over the range of 300–1100 nm were demonstrated with various applications ranging from solar-to-thermal converters to optical coatings [16.1]. Also promising are the optical-limiting (OL) properties of INT-MoS₂ in aqueous suspensions, which were shown to surpass those of CNT at 1064 and 532 nm [16.187].

16.5 Conclusions

The formation of inorganic nanotubes and fullerene-like nanostructures is now considered a generic phenomenon of inorganic compounds with layered (two-dimensional) compounds. The most prominent members of this family are WS₂ and MoS₂, which are currently produced in relatively large amounts. Therefore, the underlying principles governing the synthetic processes of these materials could be used as guidelines for a large variety of materials.

The superior qualities of INT and IF as well as their tunable properties elicit great interest due to both the fundamental questions that these nanostructures pose and the substantial breadth of potential applications. In particular, their inherent stability under harsh conditions is promising for numerous applications in various fields. Thus, study of these nanostructures has led to the observation of a number of interesting properties

offering numerous potential applications in tribology, high-energy-density batteries, composites, and catalysis. Chemical modifications (surface functionalization) of the IF and INT surfaces could lead in the future to new strategies for drug delivery, contrast agents, and a variety of other medical applications.

The progress achieved on all these fronts is still dwarfed by the numerous challenges facing the field. Controllable and reproducible synthesis of inorganic nanotubes with predefined structural parameters is one such challenge, let alone the optical and electronic properties of the nanotubes. Thus, controlling the size, shape, and resultant properties is still in its infancy. This chapter highlights the fact that a real and deep understanding of the interplay between synthesis and structure is essential, as well as comprehension of how the structure relates to the resultant properties.

Growth of Nanomaterials

17. Growth of Nanomaterials by Screw Dislocation

Fei Meng, Stephen A. Morin, Song Jin

Controlling the morphology of nanomaterials is important for their fundamental study and practical application. Especially one-dimensional nanowires, nanorods, and nanotubes and two-dimensional nanoplates possess interesting physical and chemical properties due to their structural anisotropy. The key to obtaining these morphologies is to break the symmetry of crystal growth to promote anisotropic growth. In this chapter we discuss the catalyst- and template-free screw-dislocation-driven nanomaterial growth mechanism, in which an axial screw dislocation creates self-perpetuating growth steps upon intersecting with the crystal surface and enables anisotropic crystal growth under low supersaturation conditions. The presence of screw dislocations not only alters the growth kinetics of nanomaterials, but also distorts the crystal lattice and generates a strain field, both of which lead to morphology variation of the nanomaterials. The structural characteristics associated with dislocation-driven growth can be readily detected using transmission electron microscopy techniques. A review is presented on a wide range of nanomaterials formed under various conditions whose growth has been confirmed to be driven by screw dislocations, demonstrating the generality of this mechanism. A framework for rationally synthesizing anisotropic nanomaterials via dislocation-driven growth is provided. This will enable large-scale, low-cost production of nanomaterials for various applications.

17.5 Rational Growth of Dislocation-Driven Nanomaterials – General Strategies	658
17.6 Applications	659
17.7 Summary and Perspectives	660
References	661

One of the major goals in nanoscience and nanotechnology is to synthesize nanoscale building blocks of arbitrary dimensions, morphologies, and materials with increasing complexity from the bottom up. Anisotropic

nanomaterials have already found many applications and are therefore of great interest; For example, one-dimensional (1-D) nanowires (NWs), nanorods (NRs), and nanotubes (NTs) and two-dimensional

(2-D) nanoplates have shown new fundamental physical properties and demonstrated promising utility in nanoelectronics, nanophotonics, solar energy conversion, thermoelectricity, electrochemical energy storage, and chemical and biological sensing [17.1–9]. The fundamental understanding of the growth of anisotropic nanomaterials is critically important for developing rational and controllable synthesis to yield nanoscale morphologies suited for specific applications.

Several common mechanisms or methods have been established to explain bottom-up anisotropic NW growth or enable fabrication of 1-D nanomaterials. The vapor–liquid–solid (VLS) [17.10, 11] mechanism and other analogous catalyst-driven mechanisms, such as solution–liquid–solid (SLS) [17.12, 13] and vapor–solid–solid (VSS) [17.14] growth, have been the most commonly used methods for synthesis of NWs. In VLS (or SLS) growth, a nanoscale liquid droplet is formed between a nanoparticle metal catalyst and the desired precursor species due to eutectic phase behavior, and further supersaturation of the precursor leads to precipitation and growth of crystalline NW material from the catalyst. Use of 1-D templates such as anodic aluminum oxide (AAO) is another common way to confine the growth of nanomaterials to achieve 1-D growth [17.15]. The *oriented attachment* mechanism can also result in the formation of thin 1-D NWs in solution via the assembly of zero-dimensional (0-D) nanocrystals, as recently confirmed using the in situ transmission electron microscopy

(TEM) technique [17.16, 17]. From the perspective of crystal growth, the challenge of growing anisotropic nanomaterials, including 1-D NW materials, is to break the symmetry of crystal growth to ensure that crystals grow in a highly anisotropic fashion instead of forming bulk crystals with polyhedral shapes.

In this chapter, we discuss the screw-dislocation-driven mechanism for growth of anisotropic nanomaterials, in which axial screw dislocations provide self-perpetuating steps and break the symmetry of crystal growth. The key is to manipulate the kinetics of crystal growth and enable the formation of anisotropic crystals instead of polyhedral-shaped crystals or thin films [17.18–20]. The presence of the axial screw dislocations and the consequent strain field introduces unique characteristics to the dislocation-driven nanomaterial, including macroscopic growth kinetics and variations in nanostructure morphologies, which are explained next. We then introduce the technique to characterize these features in nanoobjects to confirm the growth mechanism. The generality of this mechanism is demonstrated by a survey of a wide range of different nanomaterials whose growth has been confirmed to be driven by screw dislocations. The general rule of design is then summarized to provide a framework for rationally synthesizing anisotropic nanomaterials via dislocation-driven growth, which may eventually enable large-scale, low-cost production of nanomaterials for various practical applications.

17.1 Classical Crystal Growth Theories

Since the key to successful anisotropic growth is controlling the kinetics of crystal growth and breaking the symmetry of crystal growth, we first review the fundamental kinetics of crystal growth processes [17.21].

17.1.1 Layer-By-Layer Crystal Growth

Layer-by-layer (LBL) crystal growth is the most intuitive mechanism for the formation of the extended periodic crystal structure of solids. However, due to the high energy barriers required to nucleate new layers of atoms which create step edges that facilitate the addition of more atoms (Fig. 17.1), LBL crystal growth theory predicts that much higher concentrations of gas-phase or liquid-phase precursors than the equilibrium con-

centration are necessary to enable a reasonable crystal growth rate. In other words, LBL growth requires high supersaturation. The supersaturation σ of the system is defined by (17.1) [17.21]

$$\sigma = \ln(c/c'), \quad (17.1)$$

where c is the precursor concentration and c' is the equilibrium concentration.

Study on the kinetics of LBL growth reveals that it has an *exponential* growth rate (R_{LBL}),

$$R_{\text{LBL}} = J_0 l^2 \beta \propto e^{(-g_n/kT)} l^2 \beta, \quad (17.2)$$

where J_0 is the rate of 2-D nucleation, l is the length of the facet (assuming a square growth facet), β is

Fig. 17.1a,b Schematic illustration of the layer-by-layer crystal growth mechanism. (a) A 2-D island is nucleated and spreads to cover the active growth facet. (b) Once the first layer is completed, a new island (cluster of brown cubes) is nucleated on the first layer and the growth of a new layer begins

the step height, k is the Boltzmann constant, T is the temperature, and g_n is the energy barrier to 2-D nucleation, which is inversely proportional to supersaturation [17.21]. These expressions illustrate that LBL growth requires the formation of 2-D nuclei by overcoming the energy barrier g_n .

The prevailing catalyst-driven mechanisms, such as VLS [17.10, 11], SLS [17.12, 13], and VSS [17.14], that explain the 1-D anisotropic growth of NWs are fundamentally still LBL growth, but mediated by the catalyst droplets at the catalyst–solid interface [17.22, 23]. The nucleation barrier for LBL growth is lowered by the presence of the catalyst relative to the respective interface on the side-wall; therefore, the crystal growth is much faster at this interface. In this way, the symmetry of the crystal growth is broken and 1-D anisotropic crystal growth can proceed.

17.1.2 Screw-Dislocation-Driven Crystal Growth

Experimental observations reveal that crystal growth can actually happen under moderate supersaturation, contradicting the prediction of LBL growth theory. Frank [17.24, 25] solved this conflict by pointing out that crystals often have imperfections such as screw dislocation line defects [17.26, 27], which upon intersection with a crystal surface would make steps that propagate as spirals and thus become an endless source of crystal steps (Fig. 17.2). This theoretical model, known as the Burton–Cabrera–Frank (BCF) theory [17.24], successfully explains the observed growth rates of crystals under moderate and low supersaturation. Such surface dislocation spirals have been observed in many materials [17.28], and the dislocation-driven growth mechanism has become a cornerstone of crystal growth theory.

BCF theory predicts a dislocation growth rate ($R_{\text{dislocation}}$) that is linearly dependent on super-

Fig. 17.2a–d Illustration of screw dislocation growth spirals. (a–d) Schematic illustration of a screw dislocation spiral propagating new step edges as the crystal grows (after [17.21])

Fig. 17.3 Schematic illustration of crystal growth mechanism as a function of supersaturation. As the supersaturation increases, the dislocation, LBL, and dendritic growth mechanisms progressively dominate (after [17.20])

saturation

$$R_{\text{dislocation}} = C\sigma, \quad (17.3)$$

where C is a rate constant that depends on the maximum possible flux of monomers to the crystal surface via diffusion through the stagnant layer. This growth kinetics of the dislocation-driven mechanism is a characteristic feature that can distinguish it from other growth modes.

According to classical crystal growth theory, the growth mechanism of a crystal depends on the supersaturation. As schematically illustrated in Fig. 17.3, at low supersaturation the dislocation-driven spiral growth mechanism is followed; at intermediate supersaturation the LBL growth mechanism is followed; at high supersaturation the dendritic growth mechanism is followed.

These different growth regimes are separated by two characteristic supersaturations, namely σ^* and σ^{**} , at which the growth rate of the next mechanism overtakes the previous one (Fig. 17.3). In the context of current studies which focus on well-faceted single-crystalline nanomaterials, the dislocation growth and LBL growth mechanisms are the most relevant and are the topics of the following discussion.

17.2 Theories for Screw-Dislocation-Driven Growth of Nanomaterials

Screw dislocation has been proven to be responsible for both 1-D and 2-D crystal growth. The essence of screw-dislocation-driven nanomaterial growth, especially nanowire growth, is that, under appropriate low supersaturation conditions that favor dislocation-driven growth over LBL growth, crystal growth occurs more rapidly at the dislocation spirals along the axial direction whereas radial dimension expansion via the LBL mode is prohibited (Fig. 17.4a). In this way, the symmetry of the crystal growth is broken and highly anisotropic crystal growth is enabled by the self-perpetuating steps of screw dislocations.

The basic idea that screw dislocations can drive anisotropic growth of 1-D crystals was in fact proposed and discussed in the 1950s by Sears [17.29–32]. Indirect evidence such as lattice twist within whiskers was observed, suggesting the presence of axial screw dislocations [17.33, 34]. Decoration of axial dislocations in whiskers of alkali halides was first observed in 1958 [17.35]. Direct observation and identification

of screw dislocations in whiskers using electron microscopy was not reported until 1965, in single-crystal whiskers of aluminum nitride [17.36, 37], and later chalcotrichite (Cu_2O) [17.38]. In the modern literature, observation and confirmation of dislocation-driven NW growth was first reported in NW trees of PbS [17.18, 39] and PbSe [17.40]. In these fascinating tree-like structures, growth of the trunk is driven by screw dislocations whereas the branches are grown by the more traditional VLS NW growth mechanism.

17.2.1 Eshelby Twist

A screw dislocation disrupts the perfect periodicity within the crystal lattice and thereby causes a strain energy per unit length E that is quadratically dependent on the magnitude of the dislocation Burgers vector b , i.e.,

$$E = \frac{b^2 \mu}{4\pi} \int_{r_0}^R \frac{dr}{r} = \frac{b^2 \mu}{4\pi} \ln \left(\frac{R}{r_0} \right), \quad (17.4)$$

where μ is the shear modulus, R is the radius of the cylinder containing the dislocation, and r is the core radius of the dislocation. This stress field exerts a torque at the free ends of the rod, resulting in a twist of the rod along the axial direction (Fig. 17.4b) [17.26, 41], known as the Eshelby twist, which in turn serves as evidence of the dislocation-driven growth mechanism. This Eshelby twist is mathematically expressed as

$$\alpha = \frac{b}{\pi R^2}, \quad (17.5)$$

where α is the twist of the lattice in radians per unit length. Attempts to observe the Eshelby twist in micrometer-scale whiskers were made in the late 1950s, but the results were often inconclusive [17.34, 42]. Because of the $1/R^2$ dependence, the Eshelby twist is

Fig. 17.4a,b Illustrations of screw-dislocation-driven NW growth and the associated Eshelby twist. (a) A screw dislocation drives 1-D growth at low supersaturation, where LBL growth is prohibited (after [17.19]); (b) Eshelby twist (after [17.18])

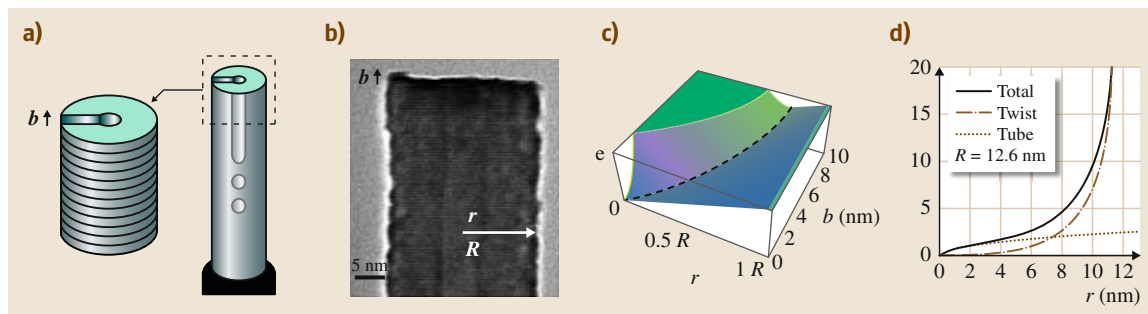

Fig. 17.5a–d Two pathways to relieve the strain energy and the estimation of b in ZnO NTs: (a) Schematic illustration of screw-dislocation-driven formation of a hollow NT. (b) High-resolution transmission electron microscopy (HRTEM) image of the tip of a ZnO NT in which the critical parameters R , r , and b can be directly measured. (c) Calculated three-dimensional (3-D) energy plot using (17.8) for the ZnO NT shown in (b); the dashed line represents the energy minimum. (d) Energy-minimized relation for b versus r/R by explicitly solving (17.8) along this energy valley for the specific ZnO NT in (b); the total contribution to b has components due to the hollow inner tube surface energy (red dash-dotted line) and to the Eshelby twist (blue dotted line) (after [17.20])

more pronounced at the nanoscale compared with in micrometer-sized whiskers, making it readily observable in NWs and NTs. Particularly in the case of hyperbranched nanostructures such as PbS and PbSe nanotrees, overgrowth of epitaxial branching nanowires allows easy visualization of the twist [17.18, 39, 40]. This allows direct measurement of the Eshelby twist and a simple estimate of the Burgers vector's screw component magnitude. In recent years, more accurate theoretical calculations of Eshelby twists based on molecular dynamics have been carried out for thin NW and NT materials [17.43, 44].

17.2.2 Dislocation-Driven Nanotube Formation

The formation of single-crystal NTs is a signature of nanomaterial growth driven by dislocations with large Burgers vector b (Fig. 17.5a). In the case of a hollow tube, the elastic energy caused by the dislocation can be expressed by modifying (17.4) as

$$E = \frac{b^2 \mu}{4\pi} \ln \left(\frac{R}{r} \right), \quad (17.6)$$

where R and r are the outer and inner tube radii, respectively [17.27]. As b increases, eventually the crystal contains enough strain energy that it exceeds the energy cost of creating a new inner surface and the dislocation core becomes hollow. This causes the formation of micropipes, which are often observed in dislocation-prone materials such as SiC or GaN and sometimes termed *open-core dislocations* [17.45, 46]. In the clas-

sical open-core dislocation model, an energy balance between the surface energy ($2\pi\gamma r$, where γ is the surface energy) and the strain energy from (17.6) (both per unit length) results in a relationship between r and b [17.45]

$$b_{\text{tube}} = \sqrt{\frac{8\pi^2 \gamma r}{\mu}}. \quad (17.7)$$

For NWs reaching this energy threshold, the solid NW becomes a hollow NT. In other words, the equilibrium morphology of 1-D nanomaterials whose growth is driven by screw dislocations should be hollow NTs when the Burgers vector is sufficiently large [17.47]. The commonly observed voided NWs [17.47, 48] might be an intermediate stage lying on the threshold, oscillating between the solid and hollow conditions due to small fluctuations in growth environment and NW thickness that subtly change the energy balance, or tubes initially formed could partially close up after synthesis.

Furthermore, forming a hollow core and producing a torque around the NW axis via the Eshelby twist mechanism are two competing pathways to alleviate the strain caused by the screw dislocations. Once the nanostructure becomes hollow, the overall energy per unit length E contains three terms: the surface energy of the hollow inner tube, the lattice strain due to the dislocation, and the reduction in lattice strain due to the Eshelby twist

$$E = 2\pi\gamma r + \frac{\mu b^2}{4\pi} \ln \left(\frac{R}{r} \right) - \frac{\mu b^2}{4\pi} \frac{(R^2 - r^2)}{(R^2 + r^2)}. \quad (17.8)$$

Fig. 17.6a–f A unified scheme illustrating dislocation-driven growth of various nanomaterial morphologies. (a) Top view and dramatized side view of an idealized nanoplate with one screw dislocation with various step velocities at the dislocation core (v_c) and the outer edges (v_o). Nanowires or nanotubes (b), nanorods (c), or nanoplates (d) are achieved when specific step velocity and supersaturation conditions are met. (e,f) Side views reveal the relationship between the nanoplate slope p , step height h , terrace width d , and supersaturation σ (after [17.50]) ◀

be alternately displayed as a plot of b versus r/R (Fig. 17.5d). It is clear from Fig. 17.5d that, when r/R is small, representing the scenario of a thick-walled NT, the total energy minimization approximates the Frank's open-core dislocation model, and most energy is relieved by making the tube hollow; however, at much larger r/R values, the total energy minimization begins to follow the Eshelby twist line, indicating that a thin-walled NT has more significant twist, as creating more surface becomes energetically unfavorable.

17.2.3 Dislocation-Driven Growth of 2-D Nanoplates

Screw dislocations can also drive 2-D anisotropic crystal growth. The key herein is to control the crystal growth step velocities at different positions from the dislocation core (Fig. 17.6a) [17.51]. In general, the velocity of steps at the core v_c should be the same as those at the outer edges of the dislocation hillocks v_o due to their crystallographic equivalence. However, the velocity of steps can be affected by environmental factors such as impurities or mass transport, such that steps created earlier in growth (thus at the outer edge v_o) develop more slowly than newly generated steps closer to the core of the dislocation (v_c), which leads to two scenarios. When v_o is slightly less than v_c , newly generated steps from the dislocation core would very slowly catch up with those at the outer edge to create a step pile-up and thus a step-free facet, which will lead to low-aspect-ratio NRs or bulk polyhedral crystals (Fig. 17.6c), particularly when under higher supersaturation and if there is significant LBL growth. Furthermore, if v_o is much less than v_c , possibly because the steps at the outer edge have more impurity pinning sites, more adsorbed surfactants [17.52], or slower mass transport kinetics [17.7], newly generated steps quickly catch up with those further out, rapidly producing a step-free facet and thus leading to almost pure 1-D growth under low supersaturation conditions

When ZnO nanotubes are used as a model system to evaluate (17.8), with the specific values of surface energy of 0.31 J/m^2 and shear modulus of 44.3 GPa [17.49], and the radii of the NT shown in Fig. 17.5b, a three-dimensional surface plot of (17.8) constructed for E versus b and r/R (Fig. 17.5b) shows that there is an energy valley (minimum) associated with certain optimized r and b values (marked with a dashed line). The energy-minimized relation between r and b can be solved by setting the energy derivative with respect to r to zero,

$$\frac{dE}{dr} = 0 \rightarrow b_{\text{total}} = \sqrt{\frac{8\pi^2\gamma r}{\mu}} \left(\frac{R^2 + r^2}{R^2 - r^2} \right). \quad (17.9)$$

The first factor in (17.9) represents the effect from Frank's open-core dislocation model in (17.7) [17.45], while the second factor is the modification due to the Eshelby twist pathway. The Eshelby twist component can also be expressed explicitly as the difference between (17.7) and (17.9),

$$b_{\text{twist}} = b_{\text{total}} - b_{\text{tube}} = \sqrt{\frac{8\pi^2\gamma r}{\mu}} \left(\frac{R^2 + r^2}{R^2 - r^2} - 1 \right). \quad (17.10)$$

This direct relation between the r and b variables along the energy valley (17.9; dashed line in Fig. 17.5c) contains the contributions to the total energy from the Eshelby twist and hollow tube components and can

(Fig. 17.6b). Finally, if v_0 is equal to v_c , which is more common in general crystal growth, all steps, regardless of whether they are newly generated steps at the dislocation core or earlier steps at the outer edge of the growth spiral, propagate at the same velocity and a step pile-up is never created; thus, the steps spread in 2-D (Fig. 17.6d).

According to BCF theory [17.51, 53], the terrace width d is inversely proportional to the supersaturation σ of the system, and thus, for the same step height h , the slope of the nanoplate hillocks ($p = h/d$) increases as the supersaturation increases (Fig. 17.6e,f). Therefore, the thickness-to-diameter ratio of 2-D nanoplates depends on the supersaturation of

the growth solutions; i.e., low-supersaturation growth favors generation of very thin nanoplates with small slopes, while higher supersaturation leads to thicker plates of increasing slope. This relationship between terrace width (and thus the slope of dislocation hillocks) and supersaturation has been well documented in crystal growth studies, such as those shown by *De Yoreo et al.* [17.52].

Despite the drastic difference between the morphologies of NWs, NTs, and nanoplates, their growth can be unified using the dislocation-driven mechanism. Understanding how to control the nanomaterial anisotropy is of great importance to design dislocation-driven growth for specific applications.

17.3 Structural Characterization of these Nanomaterials

Dislocation-driven growth is a general mechanism, and therefore the principles described above are applicable to many crystalline materials grown from solution or vapor phase. However, dislocations are mobile and especially not stable in small volumes [17.26, 27], so that postgrowth mechanical perturbation could work the dislocations out of nanomaterials. As a result, dislocations themselves might not always be directly visualized, and the operation of the dislocation-driven mechanism might have been overlooked in many anisotropic nanomaterials (especially 1-D nanomaterials) whose growth is not completely or correctly understood. Nevertheless, there is other evidence closely associated with the dislocation-driven growth mechanism that can support this mechanism, including the lattice twist, lattice tilt, and formation of hollow tubes. In this section we discuss the common techniques that can be used to characterize dislocation-driven nanomaterials.

17.3.1 Observation of Dislocation Contrast

Transmission electron microscopy (TEM) has been the most common and powerful tool used to analyze the microstructures of materials. Screw dislocations can be readily detected and their associated Burgers vectors identified using the diffraction-contrast TEM technique, which relies on additional electron diffraction due to the bending of atomic planes near the dislocation core. If an image is reconstructed from specific reciprocal-space diffraction spots \mathbf{g} that are selected by a physical aperture, these additional diffracted electrons create a visible contrast around the dislocation. However, diffraction

spots \mathbf{g} that are normal to the Burgers vector of the dislocation \mathbf{b} ($\mathbf{g} \times \mathbf{b} = 0$) produce no dislocation contrast – the *invisibility criterion* [17.54]. Therefore, the direction of a Burgers vector can be identified by taking the cross-product of two non-collinear \mathbf{g} vectors that make the dislocation contrast disappear. A general procedure for identifying the Burgers vector's direction is detailed in the following:

- First step: Tilt the sample onto an appropriate zone axis which contains the diffraction spots that are perpendicular to the potential Burgers vector's direction. Most crystal lattice types have their own habitual Burgers vectors, for example, [110] in the face-centered cubic (fcc) structure or [001] in the hexagonal closed-packed (hcp) structure [17.26]. Otherwise, the growth direction of NWs can be well used as a guide to screen the \mathbf{g} vectors and the corresponding zone axes, because the axial growth direction by definition has to be parallel to the screw component of the dislocation Burgers vector that is responsible for driving the NW growth.
- Second step: Approach the two-beam condition by further tilting the sample until almost all other reflections disappear with the exception of the transmitted beam (the zero beam) and the selected \mathbf{g} beam. Repeat these two steps to find another non-collinear \mathbf{g} beam that satisfies the invisibility criterion.
- Third step: Determine the Burgers vector direction by taking the cross-product of the \mathbf{g} vectors. Ap-

Fig. 17.7a–h Diffraction-contrast TEM imaging of the dislocation in the tree trunk: (a–c) TEM images along the $[2\bar{2}1]$ zone axis under strong two-beam conditions; (a) $g \parallel b$ conditions showing strong diffraction contrast; (c) invisibility conditions as highlighted (red circles) in the zone axis diagram (b). (a) Schematic superposition of real and reciprocal space of a dislocation-containing NW along the $[001]$ zone axis is shown to illustrate the Burgers vector relationship. (b) Low-magnification TEM image showing the tree and area analyzed. (c–e) $[1\bar{1}1]$ zone axis TEM under strong two-beam conditions. (f) $g \parallel b$ conditions and (h) invisibility conditions as highlighted (red circles) in the zone axis diagram (g) (ZAP: zone axis pattern; after [17.18])

proach the two-beam condition composed of the zero beam and the determined Burgers vector beam to verify the presence of strong dislocation contrast (the $g \parallel b$ condition that exhibits the highest contrast of dislocations).

The determination of the Burgers vector in the PbS tree-like structure can be used as an example to illustrate the entire process [17.18]. The same segment of a tree structure was tilted to the $[2\bar{2}1]$ zone axis (Fig. 17.7a–c) and the $[1\bar{1}1]$ zone axis (Fig. 17.7f–h), respectively. The dislocation meets the invisibility criterion under the perpendicular $(2\bar{2}\bar{8})$ two-beam condition near the $[2\bar{2}1]$ zone axis and the perpendicular $(\bar{2}24)$ two-beam condition near the $[1\bar{1}1]$ zone axis. Therefore, taking the cross-product of the $(2\bar{2}\bar{8})$ and $(\bar{2}24)$ vectors shows that the Burgers vector is along the $[110]$ direction, which is confirmed by the images under two-beam conditions of the parallel $[220]$ spots showing high contrast of the dislocation line. It is known that the Burgers vector of the most stable dislocations in rock-salt crystals is along $\langle 110 \rangle$, and this has been previously observed in bulk PbS crystals [17.26, 55]. Since the dislocation line direction (u) is along the $[100]$ NW growth direction, the $[110]$ Burgers vec-

tor represents a mixed dislocation: a screw dislocation component along the $[100]$ (or $[\bar{1}00]$) direction mostly responsible for driving the NW growth, and an edge dislocation component along the $[010]$ (or $[0\bar{1}0]$) direction. The role of edge dislocations in promoting crystal growth [17.56] is not clear but cannot be ruled out completely at present.

Using such methods, dislocation contrast has been conclusively observed for NWs of PbS [17.18, 39], PbSe [17.40], CdS, CdSe [17.57], AlN [17.37], ZnO [17.20, 47], α -FeOOH [17.58], $\text{Co}(\text{OH})_2$ [17.59], Cu [17.60], and Cu_2O [17.38, 48]. However, complete two-beam analysis of the dislocation and invisibility criterion has only been carried out for a smaller set of materials including PbS, CdSe, and Cu. The stability of the nanomaterials under high-vacuum and high-energy electron beam conditions inside the TEM, and the tilting angle range of the TEM goniometer are two main limiting factors to achieve a complete two-beam analysis.

17.3.2 Determination of Eshelby Twist

Various techniques based on TEM and electron diffraction have been established to identify and quantify the Eshelby twist. The most intuitive method relies on the

Fig. 17.8 TEM image of a single chiral branched NW. White boxes indicate the positions at which the CBED patterns were acquired. Upper inset: CBED pattern obtained at the top box showing [110] zone axis. Lower inset: CBED pattern obtained at the bottom box showing [100] zone axis (after [17.40])

variation of the electron diffraction on different regions of a NW caused by the rotation in the crystal lattice. Convergent-beam electron diffraction (CBED) is often chosen to acquire diffraction patterns due to its small probe area, which can minimize the interference caused by lattice rotation. In brief, the electron probe is moved along the NW's axial direction to find two distinct zone axes. The twist angle can be calculated by dividing the angular separation between the two identified zone axes by the spatial separation between the two probed areas; For example, starting with the end of the PbSe NW on the [100] zone axis (bottom of Fig. 17.8), the diffraction pattern continuously rotates about the (001) reflection as the probe moves along the wire, reaching the [110] zone axis (top of Fig. 17.8) [17.40]. These two spots are separated by $9.1 \mu\text{m}$ along the NW axis, while the [100] and [110] directions are 45° apart in the cubic structure, which gives approximately $5^\circ/\mu\text{m}$ twist of the lattice. The NW has a diameter of 96 nm , which leads to a calculated value of $b = 0.624 \text{ nm}$. This method, however, requires the NW to have a relatively large twist angle and/or length so that both zone axes are observable. In addition, this measurement is inaccurate in the presence of other geometrical distortion of the lattice, e.g., bending, because this also affects the orientation of the lattice planes and the consequent electron diffraction.

The twist contour analysis reported by Drum in 1965 provides an alternative and more accurate method to determine the sense and magnitude of the twist in crystals [17.37]. Unlike the previously discussed

method based on CBED, twist contour analysis is essentially a diffraction-contrast TEM technique. First, twist contours must be differentiated from the bend contours commonly observed in TEM of nanomaterials. Bend contours, as the name suggests, occur when a NW is bent about its axis. This distorts many atomic planes locally at the bend, causing the diffraction of electrons from this region of the crystal to be different from everywhere else. Therefore, when a zero-beam bright-field TEM image is taken of a bent object, because electrons are diffracted in such a way that virtually none of them remain in the zero beam, the bend contour appears very dark compared with everywhere else. In contrast, when real-space crystal lattice twists along the growth axis cause the reciprocal-space lattice to twist simultaneously, the various reciprocal \mathbf{g} vectors that are orthogonal to the NW growth axis come on and off the Laue condition at different angles, creating several twist contour bands. If we generically choose $-\theta$ for $-\mathbf{g}$ and $+\theta$ for $+\mathbf{g}$, which we will call θ_- , \mathbf{g}_- and θ_+ , \mathbf{g}_+ , respectively, the difference between the two angles $\Delta\theta$ can be calculated geometrically using the relation

$$\Delta\theta = (\theta_+ - \theta_-) = \left(\frac{\lambda}{2}\right) |\mathbf{g}_+ - \mathbf{g}_-|, \quad (17.11)$$

where λ is the electron wavelength (the inverse of k). Note that the approximation $\theta \approx \lambda g/2$ is made because of the large radius of the Ewald sphere for electron diffraction. For a twisting NW, the upper and lower conditions in Fig. 17.9b can be simultaneously met at different points along the NW, and the resulting twist contours can be imaged using zero-beam bright-field TEM and indexed directly using displaced-aperture dark-field TEM. Unlike bend contours, each of these twist contours is associated with one set of planes and can be easily differentiated. The measured real-space distance L between two indexed twist contours can be used to calculate the real-space twist α , effectively the Eshelby twist, of the NW using the following relation:

$$\alpha = \left(\frac{\Delta\theta}{L}\right) = \left(\frac{\lambda}{2L}\right) |\mathbf{g}_+ - \mathbf{g}_-|. \quad (17.12)$$

In practice, any \mathbf{g} vectors that are not parallel to the NW growth axis (which contains the orthogonal component) can be selected for the twist contour analysis. An angle correction is needed in this case, and (17.12) needs to be modified to

$$\alpha = \frac{\lambda}{2L} \left| \frac{\mathbf{g}_+ - \mathbf{g}_-}{\sin \beta} \right|, \quad (17.13)$$

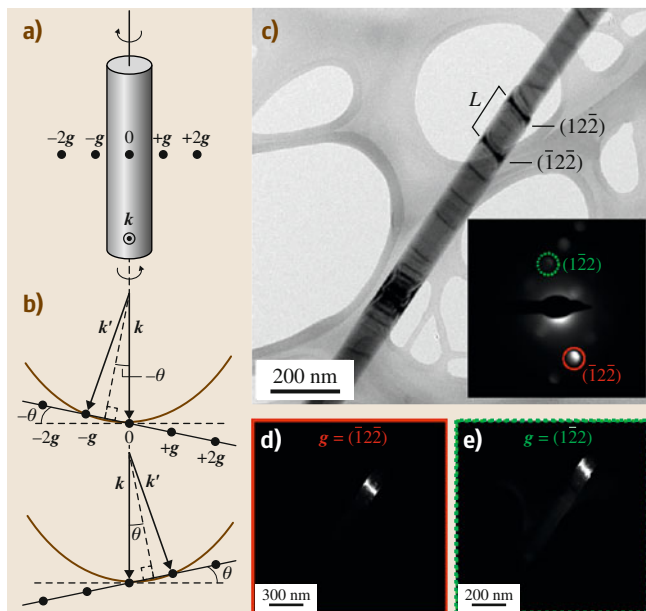

Fig. 17.9a–e Observation and determination of Eshelby twist using TEM and electron diffraction. **(a)** Schematic illustration of a NW showing g vectors orthogonal to the growth axis and the k vector of the electron beam. **(b)** Conditions where $-g$ and $+g$ vectors (top and bottom diagrams, respectively) meet the Laue condition. **(c)** Zero-beam bright-field TEM image of a representative NW showing two indexed twist contours and the physical separation L . Inset convergent-beam electron diffraction pattern. **(d, e)** Displaced-aperture dark-field TEM used to index the two labeled contours as $(\bar{1}2\bar{2})$ and $(1\bar{2}2)$ (after [17.47])

where β is the angle between $\pm g$ and the NW growth direction; For example, the ZnO NW shown in Fig. 17.9 was firstly oriented so that a pair of $\pm g$ vectors $[\pm(\bar{1}2\bar{2})]$ were selectively illuminated [17.47]. A zero-beam bright-field image (Fig. 17.9c) was then taken to record the locations of the contour bands so that the separations between them could be measured. Next, each twist contour was uniquely indexed to a specific g vector using displaced-aperture dark-field imaging (Fig. 17.9d,e). A pair of twist contour bands are clearly present in the bright-field image (Fig. 17.9c), and they are indexed to $\pm(\bar{1}2\bar{2})$ g vectors, respectively. The calculated twist for the NW shown in Fig. 17.9c is approximately $9^\circ/\mu\text{m}$ using (17.13), which is in agreement with the Eshelby twist predicted for a NW with radius of 46 nm and Burgers vector's magnitude of approximately 1.0 nm.

In practice, using twist contours to quantify Eshelby twist is much more easily implemented on NW samples than the other techniques discussed above, and

Fig. 17.10a–d Quantification of the lattice tilt using TEM and electron diffraction. **(a)** SAED showing the splitting of the diffraction spots (inset shows the split spot indicated by the arrow, scale 0.21 nm^{-1}). **(b)** CBED patterns showing the tilt of the structure from the left (above) to the right part (below) of the section of the NW. **(c)** Bright-field (BF) image showing the positions of measurement (brown circles) for each CBED pattern. The dark-brown arrow indicates the twist axis, while the light-brown arrow indicates the tilt axis in **(b)**. This is shown schematically in **(d)**. The Kikuchi bands observed have been used to measure the tilt angle (after [17.61])

twist contour analysis can quantify twist of $\approx 1^\circ/\mu\text{m}$ or less, which is a much higher resolution than the other techniques [17.18, 40, 41]. Eshelby twist has been conclusively observed for NWs or NTs of PbS [17.18, 39], PbSe [17.40], CdS, CdSe [17.57], AlN [17.37], ZnO [17.20, 47], Fe: ZnO [17.62], Er: ZnO [17.63], α -FeOOH [17.58], Cu [17.60], and Cu_2O [17.48].

17.3.3 Lattice Tilt

The screw dislocation not only causes the atomic planes to form a helicoid but also splits the crystal lattice at its core. As a consequence, the normal to the basal planes of a dislocated NW is slightly tilted in relation to the growth axis. The degree of tilt ϕ between planes on opposite sides of the screw dislocation is a function of the pitch of the helicoid, which is essentially equal to the magnitude of the Burgers vector b , and the radial position R of the measurement point

$$\cos(\phi) = \frac{1 - (b/(2\pi R))^2}{1 + (b/(2\pi R))^2} \quad (17.14)$$

Therefore, the magnitude of the Burgers vector can be derived from the tilt ϕ and R values [17.61].

Electron diffraction techniques including selected-area electron diffraction (SAED) and convergent-beam

electron diffraction (CBED) are convenient ways to determine the tilt angle ϕ . SAED usually illuminates a large area on the NW sample (hundreds of nanometers) and averages the tilt over all radial positions. The resulting pattern exhibits splitting of diffraction spots because the atomic plane normal is slightly tilted away from the NW axis. The angle of splitting in the diffraction spots is the same as that of the tilt ϕ . The average radial position R can be approximately estimated using one-half of the radius of the NW; For example, the InP NW shown in Fig. 17.10c has a radius of 12.0 nm, and its corresponding diffraction pattern (Fig. 17.10a) shows 2.0° splitting; thus the Burgers vector is calculated to be 0.69 nm, which is approximately one unit cell length of InP [17.61].

CBED, in contrast, measures the local lattice distortion due to its small probe size. The CBED pattern changes abruptly on different sides of the screw dislocation, which is visualized as a shift (Δk , in nm^{-1}) of the Kikuchi bands in reciprocal space (Fig. 17.10b). Therefore, the tilt angle ϕ can be derived from

$$\phi \approx \tan(\phi) = \frac{\Delta k}{k}, \quad (17.15)$$

where k is the wavevector of the incident electron beam. The radial position R is determined from the area being analyzed. Because NWs are thin objects, lower practical electron beam energy is preferred to make the Kikuchi bands visible. Using this CBED technique to determine the Burgers vector of the same NW shown in Fig. 17.10 returns a similar value (0.7 nm) to that obtained by the SAED technique. This measurement of lattice tilt is a newly developed technique, and has only been implemented for InP NWs [17.61].

17.3.4 Observation of Nanotubes or Voided NWs

As discussed earlier, the template-free, spontaneous formation of single-crystal inorganic NTs is a consequence of growth driven by screw dislocations with large Burg-

Fig. 17.11a–d Growth history of Cu_2O NTs and NWs revealed by TEM examination of the products with different growth times. (a) The completely hollow NT product from a 26 min reaction, (b) the partially hollow product from a 40 min reaction, and (c) the solid NW product from a 60 min reaction; (d) statistics of the observed Cu_2O NTs and NWs at different reaction times (after [17.48])

ers vectors. The NT can be conveniently visualized under TEM, as the core of the NT appears brighter than the wall due to the greater electron transmission.

In addition to NT structures whose interior is completely hollow, partially filled tubes and NWs with voids also imply the operation of the dislocation-driven mechanism; For example, investigating the growth time effect on Cu_2O NW growth revealed that the 1-D structures are almost exclusively hollow NTs at the beginning, and then were gradually filled up to become voided NWs and eventually solid NWs (Fig. 17.11) [17.48]. Hollow or voided structures have been observed in NWs/NTs of GaN [17.64], ZnO [17.20], $\alpha\text{-FeOOH}$ [17.58], Cu [17.60], Cu_2O [17.48], AlN [17.65], and In_2O_3 (doped or undoped) [17.66–68].

17.4 Generality of Dislocation-Driven Nanomaterial Growth

In this section we review a variety of different anisotropic nanomaterials whose growth has been proven to be driven by screw dislocations in contemporary nanomaterial literature and thus demonstrate

the generality of the dislocation-driven mechanism. The material classes of the nanomaterials known to form via the dislocation-driven mechanism vary from metal, metal oxide/hydroxide, metal chalcogenide, to

Fig. 17.12a–c Screw-dislocation-driven growth of PbS tree-like NWs. **(a,b)** SEM images of pinetree-like PbS NWs. **(a)** Schematic illustration to explain the growth of the pinetree structure: the trunk's growth is driven by axial screw dislocation and that of the branches by VLS (after [17.19])

metal nitride; the chemistry involved in forming the dislocation-driven nanomaterials can be distinctly different, ranging from simple hydrolysis reaction to reduction–oxidation (redox) reaction, and dislocation-driven growth can be accomplished in both vapor phase and solution phase. Despite the diversity in the physical and chemical properties of these nanomaterials, the rule of thumb in pursuit of rational synthesis of anisotropic nanomaterials is to maintain low supersaturation of the precursor to favor the dislocation-driven mechanism. We also present evidence of the dislocation-driven mechanism for each material using methods reviewed in the previous section.

17.4.1 Vapor-Phase Synthesis

The growth of NWs in vapor phase has been almost exclusively explained by the VLS and other analogous catalyst-driven mechanisms. The dislocation-driven crystal growth mechanism has long been underappreciated because of the easy visualization of a catalyst particle decorating the tip of the NW, whereas the TEM techniques to detect dislocations are not straightforward. Even in cases where catalyst particles were absent yet NW growth still occurred, researchers used to claim that the 1-D anisotropic growth was driven by self-catalyzed VLS. It should be cautioned that the role of dislocation-driven growth needs to be reexamined in these cases. Even in the presence of catalyst particles, there is still the possibility of the cooperation of both mechanisms. It is likely that, without the presence of catalyst nanoparticles, there is a higher energy barrier to nucleation of NW growth, therefore causing the low yield and slow growth rate of NWs that are commonly observed. Addition of catalyst nanoparticles promotes nanostructure growth with high yield by creating numerous nucleation sites, and thus facile and fast 1-D crystal growth is initiated. Furthermore, addition of

catalyst impurities and the fast and disordered crystal growth could potentially lead to the generation of dislocation sites that further facilitate the crystal growth process, which might become more responsible for the subsequent NW growth under the low supersaturation level.

PbS

PbS pinetree-like NWs were the first reported case of dislocation-driven growth among the modern NWs (Fig. 17.12a,b). Nanostructures of PbS are synthesized via chemical vapor deposition using PbCl_2 and elemental sulfur as precursors under argon flow with a co-flow of H_2 at atmospheric pressure and with temperatures of 600–650 °C [17.18, 39]. A piece of freshly exposed Si substrate is used to collect the NW product. The formation of the tree structure is indeed a combined effect of the operation of both the dislocation-driven NW growth mechanism and the VLS mechanism: the growth of the trunks is driven by axial dislocations, whereas the branches are formed via in situ VLS growth, as illustrated in Fig. 17.12c. The hydrogen flow plays an important role in triggering the dislocation-driven growth of the tree trunks. The chemical reactions involved are

The onset of hydrogen flow likely creates a spike in H_2S supersaturation and initiates dislocations with screw components that then propagate anisotropically to form the NW trunks. Maintaining an optimum hydrogen flow can provide a favorable supersaturation that promotes dislocation-driven trunk NW growth and enable the simultaneous growth of the VLS-driven NW branches.

PbSe

PbSe tree-like NWs (Fig. 17.8) have also been reported [17.40]. The synthesis of PbSe NWs was analogous to that of PbS due to their structural similarity, though some minor details of the chemical vapor deposition (CVD) precursors vary. Again, screw dislocation is responsible for the trunk growth, and VLS for the branch growth. One different aspect in the PbSe synthesis is that an intentional metal catalyst, bismuth in this case, was used, yet no obvious catalyst cap on the NW trunk was observed. This agrees with the hy-

Fig. 17.13a–d Evidence of dislocation-driven growth of CdS and CdSe NWs. Dislocation contrast of a CdS NW (a) and a CdSe NW (b), and twist contours on a CdS NW (c) and a CdSe NW (d) (after [17.57])

pothesis that metal particles might serve to facilitate dislocation-driven growth rather than acting as a VLS catalyst.

CdS/CdSe

CdS and CdSe share the wurtzite crystal structure, which is considered to be dislocation prone. There have been early reports on the dislocation structures in CdS/CdSe whiskers and ribbons [17.69–71]. Recently, CdS or CdSe NWs were grown via the chemical vapor deposition (CVD) process using CdCl₂ and elemental sulfur/selenium as precursors under argon flow with a co-flow of H₂ at relatively low system pressure of 40 Torr at temperatures of 600–650 °C [17.57]. Si substrates, either covered with gold nanoparticles or not, were used to collect the products. With the presence of gold nanoparticles, NWs with high yield and uniformity were obtained. Interestingly, even when the gold nanoparticle catalyst was absent, short NWs could still be grown. The vapor pressure was low in this reaction compared with most of the other reported CVD synthesis conditions [17.72–74], thus favoring dislocation-driven crystal growth.

Evidence for dislocation-driven growth was indeed detected in the NWs synthesized with the presence of gold nanoparticles. Dislocation contrast was observed in both as-synthesized CdS (Fig. 17.13a) and CdSe (Fig. 17.13b) NWs, and the Burgers vectors of the dislocation were determined to be [120] for CdSe under strong two-beam conditions. Moreover, twist contour analysis revealed the presence of Eshelby twist associated with the dislocation in both CdS (Fig. 17.13c) and CdSe (Fig. 17.13d) NWs.

These results clearly showed that dislocation-driven NW growth had occurred during the CVD growth of CdS and CdSe NWs, even when gold nanoparticle catalysts were employed for the synthesis, suggesting that both VLS growth and the dislocation-driven growth

mechanism can coexist in the growth of 1-D CdS and CdSe NWs.

AlN

AlN whiskers were one of the earliest examples whose growth was demonstrated to be driven by screw dislocation. Back in 1965, *Drum* et al. observed the dislocation contrast running through AlN whiskers and developed the twist contour analysis to verify the presence of Eshelby twist in these whiskers (Fig. 17.14a) [17.37]. More recently, hollow AlN NTs (Fig. 17.14b) were synthesized by nitridization of Al metal powder in the presence of Co(III) salts [17.65]. The spontaneous formation of the NT structure is highly suggestive of screw-dislocation-driven growth.

GaN

GaN NWs were synthesized by catalyst-free direct reaction of gallium vapor and ammonia at 1000 °C [17.64]. Cross-sectional investigation (Fig. 17.15) of these NWs revealed the presence of nanopipes. Particularly cross-

Fig. 17.14a,b Screw-dislocation-driven growth of AlN NWs. (a) Twist contour analysis of AlN whiskers; the dislocation contrast was also clearly observed (after [17.37]); (b) TEM image of AlN NTs (after [17.65])

sectional TEM imaging (Fig. 17.15b) shows interesting spiral bend contours, which were believed to be associated with screw dislocations with large Burgers vectors. This is consistent with the mechanism of NT formation that was discussed previously.

GaN NRs grown by molecular-beam epitaxy were also reported to display dislocation contrast (Fig. 17.15c) [17.75].

$\text{In}_2\text{O}_3/\text{Sn}:\text{In}_2\text{O}_3/\text{Zn}:\text{In}_2\text{O}_3$

In_2O_3 NWs were synthesized using simple thermal evaporation of InN powder at ambient condition [17.66]. Sn/Zn doping was introduced by mixing InN and SnO_2/ZnO powder followed by a similar evaporation process [17.67, 68]. The resulting undoped 1-D In_2O_3 nanostructures were indeed hollow nanopipes (Fig. 17.16a,b), which is one of the characteristics of dislocation-driven growth. More intriguingly, the doped NWs exhibited curious features such as nanoprecipitates, voids, and dislocation loops (Fig. 17.16c,d). It is likely that the formation of the nanopipe to relieve the dislocation strain energy can be locally affected by the

presence of dopants around the dislocation and the formation of nanoprecipitates and loops, leading to the observed discontinuous nanopipe.

Fe:ZnO/Er:ZnO

Fe-doped ZnO NWs were synthesized by thermal evaporation of a mixture of ZnS and Fe_2O_3 powder [17.62]. Eshelby twist was detected using twist contour analysis (Fig. 17.17a), which supports the dislocation-driven growth of these NWs.

Er-doped ZnO tree-like NWs were synthesized using a similar thermal evaporation method except that the precursors were ZnO and Er_2O_3 [17.63]. The twist of the NW trunk was evidenced by the rotation of the branches, which is indicative of the dislocation-driven growth of the trunk (Fig. 17.17b,c).

17.4.2 Solution-Phase Synthesis

Direct Hydrolysis

The hydrolysis reaction is probably one of the simplest types of chemical reactions, yet it is a versatile

Fig. 17.17a–c Screw-dislocation-driven growth of undoped and doped ZnO NWs. **(a)** Twist contour analysis of an Fe : ZnO NW (after [17.62]) and **(b,c)** SEM images of tree-like Er : ZnO NWs (after [17.63])

route to produce many important metal oxides at large scale in low-temperature aqueous solutions. ZnO, the first solution-grown dislocation-driven nanomaterial to be demonstrated, was synthesized via direct hydrolysis of Zn^{2+} in the presence of hexamethylenetetramine (HMT) as the precipitation reagent and pH buffer [17.20]. The details of the synthesis and characterization of ZnO have been discussed in previous sections. This example provides the general framework for designing the rational synthesis of anisotropic nanomaterials driven by screw dislocations. The understanding on how to control the concentration of the precursor metal ions and therefore the supersaturation level for hydrolysis in order to favor dislocation-driven crystal growth kinetics may enable rationally designed low-cost NW/NT production for practical applications. In many cases, the direct products of the hydrolysis reactions are metal oxyhydroxides and hydroxides, depending on their surface energetics, size, and environment [17.76], so that a secondary, thermal annealing treatment might be needed to form the desired metal oxides.

Iron Oxyhydroxide. Iron oxyhydroxide (FeOOH) NWs were synthesized using a continuous flow reactor (CFR) with flow of low-concentration FeCl_2 aqueous solution and co-flow of iron microparticles [17.58]. The CFR allows a *constant* low supersaturation level and enables indefinite growth time for the NWs. The contrast between the product morphologies seen for a CFR reaction and a static hydrothermal reaction with comparable conditions is drastic: there are copious amounts of fairly uniform NWs (Fig. 17.18a) for the CFR reactions, while the static hydrothermal reaction yields mainly microparticles with sparse NW growth (Fig. 17.18b). Defective particles were still produced at the initial stage of the growth where a spike of precursor supersaturation occurred, likely providing the source of dislocations, as evidenced by the observation of the seed particles at the end of the NWs (Fig. 17.18b, inset). Dislocation contrast (Fig. 17.18c), Eshelby twist

(Fig. 17.18d), and hollow structures were readily observed using TEM, confirming the dislocation-driven growth of these NWs.

The hydrolysis reaction to form FeOOH is

Direct hydrolysis of low-concentration Fe^{3+} solution seems to be the most intuitive way to gain good control of the supersaturation. However, the problem is that the hydrolysis of Fe^{3+} is so favorable (K_{sp} for $\text{Fe}(\text{OH})_3 = 4 \times 10^{-38}$) and fast that preventing such favorable hydrolysis (high supersaturation) requires an

Fig. 17.18a–d Screw-dislocation-driven growth of α -FeOOH NWs. **(a)** SEM images of α -FeOOH NWs yielded from a CFR reaction. **(b)** SEM images of α -FeOOH NWs yielded from a static hydrothermal reaction. **(c,d)** TEM characterization of α -FeOOH NWs. **(a)** Zero-beam bright-field image showing the dislocation contrast. **(d)** Twist contour analysis of an α -FeOOH NW

extreme low pH. In contrast, Fe^{2+} ions do not hydrolyze and precipitate significantly even at near-neutral pH because the K_{sp} for $\text{Fe}(\text{OH})_2$ is 8×10^{-16} , but they can be readily oxidized to Fe^{3+} by dissolved oxygen in the aqueous solution,

Secondly, the presence of Fe metal can reduce Fe^{3+} back to Fe^{2+} ions and therefore guarantee a low concentration (supersaturation) of Fe^{3+} as dictated by the $\text{Fe}^{3+}/\text{Fe}^{2+}$ redox equilibrium,

By coupling these two *protection* schemes (low-concentration flow and redox equilibrium) to the original hydrolysis reaction, a low supersaturation of Fe^{3+} ions can be maintained to guarantee slow and controlled hydrolysis, which favors dislocation-driven 1-D crystal growth. Unlike other reports of iron oxide/oxyhydroxide nanomaterial syntheses where either surfactants or organic ligands were used and argued to be important in the NW synthesis [17.77–80], this method merely requires the simple inorganic precursors Fe^{2+} and Fe.

$\text{Co}(\text{OH})_2$. $\text{Co}(\text{OH})_2$ NWs are an intermediate product during the synthesis of Co_3O_4 NWs, where cobalt nitrate is hydrolyzed in the presence of concentrated ammonia ($\text{NH}_3 \cdot \text{H}_2\text{O}$) [17.59]. The $\text{Co}(\text{OH})_2$ NWs started to grow 2 h after initiation of the reaction. NH_3 can form a series of complex compounds with Co^{2+} ions, and thus a concentrated NH_3 environment effectively reduces the concentration/supersaturation of the free Co^{2+} ions to favor dislocation-driven growth. Dislocation contrast was clearly observed in the as-synthesized $\text{Co}(\text{OH})_2$ NWs under TEM (Fig. 17.19). Unfortunately rigorous two-beam and twist contour analysis were not available, likely due to instability

of the hydroxide species under vacuum and the high-energy electron beam.

Redox Reaction

In contrast to hydrolysis reactions where single precursor ions account for the supersaturation level of the system, in a redox reaction the supersaturation is necessarily determined by both the reducing reagent(s) and the oxidizing reagent(s). Thus, using the concentration of the precursors to describe the supersaturation level in a redox system becomes ambiguous. Indeed, in this case, the best way to represent the equilibrium position of the chemical reaction (and crystal growth) is the electrochemical potential: chemical equilibrium is reached when the electrochemical potential of the reaction is zero. The supersaturation of the redox reaction system is simply the electrochemical overpotential. By tuning the electrochemical potential to be slightly over zero, the low-supersaturation condition is achieved, which favors the dislocation crystal growth regime. The necessity for multiple reactant species increases the complexity of controlling the supersaturation; nevertheless, by understanding this complexity, we can achieve better control of the supersaturation of such redox reactions to promote dislocation-driven NW growth.

Copper (Cu) NWs. Cu represents an entirely different class of materials, metals, which again demonstrates the generality of the dislocation-driven growth mechanism. Cu NWs were initially synthesized by reducing Cu^{2+} ions using hydrazine (N_2H_4) in the presence of ethylenediamine (EDA) and concentrated sodium hydroxide (7 M NaOH) in a closed vial [17.60]. The main reaction taking place to form Cu NWs is

The OH^- ion plays dual roles in the reaction: firstly, it provides a suitable pH condition that allows the redox reaction to occur (the electrochemical potential is dependent on the solution pH); and secondly, it is intrinsically a ligand that can complex with Cu^{2+} to form $\text{Cu}(\text{OH})_4^{2-}$. This complexation lowers the activity (supersaturation) of the Cu^{2+} ions, which promotes the dislocation-driven growth mechanism. Moreover, EDA is a strong complexing ligand (rather than a surfactant) capable of binding with Cu^{2+} , thus further lowering the supersaturation of the system.

Dislocation contrast was observed in many as-synthesized Cu NWs. Rigorous TEM analysis under

Fig. 17.19 Schematic illustration of dislocation-driven growth of $\text{Co}(\text{OH})_2$ NWs and their conversion into Co_3O_4 NWs (after [17.59])

strong two-beam conditions characterized the Burgers vector direction of the dislocation to be $[110]$, which is a pure screw dislocation (Fig. 17.20). Twist contour analysis confirmed the presence of an Eshelby twist structure and quantified the magnitude of the Burgers vector to be $1/2 [110]$, which is the most common Burgers vector in the face-centered cubic (fcc) structure [17.27]. Furthermore, hollow NTs of Cu were present occasionally.

Understanding of the dislocation-driven growth of Cu NWs allows improved synthesis under a much milder chemical environment. The static reaction (17.23) has two drawbacks: firstly, an extremely high concentration of NaOH (7 M) is required; and secondly, NW lengths are limited due to precursor depletion. Understanding and controlling the supersaturation of the crystal growth is the key to promote dislocation-driven growth. For the redox reaction between Cu^{2+} and N_2H_4 , the change in the free Cu^{2+} ion concentration only affects one half-cell reaction for supersaturation control. Tuning the concentration of N_2H_4 also influences the supersaturation of the reaction system. One of the roles of NaOH is complexing Cu^{2+} and reducing the concentration of free Cu^{2+} ions; thus, by compensating the reduction in NaOH concentration with an increase in the other complexing ligand, EDA, low supersaturation can be maintained and successful dislocation-driven NW growth can still be achieved. Indeed, a modified static reaction with a much lower concentration of NaOH ($\text{pH} \approx 12$) still led to the formation of Cu NWs. Since EDA is a much stronger ligand ($\beta[\text{Cu}(\text{EDA})_2] = 10^{20}$) than OH^- ($\beta[\text{Cu}(\text{OH})_4^{2-}] = 10^{16}$), a modest increase in EDA concentration can sufficiently compensate for a two order of magnitude drop in NaOH concentration. Furthermore, according to reaction (17.23), OH^- ions participate in the redox reaction that forms Cu, thus reducing the NaOH concentration also lowers the redox overpotential and crystal growth supersaturation, thus favoring dislocation-driven growth. NWs yielded from this protocol are typically $\approx 5 \mu\text{m}$ in length and 200–300 nm in diameter with slight tapering (Fig. 17.21a,b), indicating that precursor depletion occurs as the reaction proceeds. The precursor depletion problem could be solved using a CFR, which yielded much longer Cu NWs (about $30 \mu\text{m}$ on average, up to $50 \mu\text{m}$, Fig. 17.21c,d) with uniform diameter distribution.

Cuprous Oxide (Cu_2O) NWs. Natural Cu_2O (cuprite) mineral whiskers were among the earlier examples where axial screw-dislocation contrast was clearly observed in

Fig. 17.20 TEM evidence proving the dislocation-driven growth of Cu NWs/NTs (after [17.60])

Fig. 17.21a–d Improved synthesis of Cu NWs. SEM images of Cu NWs synthesized under modified conditions via static reaction (a,b) or CFR reaction (c,d) (after [17.60])

TEM [17.38]. Recently, Cu_2O NWs were synthesized using a low-concentration Fehling's reaction where Cu^{2+} ions were reduced by glucose in the presence of sodium hydroxide and sodium tartrate [17.48]. The formation of the Cu_2O in solution is similar to that of Cu in terms of the redox chemistry. However, glucose is a much weaker reducing reagent, so Cu(II) can only be reduced to Cu(I) species. Tartrate forms a Cu^{2+} –tartrate coordination complex ($K_f \approx 10^7$) that both prevents $\text{Cu}(\text{OH})_2$ precipitation and serves to reduce the concentration of free Cu^{2+} ions, lowering the supersaturation to promote dislocation-driven NW growth.

TEM characterization of these NWs only detected a few of them with dislocation contrast, since most of the NWs were actually formed by filling up the initially formed Cu_2O NTs (Fig. 17.22). Besides the dislocation contrast and spontaneous formation of NTs, the observation of the Eshelby twist in these NTs/NWs also confirms that their growth is driven by screw dislocations.

17.4.3 Solution Growth of 2-D Nanoplates

As discussed earlier, the spiral step edges generated by screw dislocations can be chemically modified, re-

Fig. 17.22 TEM evidence proving the dislocation-driven growth of Cu_2O NWs/NTs (after [17.48])

sulting in disparate step velocities. This is the key to achieve desirable anisotropic growth driven by screw dislocations. Despite the drastic differences in morphologies between 1-D NWs/NTs and 2-D nanoplates, dislocation-driven crystal growth is common to both

and the subtle kinetics of spiral step propagation associated with dislocation growth can be used to explain each. The characterization of dislocation-driven 2-D nanomaterial is more straightforward as the spiral step edges lying on the basal plane of the nanoplates can be directly observed using both scanning electron microscopy (SEM) and atomic force microscopy (AFM). Dislocation-driven 2-D growth has already been proven to be responsible for the growth of a variety of materials including zinc hydroxysulfate (ZHS), $\text{Co}(\text{OH})_2$, $\text{Ni}(\text{OH})_2$, and gold nanoplates. Here, their synthesis and characterization are discussed.

Zinc Hydroxysulfate (ZHS)

In a typical synthesis of ZHS nanoplates, aqueous solutions containing ZnSO_4 , $\text{Zn}(\text{NO}_3)_2$, and hexamethylenetetramine (HMT) are heated in sealed glass vials [17.50]. A piece of Si substrate is placed in the solution to collect the nanoplate products. SEM re-

Fig. 17.24a–c Other examples of dislocation-driven nano-plates. SEM images of representative nanoplates of (a) α -Co(OH)₂, (b) Ni(OH)₂, and (c) gold, highlighting the screw dislocation spirals (after [17.50])

vealed that the substrates are densely coated with many nanoplates (Fig. 17.23a) after this reaction procedure. In contrast, in the absence of ZnSO₄, ZnO nanorods are the exclusive reaction product [17.81, 82]. All of these nanoplates were found to contain screw dislocations using contact-mode AFM. For the representative hexagonal morphology, these dislocations were single-source dislocations and the core was located at the very center of the nanoplate (Fig. 17.23b,c). Interestingly, simple bright-field optical microscopy revealed the thin-film interference pattern generated between the surface of a nanoplate and the reflective silicon substrate surface, which demonstrated the geometry and thickness variation of the nanoplate and the location of the dislocation cores (Fig. 17.23e). Due to the dislocation hillocks, these nanoplates are in fact *pyramids* with extremely high width-to-thickness ratios. Multiple dislocation centers with different chirality were observed in larger and more complex nanoplate morphologies (Fig. 17.23d). Moreover, when nanoplates are grown on silicon surfaces with native oxides, the dislocation spirals are heavily etched, clearly revealing their morphology under standard SEM (Fig. 17.23f). Similar zinc hydroxydodecylsulfate (ZHDS) nanoplates were also reported to grow via the dislocation-driven mechanism [17.83].

Co(OH)₂

Co(OH)₂ nanoplates (Fig. 17.24a) were synthesized via direct hydrolysis of cobalt(II) chloride in the presence

of HMT as the pH buffer [17.50]. The α -Co(OH)₂ samples had high densities of nanoplates that all showed dislocations. However, due to their smaller diameter and wider terrace widths, they did not display the same dramatic thin-film interference under optical microscopy.

Ni(OH)₂

Ni(OH)₂ nanoplates (Fig. 17.24b) were synthesized similarly via direct hydrolysis of nickel(II) acetate in the presence of HMT [17.50]. The Ni(OH)₂ nanoplates were equally dense but thinner than ZHS and exhibited a propensity to form flower-like structures [17.84] similar to the off-shooting nanoplates seen in ZHS (Fig. 17.23a).

Gold

Gold nanoplates (Fig. 17.24c) were synthesized by reducing chloroauric acid (HAuCl₄) in aqueous solution using salicylic acid [17.50]. Consistent with literature [17.85], gold nanoplates form as triangles and hexagons as well as truncated triangles; however, only a small percentage of these plates clearly show dislocation spirals. Moreover, the step heights, previously estimated to be ≈ 100 Å [17.85], and thus the Burgers vectors of the dislocations observed in gold plates, are very large in comparison with the (111) spacing of 2.35 Å for gold. The surface of gold nanoplates is the (111) plane, and this should be the elementary Burgers vector.

17.5 Rational Growth of Dislocation-Driven Nanomaterials – General Strategies

The empirical understanding gained from the examples discussed above provides general guidelines for dislocation-driven nanomaterial growth, which requires two basic ingredients:

1. The presence of dislocation sources (*seeds*) to propagate the growth
2. A suitable low supersaturation condition for promoting dislocation-driven growth over LBL and other crystal growth modes [17.19].

We discuss these two aspects separately.

Manipulation of the supersaturation level to favor dislocation-driven growth of nanomaterials needs

to be specific depending on the chemistry of the materials. In general, an overall low concentration (in solution) or vapor pressure of reactants is preferred. Particularly in solution growth, introduced ligand compounds can complex with free ions of the precursor and thereby effectively reduce the activity (supersaturation) of the reactants. The versatile nature of coordination chemistry can be exploited to rationally tune the supersaturation level to promote dislocation-driven growth. The role of the *surfactants* commonly employed in many solution syntheses might need to be reexamined from the perspective of controlling the supersaturation in the solution system, since many of them are multidentate ligands. Redox chemical equilibrium or other chemical equilibrium systems can also result in a buffering effect and allow the supersaturation level to be effectively controlled. Furthermore, the employment of a continuous flow reactor (CFR) (Fig. 17.25a) can allow better control over the supersaturation than the commonly practiced closed-system growth (referred to as *static growth* later) does. Static growth, where precursors are introduced at the beginning and allowed to react to completion, suffers from a significant decline in precursor concentration (supersaturation) during the course of the reaction (Fig. 17.25b), which leads to irregular growth kinetics that are difficult to deconvolute and control. CFR can maintain a constant low supersaturation targeting the dislocation-driven regime and enable indefinite growth times.

On the other hand, to date, there are few rational routes to engineer the dislocation source. To create dislocation sources, the most common and straightforward approach is to generate defective seed crystals [17.86] under high-supersaturation reaction conditions. Ideally, the seeds are prepared separately from the growth system [17.20]; nevertheless, oftentimes an initial spike of high supersaturation of precursors in the growth system can achieve a similar objective [17.18, 39, 48, 58, 60]. Screw dislocations can also come from other crystalline substrate surfaces, since they are always present in crystals. Screw dislocations in defect-rich substrates, such as GaN thin film grown on sapphire, have been utilized to *seed* dislocation-driven growth of vertically epitaxial ZnO NWs (Fig. 17.26) from solution [17.47]. The density of the ZnO NWs is comparable to the densities of screw dislocations found in such GaN thin films, and NWs are found to grow only from the disloca-

Fig. 17.25a,b Schematic of continuous flow reactor (CFR) and supersaturation profiles. **(a)** Consisting of a jacketed chromatographic column, a heated circulating water bath, and a dual-head peristaltic pump, the CFR enables precise control over reaction temperature, precursor solution composition/flow rate, substrate location, and reaction time (heated circulating water bath not shown). **(b)** Comparison of schematic supersaturation profiles for closed-system reactions and the CFR reaction (after [17.20])

tion etch pits formed on the surface of GaN substrates that have been cleaned aggressively. It is possible that the *seeding layers* of ZnO film or other materials initially formed on various substrates that are crucial for successful growth of NWs of ZnO or other materials could play similar roles; i.e., such *seeding layers* could in fact be the highly defective substrates that contain numerous screw dislocations that then initiate dislocation-driven growth of NWs. Furthermore, this *threading* dislocation growth that propagates from substrate to NW of another material lays the foundation for the creation of NW heterostructures driven by dislocations.

17.6 Applications

The dislocation-driven nanomaterial growth mechanism is a general mechanism that can apply to any material. It does not require catalysts that form eutectics with the targeted nanomaterials and does not depend on the same material compatibility; therefore, more materials can be grown in the anisotropic fashion dictated by the dislocation. Another significant advantage of dislocation-driven growth is that it can be conveniently implemented in low-temperature aqueous solutions, which can lead to less expensive and energy-intensive production of anisotropic nanostructures of many useful materials. Furthermore, dislocation-driven growth operates at low supersaturation, which is essentially the near-equilibrium state. In this sense, the consumption of the precursors is low, so that the synthesis can be more cost-efficient.

Particularly for the significant applications of NWs and NTs in renewable energy, such as solar energy conversion, battery electrodes, and thermoelectrics, large amounts of ecologically sustainable nanomaterials made at low cost are demanded to address the large-scale energy challenges. Some Earth-abundant semiconductor materials that are promising for solar energy and other renewable energy applications suffer from poor mobility, carrier density, or minority carrier diffusion length. For many of these unconventional abundant materials, new design concepts based on nanoscale materials such as NWs may enhance their utility, because the nanoscale dimensions may circumvent their shortcomings or make them much more tolerable for applications [17.6, 87–90].

A good example are the nanomaterials of various iron-based compounds such as α -Fe₂O₃ (hematite,

Fig. 17.26 Schematic illustration of dislocation-driven growth of ZnO NWs seeded by screw dislocations in GaN substrates (after [17.47])

bandgap 2.1 eV) [17.89, 91], β -FeS₂ (pyrite, bandgap 0.95 eV) [17.92, 93], and FeF₃ [17.94, 95]. Because iron (Fe) is the fourth most abundant element in the Earth's crust, these compounds have the potential to meet or exceed the annual worldwide energy demand at a significantly lower material production cost over traditional or leading solar materials that are based on rare elements such as indium, gallium, and selenium [17.96]. For example, hematite has been intensively studied because it is a promising photoanode material for catalyzing photoelectrochemical (PEC) water splitting, yet the performance of hematite electrodes still suffers from its poor semiconducting properties [17.89, 91]. NWs of hematite could circumvent its shortcomings, and they can be conveniently converted from screw-dislocation-driven α -FeOOH NWs via thermal annealing [17.58].

Iron fluoride (FeF₃), on the other hand, is a promising high-capacity Li-ion battery cathode material that is much cheaper than the current lithium cobalt oxide (LiCoO₂) cathode material [17.94]. However, such promise has been held back by the slow ionic diffusion and low conductivity of FeF₃. FeF₃·3H₂O NWs have been synthesized following the guideline of dislocation-driven NW growth at gram scale in solution using low-concentration iron(III) nitrate and hydrofluoric acid as precursors (Fig. 17.27a) [17.95]. Due to the high solubility of FeF₃·3H₂O in water (5.92 g/100 g H₂O at 25 °C), ethanol was chosen as the solvent, in which FeF₃·3H₂O dissolves very little [17.97]. F[−] is a good complexing ligand for Fe³⁺ to make the stable FeF₆^{3−} complex ($K_f = 10^{15.04}$) [17.98], which effectively maintains the low supersaturation environment

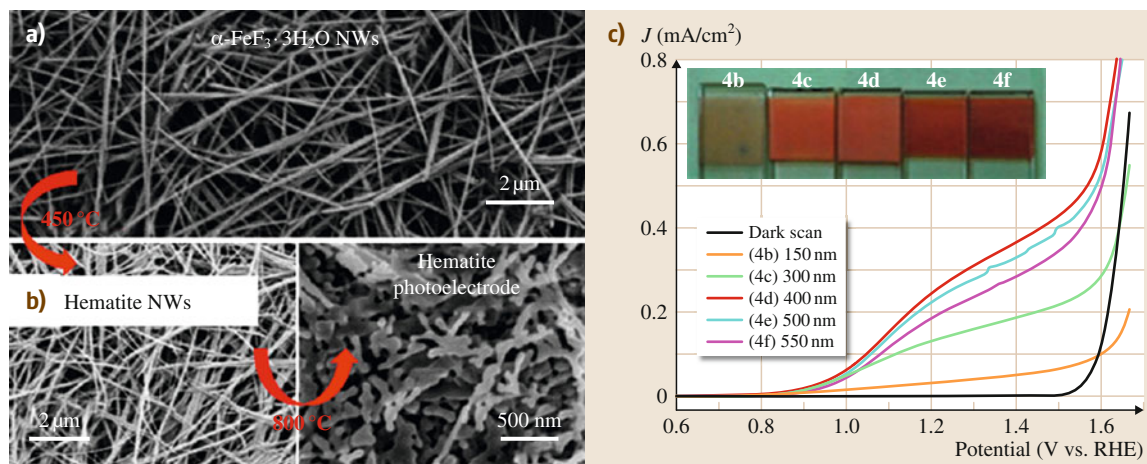

Fig. 17.27a,b Application of screw-dislocation-driven nanomaterials in solar energy conversion. SEM images of as-synthesized $\alpha\text{-FeF}_3 \cdot 3\text{H}_2\text{O}$ NWs (a) and converted hematite NW photoelectrode (b); photocurrent densities J versus bias voltage (V versus RHE) under AM1.5 G simulated solar light at 100 mW/cm² for hematite NW photoelectrodes of various thicknesses (after [17.16])

to favor NW growth. The following two reactions are responsible for NW growth:

The H_2O in the second equation comes from the hydrated Fe(III) salt and HF solution. F^- and H_2O should be considered as both reactants and ligands to the Fe^{3+} ions. This equilibrium likely helps maintain a constant and low supersaturation of $\text{FeF}_3(\text{H}_2\text{O})_3$, which is considered to be the precursor of crystal

growth for $\alpha\text{-FeF}_3 \cdot 3\text{H}_2\text{O}$ [17.99, 100]. The growth of $\alpha\text{-FeF}_3 \cdot 3\text{H}_2\text{O}$ NWs is likely driven by screw dislocations given the low supersaturation conditions applied in the synthesis [17.18–20], but the as-grown NW samples are not electron-beam stable due to the easy loss of lattice water, and thus it is impossible to either confirm or disprove this hypothesis. These $\alpha\text{-FeF}_3 \cdot 3\text{H}_2\text{O}$ NWs can be readily converted to semiconducting $\alpha\text{-Fe}_2\text{O}_3$ (hematite) NWs (Fig. 17.27b), which exhibited respectable PEC performance of 0.54 mA/cm² photocurrent density at 1.23 V versus reversible hydrogen electrode potential (Fig. 17.27c).

17.7 Summary and Perspectives

This chapter has illustrated that the screw-dislocation-driven growth mechanism is applicable to many nanomaterials grown in solution or vapor phase, with the families of materials involved ranging from oxides and hydroxides, nitrides, chalcogenides, to metals. As the understanding of dislocation-driven growth deepens, this list of examples will continue to expand in the future. The procedures for microstructural characterization and confirmation of dislocation-driven growth discussed above can guide future work on searching for dislocation-driven growth. Moreover, the dislocation mechanism and elasticity theory could be used to explain other intriguing crystal growth phenomena that

are commonly observed but often unconvincingly explained.

Fundamental studies on dislocation-driven nanomaterial growth not only enhance the understanding of anisotropic crystal growth but also open up the exploitation of large-scale, low-cost solution growth for rational catalyst-free synthesis of anisotropic nanomaterials for diverse applications, such as those for renewable energy. The discussion in Sect. 17.5 established a general framework for rational design of dislocation-driven growth of nanomaterials.

It can also be expected that by utilizing dislocations one can fabricate more complex structures, such as het-

erojunctions with abrupt crystal interface, which could be of more interest than simple NWs/NTs for many applications, including solar energy conversion [17.101]. Engineering the locations and density of dislocations in substrates can enable control over the location and morphology of dislocation-driven NWs. Furthermore, it is interesting to investigate how a single axial screw

dislocation affects the physical properties of a single NW, including its electrical and mechanical properties. Deeper understanding of the screw-dislocation-driven growth of nanomaterials and their properties, and better control over such growth, will lead to a new stage of nanomaterial design and production for various applications.

Glasses on th

18. Glasses on the Nanoscale

Hellmut Eckert, Sidney J.L. Ribeiro, Silvia H. Santagneli, Marcelo Nalin, Gael Poirier, Younès Messaddeq

Homogeneity is supposed to be a particular feature of glasses leading to the well-known isotropic optical properties and mechanical behavior. However, in some cases heterogeneity can be detected at the molecular scale. Amorphous phase separation, incipient crystallization, and concentration gradients are representative of heterogeneities that can be exploited in the preparation of nanostructured glass-derived materials.

Nuclear magnetic resonance (NMR) is one of the spectroscopic methods widely used for characterization of the structure of glassy materials, and the basis of new NMR techniques for study on the medium range is first presented in Sect. 18.1. Afterwards, nanoceramics with small crystal volume fractions and crystal dimensions of some nanometers are described, displaying new emerging properties (Sect. 18.2). Metal nanoparticles, quantum dots, and lanthanide-containing nanocrystals are some of the structures that can be grown in glasses (Sect. 18.2). Glasses are unique in the sense that they can be obtained in any mor-

phology, and a final perspective is presented for glass waveguides containing these nanoscale heterogeneities (Sect. 18.3).

Three of the most widely accepted definitions of *glasses* in classic textbooks [18.1–3] are as follows:

1. *Glasses are amorphous solids.*
2. *Glasses are amorphous materials displaying T_g (glass-transition temperature).*
3. *Any state, thermodynamically metastable, with frozen-in properties can be considered a glass.*

All these definitions take into account the out-of-equilibrium situation characterizing these materials, whose preparation and main properties have been known for centuries.

The first definition indeed highlights the noncrystalline or amorphous nature of glass, i.e., the absence

of translational symmetry. In this case it is imperative to add to the glass definition the technique used in order to check for crystallinity. In fact, powder x-ray diffraction (XRD) and electron diffraction (ED) would check for the presence of crystal domains at different volume scales. A well-defined diffraction profile could be obtained from a single nanocrystal if one uses ED. However, if the nanocrystals represent a small volume fraction of a glass sample (typically up to around 3%), they would be invisible in a diffraction pattern obtained under standard experimental conditions in commercial diffractometers.

The second definition leads one to discard amorphous materials not presenting enough internal stability as seen in *real glasses* to allow the observation of

a second-order-like phase transition (the so-called glass transition) [18.2].

The third definition, more general than the previous ones, includes all metastable phases that can be obtained for a given system. Nonequilibrium thermodynamics provides the basis for their study [18.3].

In any case, homogeneity is supposed to be a particular feature of glasses. Homogeneity leads to isotropic optical properties and mechanical behavior, which are characteristics of glasses. However, in some cases, several sophisticated characterization techniques have suggested heterogeneity at the molecular scale. Amorphous phase separation, incipient crystallization nuclei, and concentration gradients would be representative of such heterogeneities. In fact the common practice among glass producers is to avoid compositions displaying such not well-behaved properties in order to obtain good-quality glasses. As pointed out by Roy [18.4], theoretical approaches to glass theory and formation all confirm the ubiquity of nanoheterogeneity.

The important point to be stressed is that these heterogeneities can be exploited in the preparation of nanostructured glass-derived materials. In the preparation of so-called *glass ceramics*, amorphous phase separation or formation of nuclei with subsequent growth can both be perfectly controlled. Glass ceramics or nanoceramics displaying small crystal volume fractions and crystal dimensions of some nanometers can be obtained with new emerging properties. Metal nanoparticles, quantum dots, and lanthanide-containing nanocrystals are some of the interesting structures that can be grown in glasses, in most cases by selected thermal treatment or focused ultrafast (< ps) laser pulses.

As also stated by Roy in [18.4], glass provides one of the earliest examples of controlled use of science at the nanolevel in a well-established gigatechnology. The manipulation of matter at the nano- and sub-nanoscale has been the basis of the development of glasses and glass ceramics for centuries [18.4]. Therefore, nanoscale characterization plays a fundamental role in the almost endless list of potential applications that can be foreseen.

This chapter focuses on some interesting materials obtained from nanoscale control of glass systems. Firstly, the potential of new nuclear magnetic resonance (NMR) techniques in the study of medium-range order is presented.

Secondly, transparent glass ceramics are presented. Oxyfluoride glasses present heterogeneities at the molecular scale. These heterogeneities may be used to explain the unusual ionic conductivities observed experimentally. Moreover, by well-controlled heat treatments, fluoride nanocrystals may be obtained, while transparency levels remain the same as for the mother glass. It is shown that glass systems with lanthanide-containing nanocrystals well dispersed in the glass bulk present new emerging optical properties due to the synergy between the crystal and glass components.

Finally, the possibility of obtaining metal nanoparticles and quantum dots in bulk glasses is also reviewed. The exploration of quantum confinement effects in the case of semiconductor systems and the entirely new emerging area of plasmonics related to metal nanoparticles take advantage of the optical properties of these nanoscale systems.

The chapter ends with a brief section presenting concluding remarks and potential future applications and tendencies.

18.1 Studying Medium-Range Order in Glasses and Nanoceramics

Compared with crystalline solids, glasses present a formidable challenge in terms of structure elucidation. Owing to the lack of long-range periodicity in the glassy state, diffraction techniques are fairly powerless, and structural concepts typically emerge from joint interpretation of numerous, complementary spectroscopic experiments. For a comprehensive view, glass structure must be discussed on different length scales, namely:

1. *Short-range order* involving only the first atomic coordination spheres (distance region 0.15–0.3 nm)

2. *Second-nearest-neighbor environments* (0.3–0.5 nm)
3. *Nanostructure* (0.5–3 nm)
4. *Mesostructure* (3–500 nm) and, finally
5. *Microstructure* (> 500 nm).

Spectroscopic methods such as NMR, Raman, photoelectron (PE), and extended x-ray absorption fine structure (EXAFS) provide primarily local information about the first coordination sphere. Thus, EXAFS offers accurate bond distances and coordination numbers,

while **NMR** spectra contain complementary information about bonding and site geometries, allowing quantitative identification of nearest-neighbor atomic species and specific types of coordination polyhedra [18.5, 6]. While the utility of solid-state **NMR** for characterizing the short-range order of glasses was reviewed nearly 20 years ago [18.6], the present contribution concerns the study of structural issues on the 0.3–3 nm length scale (domains 2 and 3), particularly in the sub-nanometer region commonly denoted as *medium-range structure*. The structural issues addressed include:

1. The *connectivity* between different network former species
2. *Distance correlations* involving network former and network modifier species
3. The overall *spatial distribution* of the network modifier ions.

The most powerful **NMR** approach to such questions is the measurement of internuclear magnetic dipole–dipole couplings, which have a straightforward relationship to internuclear distances and their distributions. Information beyond the second coordination sphere includes nanoclustering and/or segregation phenomena, up to macroscopic phase-separation effects and crystallization mechanisms.

Solid-state **NMR** is based on the magnetic moment of nuclei carrying spin angular momentum I . The latter is subject to the fundamental laws of orientational quantization, according to

$$|\hat{I}_z| = m\hbar, \quad (18.1)$$

where m , the orientational quantum number, can adopt values within the range $(+I, I-1, \dots, -I+1, -I)$, and I is the nuclear spin quantum number. To detect nuclear magnetic moments, an external magnetic field is applied, represented by the magnetic flux density B_0 . The resulting *Zeeman interaction*, represented by the Zeeman Hamiltonian,

$$H_z = -\mu_z B_0, \quad (18.2)$$

lifts the energetic equivalence of these orientational states and causes a splitting into $2I+1$ individual levels with energies

$$E_m = -m\gamma\hbar B_0. \quad (18.3)$$

By application of electromagnetic waves satisfying the Bohr condition $\Delta E = \hbar\omega$, allowed transitions between adjacent orientational states can be stimulated and observed spectroscopically. To a first approximation, the angular resonance frequency is given by

$$\omega = \gamma B_0. \quad (18.4)$$

This resonance frequency is identical to the angular frequency, the so-called *Larmor frequency* ω_L , with which the nuclei precess in the applied magnetic field. Since the values of γ differ greatly for different kinds of nuclei, **NMR** spectroscopy is intrinsically element selective as, at a given magnetic field strength, different kinds of nuclei have different resonance and precession frequency ranges.

Figure 18.1 gives an overview of the elements amenable to solid-state **NMR** and summarizes some

of their isotopes' general features. About 50% of the elements lend themselves to solid-state NMR investigation in a rather facile manner. Limitations arise in the case of low natural abundances of the relevant NMR isotope, low values of magnetic moments, and – in particular – nuclear electric quadrupole interactions, which compete with the Zeeman interaction for nuclear spin alignment. If the quadrupole interaction is of similar strength to the Zeeman interaction or even dominant, obtaining an interpretable NMR signal will be difficult if not impossible. Likewise, if the atom under investigation shows paramagnetism originating from unpaired electron spins, no NMR signal can be obtained from its nucleus by standard measurement techniques, because the nuclear Zeeman levels are strongly affected by paramagnetic interactions and relaxation broadening effects. Consequently, the opportunities for measuring NMR of transition and rare-earth elements are severely limited.

With typical values of applied magnetic flux densities of the order of magnitude of 1 T, the frequencies lie in the radiowave region (10^7 – 10^9 MHz). The precession frequencies are measured using pulsed excitation, followed by Fourier transformation of the time-domain response signal, the so-called free induction decay.

While the nuclear precession frequencies are usually dominated by the Zeeman interaction, they are additionally influenced by a number of internal interactions, whose parameters reflect the details of the local structural environment and whose effect on the energy levels can be calculated using standard perturbation theory. The total spin Hamiltonian relevant in solid-state NMR can be written as

$$H_{\text{total}} = H_z + H_{\text{rf}} + H_{\text{cs}} + H_{\text{D}} + H_{\text{J}} + H_{\text{Q}}, \quad (18.5)$$

where $H_z + H_{\text{rf}}$ describe the interactions of the nuclear magnetic moments with the applied magnetic field and the oscillating magnetic field component associated with the externally applied radiofrequency waves. In contrast, $H_{\text{cs}} + H_{\text{D}} + H_{\text{J}} + H_{\text{Q}}$ define the relevant Hamiltonians of distinct types of internal interactions, namely:

1. The magnetic interactions of the nuclei with the surrounding electrons (*magnetic or chemical shielding*), described by H_{cs}
2. The internuclear *direct and indirect magnetic dipole–dipole interactions*, described by H_{D} and H_{J} , respectively
3. Interactions between the electric quadrupole moments of spin $> 1/2$ nuclei and the electrostatic field

gradients surrounding these nuclei (*quadrupole interaction*), described by H_{Q} .

In the solid state, all of these interactions are anisotropic and hence cause line broadening in powdered samples. A particular strength of solid-state NMR lies in the fact that the Hamiltonian of (18.5) can be simplified, using special *selective averaging* techniques. One particularly effective technique is the *magic angle sample spinning* (MAS) method which removes all of the anisotropic interactions, producing high-resolution spectra. By combining MAS with special dipolar recoupling techniques, one can look selectively at individual parts of the spin Hamiltonian under the high-resolution conditions afforded by MAS. Using the potential of *multidimensional spectroscopy*, it is further possible to separate different spin interactions into two (or more) different time (and frequency) domains and to correlate them with each other. The design of new pulse sequences is greatly aided by the availability of program packages that calculate the behavior of the spins under the influence of the external and internal interaction Hamiltonians using standard time-dependent perturbation theory [18.5–7]. Especially noteworthy is the program package *SIMPSON*, which enables the simulation of complex NMR experiments under the precise experimental conditions used at the spectrometer [18.8]. This freeware has proven invaluable in the analysis of complex experiments and profoundly influenced NMR research in many laboratories. The following sections describe a number of useful dipolar NMR experiments as well as some theoretical and practical aspects of their application to glassy materials.

18.1.1 Static Dipolar NMR Spectroscopy

Magnetic dipole–dipole couplings between the observed nuclei and those in their vicinity result in a modification of the measured precession frequencies. The effect is distance dependent and anisotropic, depending on the orientation of the internuclear distance vector relative to B_0 , contributing to the NMR line-broadening effects observed in powdered solid samples. There are homonuclear and heteronuclear contributions, whose respective Hamiltonians – within the limit of first-order perturbation theory – are given by the expressions

$$H_{\text{D,homo}} = - \left(\frac{\mu_0}{4\pi} \right) \frac{\gamma^2 \hbar^2}{r_{ij}^3} \left(\frac{3 \cos^2 \theta - 1}{2} \right) \times \left(3 \hat{I}_z^2 - \hat{I}^2 \right), \quad (18.6)$$

$$H_{D,\text{hetero}} = -\left(\frac{\mu_0}{4\pi}\right) \frac{\gamma_I \gamma_S \hbar^2}{r_{IS}^3} \left(\frac{3\cos^2\theta - 1}{2}\right) (\hat{I}_z \hat{S}_z). \quad (18.7)$$

Most importantly, both Hamiltonians are proportional to the inverse cube of the internuclear distance, providing a straightforward connection to geometric structure. The orientational dependence is governed by the term $3\cos^2\theta - 1$, where θ is the angle between the internuclear distance vector and the magnetic field direction. In systems characterized by multiple-spin interactions, the dipolar couplings are characterized by the average mean square of the local field (the second moment), which can be related to internuclear distance distributions by the *van Vleck* formulae [18.9]

$$M_{2,\text{homo}} = \frac{3}{5} \left(\frac{\mu_0}{4\pi}\right)^2 I(I+1) \gamma^4 \hbar^2 \sum_{i \neq j} r_{ij}^{-6}, \quad (18.8)$$

$$M_{2,\text{hetero}} = \frac{4}{15} \left(\frac{\mu_0}{4\pi}\right)^2 S(S+1) \gamma_I^2 \gamma_S^2 \hbar^2 \sum_S r_{IS}^{-6}. \quad (18.9)$$

Thus, homo- or heteronuclear dipolar second moments represent quantitative criteria against which structural models (derived, e.g., from molecular dynamics simulations) can be tested in a rigorous fashion. In the following sections, various experimental techniques for obtaining such dipolar second moments are described and their significance for the structural analysis of glasses is highlighted.

18.1.2 Spin-Echo Decay Spectroscopy

Homonuclear dipolar interactions can be measured selectively by Hahn spin-echo decay spectroscopy, using the pulse sequence shown in Fig. 18.2 [18.10]. For a spin-1/2 system, a plot of normalized echo intensity I/I_0 as a function of evolution time $2t_1$ is only affected by these homonuclear dipole-dipole interactions, while all the other above-mentioned types of interactions affecting solid-state NMR spectra (including heteronuclear dipole-dipole couplings) are refocused. For a multispin system, a Gaussian decay is expected (and observed),

$$\frac{I(2t_1)}{I_0} = \exp\left[-\frac{M_{2,\text{homo}}}{2}(2t_1)^2\right], \quad (18.10)$$

affording a reliable measurement of the homonuclear van Vleck second moment $M_{2,\text{homo}}^{\text{hom}}$.

The method has been widely and successfully applied for examining the spatial distribution of ^{31}P

Fig. 18.2 Timing diagram of the spin-echo decay method. The spin-echo amplitude is measured as a function of the total dipolar evolution time $2t_1$

and ^{19}F spins ($I = 1/2$) in a variety of nonoxide glasses [18.6, 11–15].

The glass systems $(1-x)\text{As}_2\text{S}_3\text{-}x\text{P}_2\text{S}_5$, $(1-x)\text{As}_2\text{P}_2\text{S}_8\text{-}x\text{Ga}_2\text{S}_3$, and $(1-x)\text{GeS}_2\text{-}x\text{P}_2\text{S}_5$ can be cited here as examples of the chalcogenide glasses families. The $(1-x)\text{As}_2\text{S}_3\text{-}x\text{P}_2\text{S}_5$ glass system was studied in [18.12]. ^{31}P NMR together with vibrational spectroscopy results were decisive in reaching the conclusion that P atoms were incorporated into the structure through the formation of molecular-like units dispersed in an As_2S_3 matrix. For low P_2S_5 relative contents, $\text{As}_2\text{P}_2\text{S}_8$ units could be identified, which become progressively interconnected as the P concentration approaches $x = 0.5$. For glasses with $x > 0.5$, there is a coexistence of $\text{As}_2\text{P}_2\text{S}_8$ groups with molecular units connecting more P atoms via P–S–P bridges such as P_4S_{10} or P_4S_9 units. The same techniques were used in [18.13] for the study of the $(1-x)\text{As}_2\text{P}_2\text{S}_8\text{-}x\text{Ga}_2\text{S}_3$ glasses. In this case, for $x < 0.2$, GaS_4E^- groups (E = nonbonding electron) were identified. For higher x values, depolymerization of the $\text{As}_2\text{P}_2\text{S}_8$ units was observed, with the formation of GaPS_4 units with each $\text{PS}_{4/2}$ unit (Q^4) species carrying a single positive formal charge.

In [18.14], neutron diffraction was used together with NMR and Raman spectroscopies in the study of $(1-x)\text{GeS}_2\text{-}x\text{P}_2\text{S}_5$ glasses. P_2S_5 addition was observed not to be in a random, homogeneous fashion. The distribution of P atoms, as reasoned from the ^{31}P M_2 values, was observed to be much more clustered than a random distribution would predict. Moreover, a significant fraction of P atoms were found in strained environ-

ments such as those found in P_4S_{10} and P_4S_9 molecular clusters.

In the next topic of this chapter, transparent glass ceramics obtained in mixed oxyfluoride glasses are described. Nanometric crystals of the β - PbF_2 phase are obtained by heat treatments at selected temperatures, with crystal-like spectroscopic properties emerging from the nanocomposite structure in $PbGeO_3$ - PbF_2 - CdF_2 glasses. Interestingly enough, the M_2 values obtained from ^{19}F NMR measurements show that F-F distances are shorter than those found if homogeneous dispersion of fluoride ions in the glass host is supposed. Fluorine-rich regions at the nanometric scale would explain the interesting properties of these mixed glasses, such as high ionic conductivity and the particular crystallization behavior [18.15].

The spin-echo decay method could be extended to the study of quadrupolar nuclei such as ^{23}Na , using a modified formula that takes into account the peculiar spin dynamics present in dipolar-coupled quadrupolar nuclei [18.17, 18].

$$M_2 = 0.9562 \left(\frac{\mu_0}{4\pi} \right)^2 \gamma^4 \hbar^2 \sum_j r_{ij}^{-6} \quad (18.11)$$

The validity of (18.11) was confirmed experimentally for homonuclear ^{23}Na - ^{23}Na dipole-dipole interactions in crystalline solids, for which the M_2 values are readily calculable from the known crystal structures [18.18].

Fig. 18.3 Dipolar second moment values $M_2(^{23}Na-^{23}Na)$ measured via the ^{23}Na spin-echo decay method, for sodium borate, phosphate, silicate, tellurite, and germanate glasses as a function of cation number density (after [18.16])

Application of this technique to a wide range of oxide glasses provided detailed quantitative information about the spatial distribution of sodium ions in different kinds of oxide glasses [18.16]. Figure 18.3 summarizes these results, plotting the $M_2(^{23}Na-^{23}Na)$ values as a function of number density. The rather different behavior of sodium silicate glasses as opposed to all the other glass-forming systems studied so far is evident from this figure: A more or less constant value of $M_2 = 4.5 \times 10^6 rad^2/s^2$ is observed at Na concentrations below $1.5 \times 10^{28} m^{-3}$, indicating significant clustering of the sodium ions. In contrast, M_2 values are much smaller in sodium borate, phosphate, tellurite, and germanate-based glass systems, and scale linearly with the sodium number density, consistent with a spatial distribution that is more or less random in space. At Na concentrations higher than $1.5 \times 10^{28} m^{-3}$, the M_2 values for the silicate glasses converge with this line, indicating that the sodium distribution can also be considered as random in this composition range. The inhomogeneous distributions of alkaline ions in silicate glasses are consistent with the proposal of *ion-conducting channels*, maintaining the possibility of long-range ion transport even at relatively low cation contents [18.19]. In contrast, this possibility does not exist if the mobile ion distribution is statistical, as this would result in very large average jump distances at low cation contents. On this basis, it is now possible to understand why at a given number density the ionic conductivities of alkali silicate glasses are significantly larger than those of the corresponding alkali borate glasses, as reported in [18.20].

18.1.3 Spin-Echo Double Resonance

It is further possible to use the principle of spin-echo decay spectroscopy for selective measurement of heteronuclear dipole-dipole interactions between an observed spin species I and a different spin species S . In this case, a 180° recoupling pulse is applied to the S spins during the dipolar evolution period [18.21]. The corresponding pulse sequence, termed spin-echo double resonance (SEDOR), compares the spin-echo intensity of the observed nuclei as a function of dipolar evolution time (a) in the absence and (b) in the presence of these recoupling pulses. Experiment (a) produces a decay $F(2t_1)/F_0$, which is largely governed by homonuclear dipole-dipole interactions, while experiment (b) results in an accelerated decay reflecting the contribution from the heteronuclear dipole-dipole

Fig. 18.4 Illustration of the SEDOR method, applied to the measurement of lithium–lithium interactions on glasses having ${}^6\text{Li}$ isotopic content of 95%

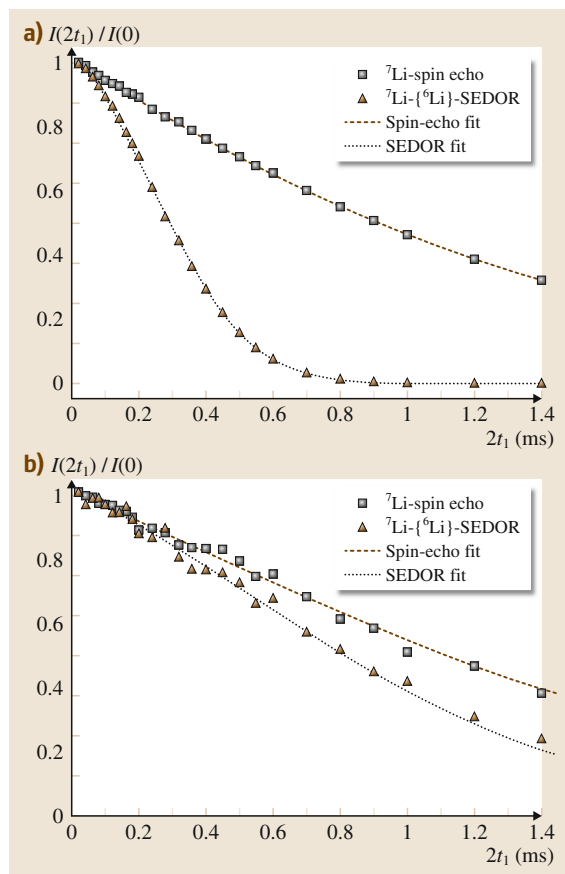

Fig. 18.5a,b ${}^7\text{Li}({}^6\text{Li})$ SEDOR measured on $(\text{Li}_2\text{O})_{0.1}-(\text{SiO}_2)_{0.9}$ glass (a) and $(\text{Li}_2\text{O})_{0.1}-(\text{B}_2\text{O}_3)_{0.9}$ glass (b). Both glasses have ${}^6\text{Li}/{}^7\text{Li}$ isotope ratio of 9 : 1. The Hahn spin-echo amplitude of the residual ${}^7\text{Li}$ nuclei is measured as a function of the dipolar evolution time $2t_1$ in the absence (squares) and the presence (triangles) of the ${}^6\text{Li}$ recoupling pulses. The dotted curves are fits to the experimental data using (18.2) (after [18.22])

Fig. 18.6 Dipolar second moment $M_2({}^6\text{Li}-{}^7\text{Li})$ measured via ${}^7\text{Li}({}^6\text{Li})$ SEDOR in lithium silicate and lithium borate glasses as a function of cation number density (after [18.22])

interaction. For multispin systems, a Gaussian decay is expected,

$$\frac{I(2t_1)}{I_0} = \frac{F(2t_1)}{F_0} \cdot \exp\left(-2t_1^2 M_2^{\text{hetero}}\right), \quad (18.12)$$

the rate of which is given by the heteronuclear second moment M_2^{hetero} [18.23]. Using the SEDOR method, the spatial distribution of the lithium ions and the extent of their clustering have been studied in lithium-oxide-containing glasses, having an isotopic enrichment level of 95% ${}^6\text{Li}$ (Fig. 18.4). Figure 18.5 compares the experimental results for a lithium silicate and a lithium borate glass with comparable lithium oxide contents (10 mol%). Clearly, the ${}^7\text{Li}$ spins in the silicate glass dephase much more rapidly in the dipolar field of the surrounding ${}^6\text{Li}$ spins, indicating much stronger dipolar interactions than in the borate glass. Figure 18.6 summarizes the dependence of M_2 on the lithium content in these glasses [18.22]. The results are found to be completely analogous to the situation in Fig. 18.3, consistent with lithium clustering in the silicate but not in the borate glass systems.

18.1.4 High-Resolution Dipolar NMR Spectroscopy

Rotational Echo Double Resonance

An even more powerful experiment, termed *rotational echo double resonance* (REDOR), is able to provide

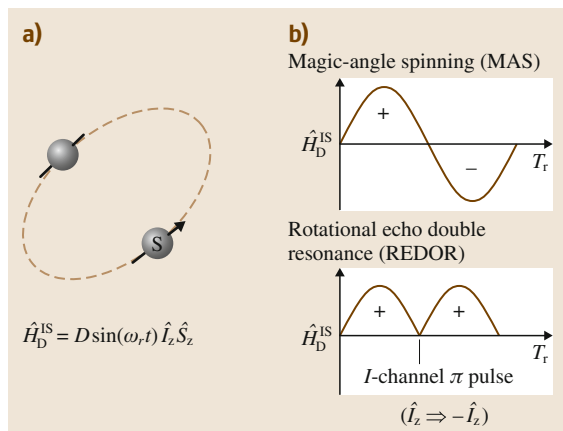

Fig. 18.7 (a) Principle of the REDOR experiment. Under MAS conditions the heteronuclear dipolar Hamiltonian oscillates sinusoidally with rotor orientation, leading to cancelation of H_D upon completion of the rotor cycle ((b), top). Sign inversion created by a π -pulse applied to the nonobserved I spins interferes with this cancelation ((b) bottom)

site-selective dipolar coupling information under the high-resolution conditions afforded by magic angle spinning [18.24]. In general, the dipolar coupling constant oscillates according to the term $\sin \omega_r t$ and is averaged out over the rotor cycle. However, if we invert the sign of the dipolar Hamiltonian by applying a π -pulse to the nonobserved I spins somewhere during the rotor cycle, this average is nonzero; the interaction is recoupled and now interferes with the ability of MAS to provide signal refocusing (Fig. 18.7).

Figure 18.8 shows a typical pulse sequence used for such purposes [18.24]. Recoupling is accomplished by 180° pulse trains applied to the I spins, while the S spin signal is detected by a rotor-synchronized Hahn spin-echo sequence. One measures the normalized difference signal $\Delta S/S_0 = (S_0 - S)/S_0$ in the absence (intensity S_0) and the presence (intensity S) of the recoupling pulses. A REDOR curve is then generated by plotting $\Delta S/S_0$ as a function of the dipolar evolution time NT_r , i.e., the duration of one rotor period multiplied by the number of rotor cycles.

For isolated two spin- $1/2$ pairs, the REDOR curve has universal character and can be directly used to extract the internuclear distance. In contrast, for larger spin clusters the REDOR curve depends on the detailed shape and distance geometry of the spin system [18.25, 26]. In glasses, one generally expects a distribution of spin geometries and magnetic dipole coupling strengths

Fig. 18.8 Timing of a REDOR pulse sequence, showing the evolution of the dipolar coupling Hamiltonian during the rotor cycle (after [18.24])

which is a priori unknown. As previously shown, this problem can be circumvented by limiting the REDOR data analysis to the initial curvature, where $\Delta S/S_0 < 0.2$ [18.26, 27]. In this limit of short dipolar evolution times, the REDOR curve is found to be geometry independent and can be approximated by

$$\frac{\Delta S}{S_0} = \frac{S_0 - S}{S_0} = \frac{4}{3\pi^2} (NT_r)^2 M_2, \quad (18.13)$$

where the average van Vleck second moment (18.9) can be extracted from a simple parabolic fit to the experimental data. For the case when dipolar coupling to $I > 1/2$ spins are studied, the results are strongly affected by the nuclear electric quadrupole couplings of the I spins. Using modified pulse sequences and data reduction routines, a dipolar analysis is still possible in such cases if the quadrupolar coupling is taken into account appropriately [18.28].

$^{29}\text{Si}(\text{Li})$ REDOR experiments have been used to study interactions between the network former and network modifier species, supplementing further evidence for lithium clustering in silicate glasses [18.29]. In sodium borate and sodium phosphate glasses, closest internuclear $^{23}\text{Na}-^{11}\text{B}$ and $^{23}\text{Na}-^{31}\text{P}$ distances have been derived from the corresponding REDOR

Fig. 18.9 $^{11}\text{B}(^{31}\text{P})$ REDOR results on a silver borophosphate glass of composition $0.5(\text{Ag}_2\text{O})\text{-}0.5(\text{B}_2\text{O}_3)_{0.5}(\text{P}_2\text{O}_5)_{0.5}$. Red and blue curves show the data for three- and four-coordinated boron atoms (after [18.32])

curves [18.30, 31]. Furthermore, REDOR has been widely implemented for quantifying network former connectivities in mixed-network former systems. As an example, Fig. 18.9 shows a $^{11}\text{B}(^{31}\text{P})$ REDOR curve obtained on a silver borophosphate glass [18.32]. In this glass, both three- and fourfold boron atoms are found in the network, and can be well differentiated by ^{11}B MAS-NMR. However, only the four-coordinated boron atoms show a sizeable REDOR effect indicating a next-nearest-neighbor relationship. In contrast, no $^{11}\text{B}\text{-O-}^{31}\text{P}$ connectivities are present for the trigonal boron species, suggesting that the latter are located rather remote from the boron atoms. As subsequent REDOR studies of other glass compositions have shown, this seems to be a rather general structural feature of borophosphate glasses [18.33–36]. Figure 18.10 summarizes the concentrations of the B–O–B, B–O–P, and P–O–P connectivities in the glass system $(\text{NaPO}_3)_{1-x}(\text{B}_2\text{O}_3)_x$, extracted from such REDOR measurements. The data are compared with the predicted concentrations of these connectivities based on a random linkage model. The large preference for heteroatomic over homoatomic linkage formation in this glass system is clearly evident, and has been quantified on the basis of such REDOR data in different borophosphate glass systems [18.33–36]. Analogously, heteroatomic bonding preferences have been observed in aluminophosphate [18.37, 38] and aluminoborate glass systems [18.39, 40].

Fig. 18.10 Comparison of measured values of the fraction of different bridging oxygen species of $(\text{B}_2\text{O}_3)_x(\text{NaPO}_3)_{1-x}$ glasses with calculations based on a statistical (St.) linkage model

Fig. 18.11 Spectral editing via $^{11}\text{B}(^{27}\text{Al})$ REDOR, demonstrated for a $(\text{Y}_2\text{O}_3)_y(\text{Al}_2\text{O}_3)_{0.4-y}(\text{B}_2\text{O}_3)_{0.6}$ glass ceramic ($y = 0.2$) for dipolar evolution time of 0.0093 s. *Top*: REDOR difference signal ($S_0 - S$), emphasizing the YAB contribution. *Bottom*: Regular rotor synchronized spin echo (S_0) and dipolar dephased signal (S), the latter emphasizing the glassy B_2O_3 contribution (after [18.41])

Figure 18.11 shows another application of REDOR to the structural analysis of a luminescent yttrium aluminoborate glass ceramic system studied along the composition line $(\text{Y}_2\text{O}_3)_y(\text{Al}_2\text{O}_3)_{0.4-y}(\text{B}_2\text{O}_3)_{0.6}$. Based on detailed NMR analysis, a quantitative crys-

Fig. 18.12a,b $^{11}B(^{27}Al)$ REDOR curves for the B(3) units of $(Y_2O_3)_{0.2}(Al_2O_3)_{0.2}(B_2O_3)_{0.6}$ glass (blue), glass ceramic (red), and the model compound $YAl_3(BO_3)_4$ (a) and comparison of the data obtained from the glass ceramics with the crystallization model of (18.14) (b) (after [18.41])

tallization model expressed by

$$\begin{aligned}
 &(B_2O_3)_{0.6}(Al_2O_3)_{0.4-y}(Y_2O_3)_y \\
 &\rightarrow [(0.8/3) - (2y/3)]YAl_3(BO_3)_4 \\
 &\quad + [(8y/3) - 0.8/3]YBO_3 + 0.2B_2O_3 \quad (18.14)
 \end{aligned}$$

was formulated, allowing the phase composition to be predicted directly from the glass composition y [18.41]. Equation (18.14) predicts the formation of two types of trigonal boron species: those associated with the crystalline compound $YAl_3(BO_3)_4$ (YAB), and those associated with glassy B_2O_3 (in the second crystallized phase, YBO_3 , the boron atoms are four-coordinated). While the ^{11}B MAS-NMR line shapes of these two trigonal boron units indeed overlap strongly, they are

Fig. 18.13 Two-dimensional homonuclear J -resolved spectroscopy. Following preparation by a $\pi/2$ pulse, evolution takes place under the influence of homonuclear J -coupling during the evolution time t_1 . Chemical shift and heteronuclear J -coupling evolution are refocused by the central π -pulse, and direct dipolar couplings are averaged out by MAS. The evolution is stopped by the second $\pi/2$ -pulse, while the third $\pi/2$ -pulse is used for detection. During the acquisition period t_2 , the regular MAS Hamiltonian is effective

unambiguously differentiated on the basis of the heteronuclear ^{11}B - ^{27}Al magnetic dipole-dipole coupling, which can be probed by using $^{11}B(^{27}Al)$ REDOR experiments. Figure 18.11 illustrates for a glass ceramic with $y = 0.2$ that the two spectral components can be completely separated by a REDOR experiment executed with a sufficiently long dipolar evolution time. The REDOR difference signal is identical to that of crystalline YAB, while the nondephased spin-echo signal closely resembles that of glassy B_2O_3 . To test the quantitative aspects of the aforementioned crystallization scenario, we can determine the fraction of trigonal boron atoms that interact with aluminum atoms from these REDOR experiments; For example, for the composition $y = 0.2$, (18.14) predicts that 57% of the three-coordinated boron atoms arise from YAB. These are expected to show a REDOR effect, whereas 43% of the three-coordinated boron atoms belong to glassy B_2O_3 , which do not interact with aluminum. Figure 18.12a shows the experimental REDOR curves obtained for the three-coordinated boron atoms on the $y = 0.20$ glass, on the glass ceramic, and on YAB. In the glass, the normalized difference signal approaches 1.0 at long dipolar evolution times, indicating that all of the threefold boron atoms interact with aluminum to some extent. This REDOR curve is consistent with a homogeneous elemental distribution in the glass [18.42]. In contrast, the glass-to-glass ceramic transition produces a pronounced change in the REDOR curve, indicating a dramatic rearrangement in the medium-range environment. The REDOR difference signal approaches 0.51, which is close to the value of 0.57 predicted from (18.14). Figure 18.12b juxtaposes the experimental REDOR

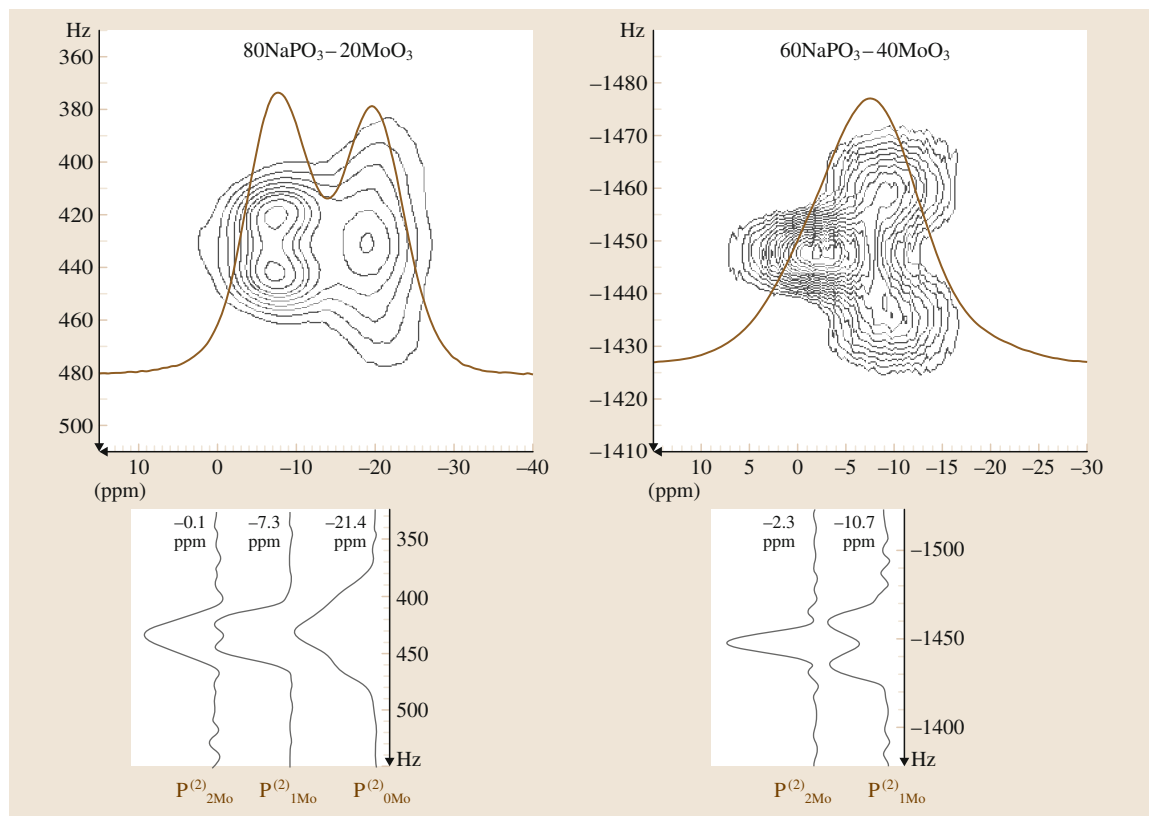

Fig. 18.14 ^{31}P J -resolved spectra of two representative $(\text{NaPO}_3)_{1-x}(\text{MoO}_3)_x$ glasses. The individual J -coupling multiplets are resolved in the second dimension (after [18.43])

data with a simulation in which the experimental data obtained on **YAB** are scaled by the factor 0.57, suggesting close agreement with the crystallization model.

18.1.5 Homonuclear J -Resolved Spectroscopy

The technique of homonuclear J -resolved spectroscopy exploits the presence of indirect magnetic dipole–dipole interactions between species that are connected via chemical bonds to specify homonuclear connectivity. The pulse sequence (Fig. 18.13) combines the two types of selective averaging afforded by **MAS** and the Hahn spin echo, in a two-dimensional experiment [18.44, 45]. In glassy solids, the **MAS-NMR** peak width is often dominated by distributions of isotropic chemical shifts, which makes it generally impossible to resolve peak splitting produced by indirect spin–spin interactions in directly acquired spectra. This problem is solved by

conducting a Hahn spin echo in the indirect (t_1) dimension of a two-dimensional **NMR** experiment: At the end of each evolution period t_1 the inhomogeneous broadening is refocused, so that the amplitude and phase of the signal are exclusively governed by the strength of the isotropic J -coupling. Thus, the corresponding signal observed after Fourier-transforming the data acquired along the time domain t_1 allows selective measurement of the homonuclear J -interaction.

Figure 18.14 shows an application to $(\text{NaPO}_3)_{1-x}(\text{MoO}_3)_x$ glasses [18.43]. The standard solid-state ^{31}P **MAS-NMR** spectra of these glasses reveal that addition of MoO_3 to NaPO_3 glass successively replaces the regular metaphosphate ($\text{P}^{(2)}$) site near -20 ppm by a new well-defined resonance near -8 ppm, which dominates the spectrum at $x = 0.30$; at higher MoO_3 contents the spectra are rather poorly resolved. The structural interpretation of these data is greatly facilitated by J -resolved spectra. For the -20 ppm signal, these spectra show the expected triplet consistent with the two

P–O–P linkages present in the $P^{(2)}$ sites. Furthermore, both a doublet component (one P–O–P linkage, signal near -8 ppm), and a singlet component (no P–O–P linkage, signal near -3 ppm) can be identified. The relative signal areas lead to the conclusion that, for each MoO_3 unit added to the glass, approximately two $P_{OMo}^{(2)}$ units are transformed into $P_{1Mo}^{(2)}$ groups. In principle, the process of P–O–Mo interlinking operative in this composition region could produce both $P_{1Mo}^{(2)}$ and $P_{2Mo}^{(2)}$ units. However, the J -resolved spectra actually give no evidence for the formation of $P_{2Mo}^{(2)}$ units for $x < 0.30$. This result is consistent with a simple *binary* structural transformation model, in which the MoO_3 component first converts all the $P_{OMo}^{(2)}$ polyphosphate chains into $P_{1Mo}^{(2)}$ units before the latter are converted to $P_{2Mo}^{(2)}$ units (or other structures without P–O–P linkages) at higher MoO_3 contents.

Recoupling of the homonuclear magnetic dipole–dipole interactions can also be exploited to prove

18.2 Nanoceramics

18.2.1 Lanthanide-Containing Transparent Glass Ceramics

Glass ceramics are polycrystalline materials obtained from controlled crystallization of glasses. This is the textbook definition [18.48], and the important aspect differentiating these materials from classic ceramics relies on the fact that the crystal phase is produced from the glass phase, by a well-controlled nucleation and growth mechanism. It is therefore possible to obtain highly homogeneous materials, with uniform grain size distributions and no porosity. It is out of the scope of this chapter to discuss the large field of glass ceramics. The interested reader is referred to the huge literature on that subject [18.49–51].

One of the interesting points concerning glass ceramics is related to the fact that it is possible to obtain transparent materials. Basically, it is necessary that both the crystals' optical anisotropy and the refractive index difference between the crystal and glass phases be small [18.52].

Historically, systematic research on transparent glass ceramics started with *Stookey's* works in the 1950s using colloidal metal particles in the nucleation of glasses [18.53]. Nuclei should promote an amorphous phase separation, and the crystal phase would be obtained from one of the amorphous phases [18.48–51].

In parallel, *Hummel* discovered that negative expansion coefficients were obtained from crystal aggregates

homonuclear network connectivity on the basis of two-dimensional zero- or double-quantum NMR methods. Such information is derived from the presence (or absence) of cross-peaks linking resolved resonances attributable to distinct chemical species via spin diffusion or coherence transfer. To date, this type of analysis has been predominantly applied to spin-1/2 nuclei, specifically ^{29}Si and ^{31}P in binary silicate [18.46] and phosphate glasses [18.47]; For example, the observation of cross-peaks in two-dimensional (2-D) exchange, radiofrequency-driven recoupling (RFDR), as well as double-quantum (DQ) experiments unambiguously reveals the occurrence of $Q^{(1)}$ – $Q^{(2)}$ and $Q^{(2)}$ – $Q^{(3)}$ linkages in binary alkali phosphate glasses. The intensities of these cross-peaks strongly suggest that in binary lithium, sodium, silver, and lead phosphate glasses the phosphorus $Q^{(n)}$ units are linked in a more or less random fashion.

of β -eucryptite ($Li_2O-Al_2O_3-2SiO_2$) [18.54]. *Stookey's* and *Hummel's* ideas were then combined to prepare materials with expansion coefficient values close to zero. Thermal shock-resistant materials stable in dimension could be prepared. Kitchenware based on these materials has been available now for more than two decades [18.55].

When optically active ions are present in the glass phase, the controlled crystallization can give rise to nanocomposites displaying unique properties due to the synergy between the nanocrystalline and parent glass phases. From the spectroscopic point of view, several interesting applications may be foreseen when the optically active ion concentrates in the crystalline phase. Among the first materials produced with that aim were Cr^{3+} -doped glasses and glass ceramics studies in the 1980s by *Reisfeld* and *Jorgensen* [18.56, 57]. The Cr^{3+} emission quantum efficiency was observed to increase on going from the base glass to the glass ceramic, with the optical quality of the materials being preserved due to the crystal size, volume fraction, and matching of refractive index between the crystalline phase and the mother glass. These materials were therefore proposed as laser hosts or concentrators for photovoltaic Si solar cells [18.56–58].

Lanthanide ions have also been explored due to their characteristic spectroscopic properties allowing many different applications [18.59–61]. Lanthanide-doped glasses have been studied for more than 60 years. Phos-

phors, laser hosts, and optical amplifiers are some of the potential applications [18.62–64]. Concerning spectroscopic properties, the inhomogeneous broadening of the spectral lines, due to the multisite distribution, is one of the particular characteristics observed. The line broadening can be either an interesting feature to be exploited or a problem to be solved, depending on the specific application. If one looks for a broad spectral profile within which induced emission will be used for optical amplification for example, glasses appear to be the ideal host material. In optical telecommunications, the larger the bandwidth, the larger the number of optical channels that can be used. Glasses and fibers displaying the largest bandwidths for the Er³⁺ emission band at 1.5 μm are the *holy grail* in modern telecommunications optics [18.65]. However, if one looks for a laser host with enhanced emission cross-section at a given wavelength, glasses will not be the best option. Crystals with well-defined coordination sites would be better [18.66].

Transparent glass ceramics can combine in fact the best of both worlds: that of glass materials and that of crystals. Glass preparation is no doubt much simpler than the preparation of crystals. Flexibility of chemical compositions, sizes, and forms are some of the important glass characteristics. Crystal properties on the other hand may be optimized depending on the chemical nature and structure. Spectroscopic properties of active metal ion centers have been well explored for the many different well-known applications of crystals.

For lanthanide ions, fluoride crystals are especially attractive host matrices. They present compelling advantages for optical applications due to their unique combination of low phonon energy, high ultraviolet (UV) absorption edge energy, and relatively weak crystal field [18.65, 82]. Interestingly enough, some fluoride crystals may be obtained from controlled crystallization of mixed oxyfluoride glasses. In the 1970s, interesting ceramic materials were obtained from composites of glass-forming oxides such as SiO₂, GeO₂, and P₂O₅ and lead fluoride and lanthanide ion precursors. Efficient infrared to visible conversion was observed for those materials [18.83, 84]. Some years later, Wang and Ohwaki showed that crystallization of related glasses could be controlled, leading to lanthanide-containing Pb_xCd_{1-x}F₂ crystals of nanometric dimensions. Infrared (IR) to visible up-conversion involving Yb³⁺ and Er³⁺ ions was observed to be more efficient in the transparent glass ceramic than in the parent glass [18.67].

Those early observations triggered intense activity from different research groups, and somewhat different oxyfluoride glass compositions have been exploited in the last two decades. Table 18.1 presents a not exhaustive list of glass systems being studied. The main precursors used in the glass preparation and the main crystal phases obtained by heat treatment of the mother glass are indicated, together with the respective references. For a systematic review on transparent glass ceramics also dealing with other individual oxide

Fig. 18.15 DSC scans obtained for glasses with compositions (mol%): (a) 60PbGeO₃-10PbF₂-30CdF₂, (b) the same glass as (a) doped with 0.5% Eu³⁺, and (c) the same glass as (a) doped with 0.5% Er³⁺ (after [18.69])

and/or fluoride systems, the interested reader is referred to [18.85].

The common characteristic of all glass systems mentioned in Table 18.1 is that heat treatments at selected temperatures lead to transparent glass ceramics displaying a fluoride crystal phase dispersed in an oxide glass host.

Figure 18.15 shows differential scanning calorimetry (DSC) scans obtained for glasses with composition (mol%) 60PbGeO₃-10PbF₂-30CdF₂. Characteristic temperatures (T_g glass-transition temperature, T_x onset of glass crystallization, and T_p glass crystallization peak) obtained for the undoped glass (Fig. 18.15(a)) are $T_g = 302^\circ\text{C}$, $T_x = 449^\circ\text{C}$, and $T_p = 476^\circ\text{C}$. With the addition of 0.5% Eu³⁺ these temperature values are observed to shift to $T_g = 300^\circ\text{C}$, $T_x = 458^\circ\text{C}$, and $T_p = 486^\circ\text{C}$. An additional exothermic effect (marked with an arrow in the figure) is observed near T_g , at 331°C . For the Er³⁺-doped sample, these temperature values are $T_g = 292^\circ\text{C}$, $T_x = 470^\circ\text{C}$, and $T_p = 484^\circ\text{C}$. The peak near T_g is also observed at 324°C (also marked with an arrow). These general features are also common to all oxyfluoride glass systems listed in Table 18.1; that is, the addition of lanthanide ions leads to the observation of a *ceramization* peak at temperatures near T_g . Heat treatments around those temperatures lead to homogeneous precipitation of PbF₂ nanocrystals

Fig. 18.16 x-Ray diffraction patterns. (a) Glass with composition 60PbGeO₃-10PbF₂-30CdF₂ containing 0.5% Eu³⁺, (b) transparent glass ceramic obtained after 60 h heat treatment at 331°C of the (a) glass, (c) glass with composition 60PbGeO₃-10PbF₂-30CdF₂ containing 0.5% Er³⁺, and (d) transparent glass ceramic obtained after 60 h heat treatment at 324°C of the (c) glass (after [18.69])

clearly identified from x-ray diffraction patterns and transmission electron microscopy (TEM) images, as presented in [18.69] and also reproduced in Figs. 18.16 and 18.17.

The glass ceramics thus obtained are transparent. Moreover, the lanthanide ions concentrate in the crystal phase, as observed from photoexcitation and photoluminescence spectra. In particular, Eu³⁺ ions are known for their sensitivity to the crystal field, with the spectroscopic properties being used to probe the metal ion environments [18.86–89]. In oxyfluoride glasses the transition from the mother glass to the final transparent glass ceramics can be indeed well followed by monitoring Eu³⁺ spectra.

Figure 18.18 [18.86] shows Eu³⁺ emission spectra obtained for the mother glass and the transparent glass ceramic, with the peaks being assigned to transitions between levels of the 4f⁶ electronic configuration. Following the excitation to the Eu³⁺L₆ energy level, at around 394 nm, nonradiative decays populate the ⁵D_{0,1,2} levels, from which emission is observed. The

Fig. 18.17 TEM micrograph obtained for a transparent Er^{3+} -doped sample submitted to 60 h heat treatment at 324°C (after [18.69])

proximity in energy of these levels makes emission from the upper levels ($^5D_{1,2}$) highly sensitive to the host phonon energies and also to so-called concentration quenching.

Figure 18.18 clearly shows the changes observed for relative intensities with the transition from the glass to the crystalline environment. Also, a decrease is observed for the relative intensity of the bands assigned to transitions from excited states $^5D_{1,2}$ and 5D_0 . With the crystallization and the consequent concentration of lanthanide ions in the crystal phases, the volume concentration of the active ions increases relative to the mother glass. Energy transfer processes that depend on the ion-ion distance will therefore be affected by the ceramization. It is in fact observed that concentration quenching and IR-to-visible up-conversion efficiencies all increase [18.67–81, 83–91]. This effect is clearly observed in Fig. 18.18 with the decrease in the relative intensity for transition arising from the upper $^5D_{1,2}$ levels compared with those arising from the lower 5D_0 level.

Figure 18.19 [18.86] shows vibronic spectra appearing together with the excitation band assigned to the $^7F_0 \rightarrow ^5D_2$ Eu^{3+} transition at $21\,560\text{ cm}^{-1}$ (463.8 nm). Spectra obtained for the mother glass, the transparent glass ceramic, and also a Eu^{3+} -containing lead germanate glass ($\text{PbGeO}_3:\text{Eu}^{3+}$ (0.5 mol%)) are presented. Numbers in the figure refer to relative positions of the bands taking the electronic line as a reference. These sidebands can be attributed to vibrational

Fig. 18.18 Room-temperature Eu^{3+} emission spectra ($\lambda_{\text{exc}} = 394\text{ nm}$). (a) Glass with composition $60\text{PbGeO}_3\text{-}10\text{PbF}_2\text{-}30\text{CdF}_2$ containing 0.5% Eu^{3+} , (b) transparent glass ceramic obtained after 60 h heat treatment at 331°C of the (a) glass. Assignments (Eu^{3+} electronic levels) 1 – $^5D_2 \rightarrow ^7F_3$; 2 – $^5D_1 \rightarrow ^7F_0$; 3 – $^5D_1 \rightarrow ^7F_1$; 4 – $^5D_1 \rightarrow ^7F_2$; 5 – $^5D_0 \rightarrow ^7F_0$; 6 – $^5D_0 \rightarrow ^7F_1$; 7 – $^5D_0 \rightarrow ^7F_2$; 8 – $^5D_0 \rightarrow ^7F_3$; 9 – $^5D_0 \rightarrow ^7F_4$ (after [18.86])

modes coupled to the Eu^{3+} electronic state. Considering the germanate glass, the vibronic bands at 653 and 750 cm^{-1} are related to Q^2 structures of the germanate chain, where Q^n is the usual nomenclature identifying the number n of bridging oxygen atoms connecting GeO_4 tetrahedra. In the spectrum obtained for the fluorogermanate glass, bands at 562 , 689 , and 786 cm^{-1} correspond to Q^2 structures with some substitution of fluoride ions for oxide ions in the glass network in the vicinity of Eu^{3+} ions. The vibrational mode at 219 cm^{-1} is attributed to Eu^{3+} ions strongly interacting with metal fluoride-rich regions. With the glass-to-glass ceramic transition vibrational modes of 94 and 201 cm^{-1} could be identified, related to the $\text{PbF}_2:\text{Eu}^{3+}$ crystal phase. The vibronic spectrum obtained for the glass ceramic still shows the interaction of Eu^{3+} ions with the fluorogermanate network, since bands are observed at 556 , 676 , and 778 cm^{-1} . Therefore the partition of Eu^{3+} ions between the crystalline fluoride and amorphous germanate phases can be well monitored by Eu^{3+} vibronic spectroscopy, which highlights the role of Eu^{3+} as probes of the structure.

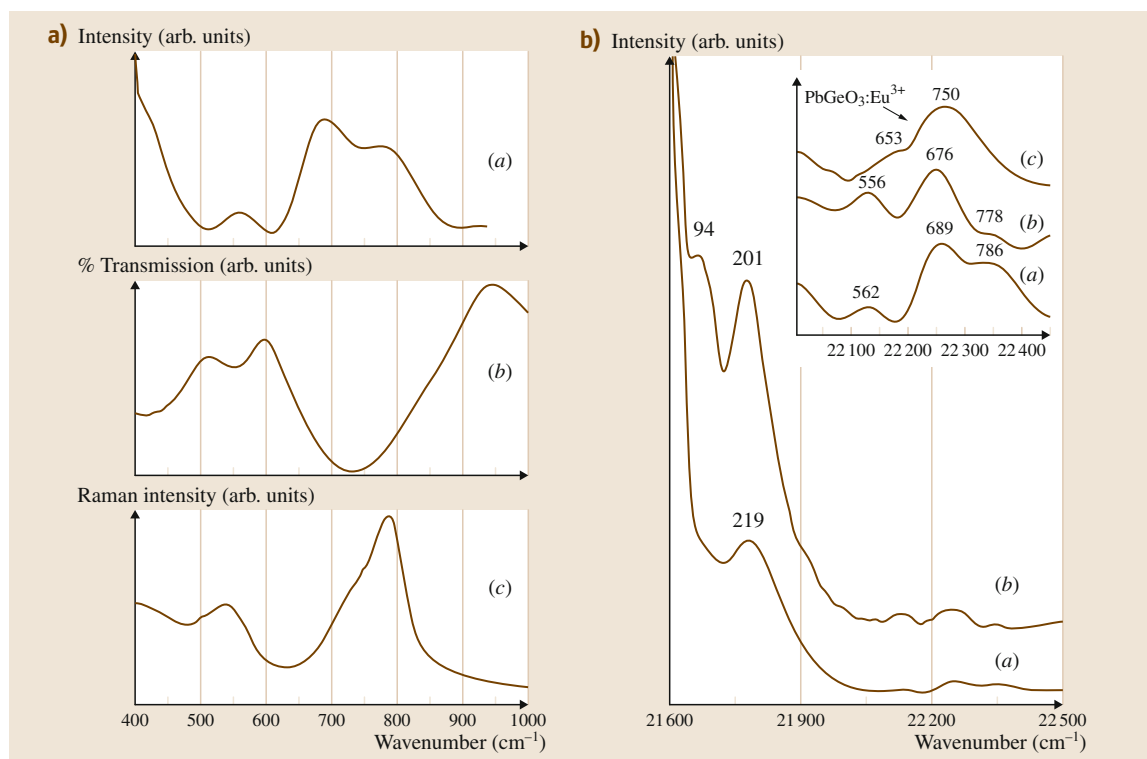

Fig. 18.19 (b) Eu^{3+} vibronic spectra. (a) Glass with composition $60\text{PbGeO}_3\text{-}10\text{PbF}_2\text{-}30\text{CdF}_2$ containing 0.5% Eu^{3+} , (b) transparent glass ceramic obtained after 60 h heat treatment at 331°C of the (a) glass. *Inset:* Detail for the germanate spectral regions with the additional vibronic spectrum observed in $\text{PbGeO}_3\text{:Eu}^{3+}$ (c). (a) Eu^{3+} vibronic spectrum for the $60\text{PbGeO}_3\text{-}10\text{PbF}_2\text{-}30\text{CdF}_2$ (0.5% Eu^{3+}) glass with the electronic line at $21\,560\text{ cm}^{-1}$ taken as a reference (zero) (a); (b) infrared transmission spectrum and (c) Raman scattering spectrum obtained from the same sample (after [18.86])

Figure 18.19 also shows the relationship between the vibronic spectrum, the infrared transmission, and Raman scattering spectra obtained for the fluorogermanate glass. The same vibrational modes seem to be operative in the three spectra.

The exact mechanism occurring in the crystallization of oxyfluoride glasses is still a matter of discussion. It is clear from ^{19}F NMR measurements that heterogeneities, in this case associated with clustering of fluoride ions, occur in the mother glasses, which can no longer be considered homogeneous at the molecular scale [18.15, 86]. Fluoride-rich regions would lead to the ionic conduction pathways claimed to explain the unusual ionic conduction properties displayed by oxyfluoride glasses and also their particular crystallization behavior [18.15, 86].

The addition of lanthanide ions clearly influences the crystallization process. However, this nucleating action is not well understood. Indeed, EXAFS mea-

surements lead to the suggestion that the antecedent formation of ErF_3 phase is followed by the crystallization of the PbF_2 , $\text{Pb}_x\text{Cd}_{1-x}\text{F}_2$, LaF_3 , and other phases [18.72]. Eu^{3+} spectroscopic data also point to the existence of heterogeneities characterized by fluoride-rich regions [18.81, 86–88], corroborating the model proposed in [18.15, 86].

18.2.2 Metal Nanoparticles in Glasses

One of the earliest examples highlighting the important role played by nanoscale heterogeneities in glasses is the well-known Roman Lycurgus Cup from the 4th century AD [18.92]. It looks green under reflected light and red under transmitted light. Other masterpieces of the glass world, the red Venetian glasses from the 13th century, do not display the green reflected color. Both glasses are known to contain colloidal metal particles: Au-Ag in Roman glass and Au in Venetian glass. Per-

haps neither the Romans nor Venetians were aware that surface plasmon resonances (SPR) due to metallic heterogeneities could be claimed, together with scattering due to the sizes of the particles in the case of the Roman glass, to explain the amazing color effects they achieved.

Beyond the subject of glass art, potential technological applications of such nanoscale heterogeneous systems have emerged in the last decades. In fact, the study of metallic nanostructures and their applications has expanded in the past years into a major field called *plasmonics* [18.94]. SPR localized near the boundary between the metal nanostructure and the surrounding dielectric also produces an enhanced electromagnetic field at the interface. This enhanced field is the basis of two important applications related to metallic nanoparticles, namely:

1. The enhancement of intensities of intra-4f electronic transitions of lanthanide ions close to the particles [18.95]
2. The enhancement of Raman lines attributed to some vibrational modes of molecules close to the particles [18.96,97].

Several families of oxide glasses containing metallic nanoparticles have been reported in the literature, including silica [18.98–113], borates [18.114, 115], phosphates [18.116–129], and heavy metal oxide glasses (HMOG) [18.118–135]. Nanoparticles being studied include silver (Ag), gold (Au), platinum (Pt) and copper (Cu), nickel (Ni), cobalt (Co), iron (Fe), and bismuth (Bi).

SPR in glasses is the phenomenon responsible for the colors observed. In fact, the absorption band may be localized from the near-infrared to the limit between the visible and ultraviolet regions. The metal–dielectric boundary on the nanoscale leads to changes in the optical properties, making them size and shape dependent. The SPR also depends on the dielectric refractive index, as shown below.

To take advantage of the unique properties of the metallic nanoparticles, it is interesting to prepare samples with size distributions below an average of 25 nm. This scenario allows use of the quantum confinement effect while light scattering can be neglected. The increase in size (considering, for example, the spherical shape) leads to a red-shift in the SPR band [18.136]. Such an effect is usually observed when glasses are annealed during different periods of time or at distinct temperatures, or even when exposed to different doses of laser light. Figure 18.20 shows the evolu-

Fig. 18.20 Absorption spectra obtained for a glass sample of composition $(0.6\text{KPO}_3\text{-}0.4\text{WO}_3)_{0.85}\text{-AgCl}_{0.15}$. The evolution of the SPR band with the duration of heat treatment is shown. From the lower spectrum obtained for the base glass, spectra are shown with increasing absorption for the same sample treated for 10, 65, 75, 85, 110, and 130 min at 450 °C. The inset shows a TEM image for the sample treated for 250 min. Black dots are silver particles (4–10 nm) distributed in the glass bulk (scale bar = 100 nm, after [18.93])

tion of the SPR band due to silver nanoparticles with heat treatments performed for different periods of time in glasses with composition $(0.6\text{KPO}_3\text{-}0.4\text{WO}_3)_{0.85}\text{-AgCl}_{0.15}$ [18.93]. Figure 18.20 also shows a TEM image of the nanoparticles thus obtained. A red-shift (535–550 nm) is observed for longer treatments, related to increasing sizes of the nanoparticles. The intensity of the band is mostly related to the number of particles, which also increase with the increasing duration of heat treatment. Increasing the size of the nanoparticles, by either heat treatment or laser irradiation, can be explained using the Ostwald ripening approach [18.137] where atoms or very small particles join together to form larger clusters. For most glass compositions, the crystal growth takes place at temperatures above the glass-transition temperature because, in such conditions, the glass viscosity decreases and atomic diffusion starts to become more important, allowing Ostwald ripening.

The dependence of the SPR on the refractive index (at 632 nm) n of the medium is shown in Fig. 18.21. Values are obtained from the literature (indicated in the figure) for silver particles in different glasses. Al-

Fig. 18.21 Maximum observed for Ag SPR bands (λ_{SPR}) as a function of the refractive index of the glass host. References are cited in the figure

though the particle sizes were observed to vary from 1.6 to 28 nm among the glass systems, the almost 300 nm shift cannot be attributed only to size effects. Refractive index plays an important role here.

Three main techniques have been used in the preparation of glasses containing metallic nanoparticles: ion implantation, ionic exchange, and melt quenching. Ion implantation has been successfully used to introduce ionic transition metals, such as Ag^+ , Au^{2+} , Cu^+ [18.138], Ni^{2+} [18.100], and Co^{2+} [18.139]. However, in all cases, annealing processes are necessary to promote the reduction from ion to metal and the consequent formation of nanoparticles. One of the drawbacks of this technique is the intrinsic heterogeneous distribution of the nanoparticles, since ions are implanted only within a few microns from the glass surface.

Ionic exchange methods have been largely used due to their simplicity. Basically, a Na^+ -rich glass composition is submitted to ionic exchange in a molten salt bath. Subsequently, the ion-exchanged glass must be submitted to UV irradiation or thermal annealing to effect nanoparticle formation. This method is widely employed to introduce Ag atoms into the glass composition.

The most employed method to prepare metallic nanoparticles embedded in oxide glasses is the melt-quenching technique. It consists in introducing the metal atom of interest together with the other components of the glass which will be later melted at high temperatures and, subsequently, quenched to tempera-

tures below T_g . The metal-containing starting materials include chlorides, nitrates, oxalates, among other salts that will decompose during the melting process, forming ions. Alternatively, metal atoms can be directly introduced into the glass structure. In both cases, nanoparticles are hardly observed in the quenched glass. Nanoparticle clustering and growth occur by subsequent annealing of the glasses at temperatures close to or higher than T_g . Thermal treatment above T_g is efficient because the glass viscosity decreases above this temperature and the diffusion of the atoms is facilitated.

Melt-quenching may be used in conjunction with laser and x-ray irradiation of the glasses. Usually, glass samples are previously irradiated and later submitted to a fast annealing step inducing crystallization only in the irradiated region. Three-dimensional (3-D) nanostructures can be fabricated by using focused femtosecond laser beams [18.140].

18.2.3 Quantum Dots in Glasses

As shown in the previous section, metallic nanoparticles exhibit major changes in the optical spectra derived from effects that can be explained using a classical dielectric picture.

Glass nanoheterogeneities may also be composed of semiconductor nanoparticles, leading to amazing optical properties as well. In this case the quantum confinement produces quantization of the electron and hole energy states that lead to major modification in the optical spectra. Therefore, *quantum dots* (QD) are nanoparticles of semiconductors representing the case of an electron trapped in a three-dimensional box.

QD generally range from 2–10 nm in diameter, but the maximum size of a semiconductor to be considered a QD depends on several parameters. A classical semiconductor is a material that has a small bandgap between the valence and conduction band, allowing electrons to be excited to the conduction band, leaving behind a hole in the valence band. In this model, the exciton Bohr radius is the average separation of the electron–hole pair.

For a semiconductor nanocrystal to exhibit quantum confinement or quantum size effects and be considered a QD, the size of the crystal must be smaller than the exciton Bohr radius [18.141]. This quantum confinement causes the energy bands observed in the bulk material to turn into discrete energy levels, resulting in intermediate properties between the bulk material and discrete molecules and new optical and electronic behaviors [18.142–145].

QD were first discovered by *Ekimov* [18.146] in a glass matrix and by *Brus* in colloidal solutions, and are often composed of binary alloys such as cadmium chalcogenides (CdS, CdSe, CdTe) [18.147–150] or lead chalcogenides (PbS, PbSe, PbTe) [18.151–157], even if several works have reported ternary QDs (CdSSe) [18.158] or oxide compounds [18.159–162]. These binary chemical compositions, labeled II–VI and IV–VI QD, have been largely investigated because of their relatively large exciton Bohr radii compared with other compounds. In this sense, lead chalcogenide QD exhibit the largest exciton Bohr radii of about 18 nm for PbS and 46 nm for PbSe, resulting in a quantum confinement effect for a large diameter range and thus tunable absorption and emission wavelengths [18.152, 162].

Among the wide diversity of methods available for preparation of semiconductor nanocrystals, colloidal chemistry appears as a powerful method for high-quality QD with emission efficiencies as large as 20% of commercial dyes [18.153, 154, 163]. However, QD suspensions or powders are unstable, mainly due to agglomeration and coalescence processes. For these reasons, attempts have been made to incorporate QD into robust solids which can allow QD stability and easier device manufacture for technological applications. In this way QD have been obtained in polymers [18.164] and zeolites [18.165], both in the form of thin films [18.166] and inside bulk glasses prepared by both sol–gel and melt-quenching methods [18.167–169]. Incorporation of QD in glasses has been so far the most promising and investigated choice, since the final materials present both mechanical and chemical stability as well as simple manufacture into fibers or bulk devices with specific shapes. Many works in the literature have reported preparation and optical characterizations of QD in silicate- and phosphate-based glasses as well as a few works on QD-containing chalcogenide glasses [18.157, 170–176]. The most promising quantum-dot compositions for nanostructured glasses are II–VI semiconductors such as cadmium chalcogenides (CdS, CdSe, CdTe) and IV–VI semiconductors such as lead chalcogenides (PbS, PbSe, PbTe) because of their quantum confinement properties in a large diameter range. However, some works have described the preparation and optical properties of oxide quantum dots such as ZnO, In₂O₃ or SnO₂ embedded in glasses [18.159–161, 177].

Several methodologies such as radiofrequency (RF) sputtering [18.178], ion implantation [18.179], and melt quenching of starting materials [18.170–175] are avail-

able for the incorporation of quantum dots, the latter being the most simple, versatile, and employed method for nanostructured semiconductor glasses. The semiconductor compound is generally added to the other starting materials of the glass composition, and the mixture is melted and quenched at around T_g as in classical glass preparation. QD generally do not form at this stage, and the semiconductor compound is dispersed homogeneously in the final glass, resulting in a sample with the same optical characteristics (color and transparency) as the undoped composition. As in the case of metallic particles, QD will nucleate and grow under heat treatments at selected temperature, usually above T_g .

Depending on the glass melting temperature, important chemical losses can occur by thermal decomposition or sublimation, since these chalcogenide compounds are unstable at high temperatures [18.174]. As a result, the final semiconductor concentration is in general lower than the desired one and is hard to control in the final sample. Such behavior is particularly well known in silicate glasses containing PbS and PbSe quantum dots because of the high melting temperatures (around 1300 °C) and high tendency of lead chalcogenides to decompose above their melting temperature (1118 °C for PbS and 1080 °C for PbSe). In these cases, several methodologies can be adopted to maintain a desired semiconductor concentration. Many authors describe the use of a large excess of the compound (about tenfold) in the starting materials to obtain a relatively high final concentration [18.180]. Other researchers bring each element from distinct compounds with higher melting temperatures T_m . As an example, ZnSe ($T_m = 1520$ °C) and PbO can be introduced in the starting materials of a silicate glass for final PbSe-containing glasses [18.157]. As mentioned above, after the glass preparation, one- or two-stage heat treatments at temperatures between the glass transition and the onset of crystallization must be applied to induce quantum dot nucleation from amorphous phase separation and further growth of the nanometric particles [18.181, 182]. The main difficulty in multicomponent glasses is to ensure the single precipitation of the desired semiconductor phase without crystallization of the other glass components. Specific compounds such as ZnO can be added to the starting materials in multicomponent glasses to act as nucleating agents for selective crystallization of the semiconductor phase [18.162].

The appearance of discrete energetic levels associated with quantum size effects with energy gaps tuned by the quantum dot size leads to several new exciting properties and applications related to absorption and

emission processes in the visible and near-infrared regions [18.152]. Such materials are used as commercial optical cutoff filters in the visible [18.183, 184] and optical devices for near-infrared luminescence useful in telecommunications; For example, PbS luminescence in silicate glasses can be tuned in the range of 1.2–1.7 μm depending on the particle diameter below the exciton Bohr radius, and these materials are used as broadband optical amplifiers [18.185]. Other

optical applications are related to their highly nonlinear optical properties and fast response times, which make them suitable for Raman amplifiers [18.186], active optical emitters [18.187], saturable absorbers for mode-locking and Q-switching of near-infrared lasers, and ultrafast signal switches [18.188, 189]. Some works have also reported more efficient luminescence properties of rare-earth ions when embedded inside quantum dots [18.161, 190–192].

18.3 Perspectives and Concluding Remarks

Glasses may present heterogeneities at the nanoscale that have been avoided by traditional glassmakers, to whom homogeneity is a fundamental glass property. However, the presence of heterogeneities may lead to amazing properties that may turn simple objects into icons of a given civilization, such as the already mentioned beautiful Lycurgus Cup fabricated by the Romans. From there, an entirely new area, plasmonics, is being explored today [18.94, 193].

Nanoscale heterogeneities may be characterized by sophisticated spectroscopic techniques. This chapter presents a special focus on modern NMR techniques. The results presented in Sect. 18.1 document the great power and potential of modern solid-state NMR spectroscopy to provide detailed information on the structural organization of disordered materials at the subnanometer distance scale. Figure 18.22 summarizes the key features of the technique in relation to other methods.

During the past decade a substantial amount of information has been accumulated, much of which remains at the conceptual and qualitative level at the present time. Still there are numerous experimental and theoretical difficulties to overcome that relate directly to the measurement; For example, reliable quantification of *homonuclear* dipole–dipole interactions under high-resolution conditions (with MAS) is still an unsolved problem, in particular when quadrupolar nuclei are involved. Likewise, no rigorous strategy seems to be available at present for quantitative measurement of heteronuclear dipolar coupling between two quadrupolar nuclear species. Nevertheless, the systematic composition-dependent exploration of chemical systems offers a lot of fundamental insight into the structure–property relation of disordered materials. In this connection it is of utmost importance that NMR spectroscopy remains a vital and attractive research area in its own right. Assuredly, the continued influx of new solid-state NMR technology into this research area will provide an active stimulus for the study of increasingly sophisticated structural issues on increasingly complex materials. In the future, we expect that this research area will also greatly benefit from the continuing improvement and refinement of the calculational and modeling approaches used to *translate* spectroscopic observables into structural information.

This chapter also described the amazing properties that emerge due to the presence of specific heterogeneities in glasses, that is, lanthanide-containing nanocrystals, metallic nanoparticles, and quantum dots. Glasses themselves are unique materials considering the wide range of optical applications available by intelligent choice of glass compositions [18.194].

Control of the composition and dimensions of nanoscale structures, and therefore their structural study, is of utmost importance in order to explore the almost endless list of possible applications.

Local selectivity:	Disorder/Lack of periodicity
Element selectivity:	Compositional complexity Low scattering contrast (H; Si/Al)
Interaction selectivity:	Distance measurements Connectivity information Electron density information
Uniform sensitivity:	Quantitative applications
Dynamic sensitivity:	Motional processes on continuous timescale (10^2 to 10^{-9} s)
Low detection sensitivity:	10^{17} to 10^{18} spins required
Bulk method:	Poor spatial resolution Surfaces/interfaces difficult to study
Magnetic interference:	Transition metals, rare earths limited

Fig. 18.22 Key features of solid-state NMR as a technique in the solid-state sciences. Strengths are shown on a yellow background, weaknesses on a purple background

NMR together with vibrational spectroscopy, extended x-ray absorption fine structure (EXAFS), and the spectroscopic properties of lanthanide probe ions allow fundamental characterization of the glass structure at the nanoscale. Indeed, mixed oxyfluoride glasses may present emerging ionic conductivity properties that are distinct from the properties of the individual oxide and fluoride components. Heterogeneities (fluorine-rich regions) proposed from the analysis of data from all the spectroscopic techniques cited above may be used to explain the new properties. The presence of such heterogeneities at the molecular scale also explains the particular crystallization mechanism observed for these mixed glasses, allowing one to obtain transparent glass ceramics displaying crystal-like spectroscopic properties [18.15]. The multifunctionality of such systems may be useful in new applications, as in the enhancement of the photovoltaic efficiency of silicon cells proposed in [18.195]. Transparent glass ceramics presenting lanthanide ions well concentrated in the crystal phase may present optimized efficiency in converting energy ranging from regions for which silicon photovoltaic cells are not sensitive to those where light can be efficiently converted to electric current, near the silicon energy bandgap.

Optical properties due to the presence of metallic nanoparticles may also be tuned through control of sizes and shapes together with the dielectric host properties. The new area of plasmonics mainly hinges on such control [18.94, 193]. The possibility of using femtosecond lasers to build 3-D metallic nanostructures in the glass bulk opens a wide range of new applications [18.140].

Concerning glass containing QD, applications based on the quantum confinement properties are only at the infancy stage. Emission properties may, for example, be exploited to obtain completely new luminescent materials and laser systems that may find applications in photonics as well as in biology [18.196, 197]. Glass coating on QD is also feasible, preventing quenching and leaching effects in optical applications [18.197]. New nanocomposites of QD-metallic nanoparticles have also been proposed for innovative light-emitting diodes [18.198].

One of the amazing properties giving glasses utmost importance is without doubt their processability. Glasses may be obtained in any form, and waveguides, in the form of either optical fibers or thin films, are some of the best examples of the functionality that can be added to the glass world. In this way, optical fibers and planar waveguides containing quantum dots and metal nanoparticles constitute important materials to be cited in these concluding remarks concerning future applications. Real-time remote detection, miniaturization, immunity to electromagnetic interference, and multiplexing ability are some of the important characteristics of optical fibers. Photostability and multiplexing capability are unique features of QD that can provide new and interesting solutions for fiber sensing. Several examples of such applications may be found in [18.199, 200], where the optical sensing properties of QD heterogeneities present in the glass host allow unique sensing characteristics. The relatively recent advent of photonic crystal fibers (PCF) enlarges the field of applications of these QD-containing waveguides [18.201].

Optical fibers containing metal nanoparticles also find interesting applications in different areas. By incorporating optical fiber-based devices into woven and nonwoven fabrics, one can distribute these devices across large areas. By incorporating metallic nanoparticles (and also QDs) inside optical fibers, continuous fibers are obtained that can be woven, or placed into nonwoven textiles. Interesting new sensors are obtained in this way [18.202].

PCFs containing metal nanoparticles can also be prepared, constituting integrated next-generation plasmonic devices. Proof-of-principle experiments have been demonstrated with liquids of different refractive indices where the dependence of the localized surface plasmon resonance (LSPR) on the surroundings was confirmed [18.203].

In conclusion, the study of glasses at the nanoscale paves the way for innovative applications of glasses and nanocomposites that can be prepared from the base glass. The synergy existing between guest heterogeneity and glass host leads to the emergence of entirely new properties that are impossible to obtain from other materials.

Carbon in Polymer

Robert J. Young, Libo Deng, Lei Gong, Ian A. Kinloch

This chapter provides insight into the composition, preparation, properties, and applications of composites based on polymer matrix and different forms of nanosized carbon filler. Carbon nanotube and graphene filler materials are discussed in greater detail. The dispersion and orientation of these fillers and the interfacial adhesion between the filler and the matrix material play important roles in determining the mechanical, electrical, and other properties of the composites created. Accordingly, this chapter describes the role as well as the characterization techniques of these properties.

In particular, it will be shown how Raman spectroscopy is becoming an important noninvasive technique both to characterize the electronic structure and to follow the deformation behavior of carbon-based nanomaterials. Such spectroscopic knowledge reveals the intrinsic properties of these nanomaterials, the interaction of the reinforcement with the surrounding environment, and hence the efficiency of the mechanical reinforcement in these composites.

19.1 Materials Basics

The past 25 years has seen a massive growth of interest in the different forms of carbon-based nanomaterials shown in Fig. 19.1. The discovery of C_{60} buckyballs in 1985 [19.1] spurred an upsurge of research activity leading to the identification of carbon nanotubes in 1991 [19.2] and graphene in 2004 [19.3]. The importance of these findings has been recognized in the awards of Nobel Prizes for both Chemistry (for C_{60}

in 1996) and Physics (for graphene in 2010). Much of the original interest in these carbon-based nanomaterials was because of their electronic properties but direct measurements of the mechanical properties of both nanotubes and graphene led to it becoming increasingly clear that the materials have considerable potential as mechanical reinforcements in nanocomposites. Such excellent mechanical properties of nanotubes

Fig. 19.1 Family of all graphitic forms. Graphene is the 2-D building material for carbon materials of all other dimensionalities. It can be wrapped up into 0-D C_{60} buckyballs, rolled into 1-D nanotubes or stacked into 3-D graphite (after [19.4])

and graphene are related to the strong sp^2 hybridized carbon-carbon bonds and the perfect hexagonal structures from which they are built.

Most of the interest in the use of carbon-based nanomaterials as a composite reinforcement has been concerned with carbon nanotubes and graphene rather than C_{60} as it is well-known that reinforcement by particles is generally less efficient than reinforcement by fibers or platelets [19.5]. Other forms of carbon-based nanomaterials such as carbon black have been used as reinforcements for polymers for over 100 years. For example, a large increase in the Young's modulus and improvements in wear resistance are found when carbon black is incorporated into natural rubber [19.5]. Although carbon black is basically a particulate filler the material has *structure* whereby the particles form networks that lead to better reinforcement than would be encountered with individual particles.

19.1.1 Carbon Nanotubes

Carbon nanotubes (CNTs) are long cylinders of covalently bonded carbon atoms. The carbon atoms are arranged on a hexagonal network and each of them has three neighbours with which they form strong sp^2 hybridized carbon-carbon bonds. There are basically two main types of carbon nanotubes as shown in Fig. 19.2, according to the numbers of graphene cylinder in their structure: single-wall nanotubes (SWNTs) and multi-walled nanotubes (MWNTs); double-wall nanotubes (DWNTs) are a special case of MWNTs [19.6].

An SWNT can be considered as a seamless roll of a single graphene sheet. The nanotube is one atom in thickness (which is 0.34 nm), tens of atoms in circumference, and up to a few millimeters in length. The different ways of rolling graphene into tubes are described by the chirality as defined by the circumferential

Fig. 19.2a,b Schematic representations of (a) single- and (b) double-walled carbon nanotubes. Multi-walled nanotubes can have up to 20 layers of nested tubes. (courtesy Dr. F. Ding, Hong Kong Polytechnic University)

vector [19.6]

$$C_h = na_1 + ma_2, \quad (19.1)$$

where n and m is the length along the unit vectors of the two lattice vectors. **MWNTs** are made of many coaxial single-wall nanotubes with an interlayer separation of 0.34 nm, and each of the walls may possess different chiralities.

Preparation

Three methods are employed widely to prepare nanotubes: arc-discharge, laser ablation, and chemical vapor deposition (CVD) [19.7]. The first two methods involve the condensation of hot gaseous carbon atoms generated from the evaporation of solid carbon while in the CVD process, a gaseous carbon source is decomposed catalytically and the nanotubes are deposited on a substrate or grown from a substrate. Catalytic-grown nanotubes have fewer impurities but have more defects than the arc-grown CNTs. The arc-grown CNTs are therefore mechanically stronger than the CVD-CNTs, but the latter will almost certainly find more applications. This is because the length and structure are more controllable in a CVD process than in other methods, and this process is also more amenable to being scaled-up for industrial production [19.7].

Properties

The high aspect ratio, the strong sp^2 carbon-carbon bonds, and the one-dimensional confinement of electronic states, confer CNTs with a range of interesting

physical properties such as unique electronic properties, excellent mechanical properties, and good thermal conductivity and electrical conductivity.

SWNTs behave as either semiconductors or metals, depending on the remainder of $(n - m)$ divided by 3: those with $n - m = 3k$ are metallic nanotubes while those with $n - m = 3k \pm 1$ are semiconducting nanotubes (where k is integer) [19.7]. Therefore, approximately one third of **SWNTs** are metallic and the rest are semiconducting. For semiconducting nanotubes, the band gap decreases as the diameter increases [19.8].

Deformation has a significant effect on the electronic structure of nanotubes. The effect of strain on the electronic structure depends on the deformation mode (i.e. uniaxial strain, torsional strain or radial deformation) and the nanotube chirality. For example, uniaxial strain opens the band gap of nonarmchair metallic nanotubes but has no effect on armchair nanotubes. Torsional strain can change the electronic structure of armchair nanotubes but does not affect zigzag nanotubes [19.8].

Nanotubes and graphite share the same hexagonal network of sp^2 carbons in their structure. Mechanical properties of nanotubes are therefore expected to be comparable with graphite which has in-plane Young's modulus of 1.06 and strength of 130 GPa [19.9, 10]. In fact, some computer simulation work soon after the discovery of nanotubes did predict similar mechanical properties to those of graphite [19.11]. The first actual mechanical measurement on nanotubes was performed using transmission electron microscopy (TEM) in 1996 [19.12]. Since then, bending tests using an

Table 19.1 Physical properties of CNTs and other engineering materials (after [19.14])

Material	Mechanical properties		Thermal conductivity (W/(m K))	Electrical conductivity (S/m)
	Young's modulus (GPa)	Strength (GPa)		
Carbon nanotubes	100	30–100	> 3000	10^6 – 10^7
Carbon fiber (pitch-based)	300–700	5–7	1000	2 – 8.5×10^6
Copper	110–128		400	6×10^7

atomic force microscopy (AFM) tip have been developed and used widely [19.13]. A modulus for SWNTs of 1.0 TPa and 0.3–0.9 TPa for MWNTs, and tensile strength of 50–150 GPa for SWNTs and 10–50 GPa for MWNTs are generally quoted by the scientific community. The actual values vary from nanotube to nanotube, cover a wide range, and depend on many factors such as the nanotube type, preparation method, purity and diameter.

Theoretical work has predicted a very high thermal conductivity for CNTs, of approximately 6000 W/(m K), while experimental work has recorded a value of 3000 W/(m K). MWNTs have been found to also exhibit good electrical conductivity, which is in the range of 10^6 – 10^7 S/m (as a comparison, the copper has a thermal conductivity of 400 W/(m K) and electrical conductivity of 6×10^7 S/m) [19.14]. The physical properties of CNTs and a comparison with typical engineering materials are summarized in Table 19.1.

19.1.2 Graphene

Graphene is the basic building block of all graphitic forms of carbon and consists of a single atomic layer of sp^2 hybridized carbon atoms arranged in a honeycomb structure as shown in Fig. 19.1. There has been an explosion of interest in the study of the structure and properties of graphene following the first report in 2004 of the preparation and isolation of single graphene layers by Novoselov and coworkers [19.3] in Manchester, UK, for which they were awarded the 2010 Nobel Prize in Physics. It had long been thought that the isolation and study of single layer graphene would not be feasible since such 2-D crystals would be unstable thermodynamically [19.15] and/or might roll up into scrolls if prepared as single atomic layers [19.16]. Subsequent studies have shown that this is certainly not the case.

Preparation

Considerable effort has been put into the development of methods of preparing high quality graphene in large quantities for both research purposes and with a view to eventual applications [19.17]. Since the first isolation of

graphene in 2004 two general approaches have been developed to prepare the material. One is to take graphite and break it down into graphene by techniques such as a mechanical cleavage or exfoliation (sometimes termed *top-down*). The other method is to synthesize graphene using techniques such as *chemical vapour deposition CVD* (often known as *bottom-up*).

Expanded graphite was developed more than 100 years as a filler for the newly-developed polymer resins and it has been investigated continually over the intervening period [19.18, 19]. In more recent times there have been other developments in the preparation of thinner forms of graphite, known as graphite nanoplatelets (GNPs) [19.20] which can be produced by a number of techniques that include the exposure of acid-intercalated graphite to microwave radiation, ball-milling and ultrasonication. The addition of GNPs has been found to lead to substantial improvements in the mechanical and electrical properties of polymers at lower loadings than would be needed with expanded graphite [19.21, 22]. Although the definition of GNPs strictly covers all types of graphitic material from 100 nm thick platelets down to single layers [19.20], it is the availability of single- or few-layer graphene that has caused by far the most excitement in recent times.

The simplest, and probably the most celebrated, way of preparing small samples of single- or few-layer graphene is by the mechanical cleavage (repeated peeling of graphene layers with adhesive tape) from either highly-oriented pyrolytic graphite or good-quality natural graphite [19.3]. An optical micrograph of a sample prepared by mechanical cleavage and deposited upon a polymer substrate is shown in Fig. 19.3. This method typically produces a mixture of one-, two- and many-layer graphene flakes with dimensions of the order of tens of micrometers.

As soon as the interest in graphene for use in applications that required high volumes of material, such as in composites, people tried to develop methods of undertaking large-scale exfoliation. One of the first successful methods was the exfoliation and dispersion of graphite in organic solvents such as *N*-methylpyrrolidone [19.23, 24]. The method yields about

Fig. 19.3 (a) Optical micrograph of a graphene monolayer (indicated by an *arrow*) prepared by mechanical cleavage and deposited on a polymer substrate. (courtesy K.S. Novoselov, Univ. Manchester) (b) Schematic representation of a graphene monolayer on the atomic level (courtesy F. Ding, Hong Kong Polytechnic Univ.)

1% of graphene monolayers along with bi-layer and multilayer material. Although the graphene produced by this method is relatively defect-free and not oxidized the lateral dimensions of the monolayers are typically only of the order of a few micrometers.

Graphite oxide was first prepared over 150 years ago by *Brodie* in his attempt to determine the *atomic weight* of graphite [19.25] through oxidation using potassium chlorate and fuming nitric acid. Two methods used these days are based upon the development of the Brodie method by *Staudenmaier* [19.26] which was then refined by *Hummers* and *Offeman* [19.27] who employed a water-free mixture of concentrated sulfuric acid, sodium nitrate and potassium permanganate to treat the graphite more quickly and safely. The Brodie material was found to be highly-oxidized with a C/O/H ratio of around 2.2/1/0.8 [19.25] which is typical of graphite oxide produced by these chemical routes. The current state-of-the-art in the preparation of graphite ox-

ide has been summarized and reviewed by *Ruoff* and coworkers [19.28, 29].

Graphite oxide is made up of stacks of *graphene oxide* sheets, with an interlayer spacing of between 0.6 and 1.0 nm depending upon the relative humidity [19.28], in a similar way to which graphite is made up of stacks of more closely spaced graphene sheets. An important difference, however, is that graphite oxide can be readily exfoliated by simple sonication to produce colloidal suspensions of graphene oxide sheets using a range of solvents [19.28, 29] which has led to the present upsurge of interest in the material with the view to scaling up production to produce material in large quantities for applications such as in composites. The graphene oxide that is produced directly from graphite oxide is not particularly useful in that it is thermally unstable and does not conduct electricity. Its properties are greatly improved through reduction, either chemical or thermal, although it has not yet proven to be possible to reduce the material fully back to graphene.

Properties

The original excitement in graphene was because of its electronic properties, with its charge carriers exhibiting very high intrinsic mobility, having zero effective mass and being able to travel distances of micrometers at room temperature without being scattered [19.4, 30]. The majority of the initial research upon graphene concentrated upon these electronic properties and was aimed at applications such as in electronic devices [19.31, 32].

Interest in the material has now broadened considerably as it was soon realized that graphene might have other interesting physical properties such as high levels of thermal conductivity, stiffness and strength, coupled with impermeability to gases. One obvious application was in the field of nanocomposites [19.33] and researchers working upon nanocomposites using other forms of nanocarbon such nanotubes, and nanoclays were soon able to refocus their efforts towards graphene nanocomposites. In addition there was preexisting expertise in exfoliating graphite (e.g. expanded graphite) and in the preparation of graphene oxide (originally termed *graphite oxide*). The latter was shown to be relevant to the study of graphene, in that it can be reduced chemically towards a material that is closely related to graphene.

The direct determination of the mechanical properties of monolayer graphene was first undertaken by *Lee et al.* [19.34] by the nanoindentation of graphene membranes, suspended over holes of around 1.0 and

Fig. 19.4 Measured [19.34] and calculated [19.35] stress–strain curve for the deformation of a graphene monolayer

1.5 μm in diameter on a silicon substrate, in an AFM. The monolayers were found using optical microscopy and identified using Raman spectroscopy. The variation of force with indentation depth was determined and the

stress–strain curve was derived assuming the graphene behaves mechanically as a 2-D membrane with a thickness of 0.335 nm. The graphene was found to break at large displacements with fracture starting at the indentation point. Figure 19.4 shows the stress–strain curve for the graphene derived from the analysis of the indentation experiments and it can be seen that it becomes nonlinear as the strain increases with fracture occurring at a strain in excess of 20%.

Earlier, in 2007, Liu et al. [19.35] undertook an ab initio calculation, using density functional theory, of the stress–strain curve of a single layer graphene and this is also plotted in Fig. 19.4. It can be seen that there is remarkably good agreement between the experimentally-derived curve and the theoretical analysis. The experimentally-determined value of Young’s modulus [19.34] is 1000 ± 100 GPa which compares very well with the theoretical estimate [19.35] of 1050 GPa and the value of 1020 GPa determined many years ago for bulk graphite [19.36]. The strength of the graphene monolayer was found experimentally to be 130 ± 10 GPa which is of the order of $E/8$, where E is the Young’s modulus, and close to the generally-accepted value of the theoretical strength of a defect-free material [19.37]. The failure stress can also be determined from the peak stress in the stress–strain curve calculated using density functional theory in Fig. 19.4. The high-strain behavior is found to differ slightly depending upon the crystallographic direction in which the graphene is deformed [19.35] and the strength is predicted to be in the range 107–121 GPa, again in very good agreement with the experimental measurements.

It is to be expected that the mechanical properties of graphene oxide are inferior to those of graphene due to the disruption of the structure through oxidation and the presence of sp^3 rather than sp^2 bonding. The elastic deformation of chemically-reduced graphene oxide has been investigated by Gomez-Navarro et al. [19.38], again using an AFM indentation technique on a suspended film of material. In this case they suspended single layers of graphene oxide up to $1 \mu\text{m}^2$ in size over a trench in a SiO_2/Si wafer and monitored force-displacement curves when the AFM tip was pushed into the film. They determined a Young’s modulus of 250 ± 150 GPa, although there was considerable scatter in their data. In addition they noted that graphene oxide sheets consisting of 3 or more layers had a Young’s modulus an order of magnitude lower than this value.

Fig. 19.5a A typical Raman spectrum of SWNTs showing the four characteristic bands

19.1.3 Raman Spectroscopy and the Deformation of Carbon Nanomaterials

The Raman spectroscopy of different carbon nanomaterials has become an important research topic since the first work on CNTs was published in 1997. This technique is particularly useful for investigation of the properties of SWNTs due to the resonance effects. Four characteristic Raman bands are found for SWNTs, namely the radial breathing modes (RBMs), G-band, D-band and G'-band (also called the 2-D band) carry a large amount of structural information and have been studied in most detail, although several other weaker and broader features have also been observed in the nanotube spectra [19.39]. A typical Raman spectrum of SWNTs is shown in Fig. 19.5a.

Raman spectroscopy can also be used to characterize and identify different forms of graphene as shown in Fig. 19.5b and, in addition, the Young's modulus of graphene can also be determined indirectly from stress-induced Raman band shifts. Stress-induced Raman band shifts have been found to occur for a number of high-performance materials such as high-modulus polymer fibers [19.40], carbon fibers [19.41] and CNTs [19.42]. It is found that in general the rate of band shift per unit strain scales with the Young's modulus of the material [19.40]. When carbon fibers are subjected to tension there is an approximately linear shift of the G and G' (or 2-D) band positions to lower wavenumber with strain [19.41, 43]. Cooper et al. [19.43] showed that for the G' band, the rate of shift increased with the carbon fiber modulus. They went on to show that there was in fact a linear dependence of the shift rate upon modulus which implied that there is a universal dependence of band shift upon stress for the G' band of $-5 \text{ cm}^{-1}/\text{GPa}$ [19.43]. Both CNTs and graphene have well-defined G' bands and assuming that the universal calibration for carbon fibers can be used for the same band in other forms of carbon, then the Young's modulus of these other material can be estimated.

Large stress-induced shifts of both the G and G' bands are found when graphene is subjected to stress [19.44–49] and this phenomenon has recently been reviewed by Ferralis [19.50]. The simplest way of deforming the material is to deposit exfoliated material on a substrate which is then stretched or flexed in a Raman spectrometer. The behavior is shown in Fig. 19.6 for the deformation of monolayer graphene on a poly(methyl methacrylate) beam [19.47]. It can

Fig. 19.5b Typical Raman spectra of mechanically cleaved graphene with different numbers of layers

Fig. 19.6 Shift of the G' Raman band with strain for single-layer graphene

be seen that there is a large shift in the position of the G' band with strain and the slope of the line is of the order of $-60 \pm 5 \text{ cm}^{-1}/\%$ strain. Using the universal calibration of $-5 \text{ cm}^{-1}/\text{GPa}$ for carbon fibers, this slope corresponds to a Young's modulus for a graphene monolayer of $(-60 \times 100)/(-5) \text{ GPa}$, equivalent to $1200 \pm 100 \text{ GPa}$ and similar to the values measured both directly and calculated theoretically.

19.2 Carbon Nanotube Composites

One of the best ways to fulfil the enormous potential of CNTs is to incorporate them into polymers. It has been demonstrated CNTs can significantly improve the mechanical properties, electrical conductivity, thermal conductivity, thermal stability and fire-retardant ability of polymers [19.7]. There has been impressive progress and interests are still growing in this area since the first polymer/CNT composite was prepared by Ajayan et al. in 1994 (their initial purpose, though, was not to make a composite but to prepare a TEM sample) [19.52].

Mechanical reinforcement on polymers is probably one of the most promising applications of nanotubes. In fact, CNTs have shown reinforcement in Young's modulus, tensile strength and toughness for a variety of polymers and the amount of nanotubes required to achieve significant improvement is much lower than the conventional fillers such as high performance fibers and clay. The extraordinary mechanical properties, high specific surface area, and high aspect ratio make nanotubes ideal candidates for polymer reinforcement [19.53–55].

This section reviews the preparation methods, mechanical properties, the factors that determine the mechanical properties of polymer/CNT composites and the techniques to characterize these factors. The preparation and properties of polymer/CNT bulk composites and composite fibers are considered separately. While

there are numerous articles dealing with mechanical reinforcement of polymers by nanotubes, only a few typical examples are summarized.

19.2.1 Preparation and Properties of Bulk Composites

Most studies on CNT composites have been carried out with bulk composites due to their ease of preparation. The basic methods to produce CNT composites are solution processing and melt processing, and other methods have been developed, by firstly dispersing and integrating nanotubes with polymers and then by using solution or melt processing to prepare the final composites.

Solution processing is probably the most common method for the preparation of polymer/CNT composites. In a typical process [19.7, 9, 53], the nanotubes are firstly dispersed in a solvent, the nanotube dispersion is then mixed with the polymer solution by energetic agitation and finally the composite is obtained by either controlled evaporation or coagulation. Any polymers that are soluble can be processed using this method in theory and small amount of nanotubes leads to significant improvement in mechanical properties of the polymer in most cases. For example, Ryan et al. incorporated different types of nanotubes into poly(vinyl alcohol) (PVA) matrix and prepared thin films by solution processing [19.56]. They observed a threefold increase in Young's modulus and twofold increase in tensile strength for the composite containing only 0.1% of Elicarb SWNTs. The exceptional high efficiency of reinforcement is thought to be related to crystallization of polymers nucleated by the nanotubes. Zhang et al. also observed a 60% increase in Young's modulus and a 200% increase in tensile strength of PVA by adding 5% of HiPco SWNTs [19.51]. Figure 19.7 shows typical stress–strain curves of the neat PVA and PVA/SWNT composite films.

Melt processing is a common alternative technique to prepare polymer nanocomposites for polymers that are insoluble in solvent but melt when heated and it is most suitable for industrial production [19.9]. This method includes three steps [19.7, 9, 53]: the polymers are firstly melted to form a viscous liquid, nanotubes are then added into the melt and dispersed by a high shear force and finally composites are obtained by compression molding or extrusion. Good mechanical reinforcing efficiency has been found in a range of com-

Fig. 19.7 Typical stress–strain curves for PVA and PVA/SWNT films (after [19.51])

posites that are fabricated using melt processing. *Liu et al.* prepared a nylon-6 (PA 6)/MWNTs composite using a melt-compounding approach [19.57]. The elastic modulus and yield strength were improved by 214 and 162%, respectively for composites with 2% MWNTs loading and the reinforcement was explained as a consequence of strong interfacial adhesion in the composite. *Díez-Pascual et al.* produced poly(ether ether ketone) (PEEK)/SWNT composites using a similar method and observed a 27% increase in storage modulus at room temperature at 1% loading of arc-SWNTs [19.58]. Nanotubes have been incorporated into other polymers such as polypropylene (PP), poly(methyl methacrylate) (PMMA), polycarbonate (PC), and polystyrene (PS) using this process.

Other methods such as in-situ polymerization and solid-state pulverization have also been employed to prepare CNT composites. In an in-situ polymerization process, polymerization of the monomers occur on nanotube surface such that the polymers are grafted onto the nanotubes, the polymer-modified nanotubes are then processed by solution or melt processing. The main advantage of this method lies in that it provides a better dispersion of nanotube and stronger interface between the nanotubes and the polymer matrix. *Velasco-Santos et al.* introduced chemically functionalized MWNTs into PMMA matrix by in-situ polymerization. With 1% of MWNTs, the storage modulus and tensile strength of the matrix were improved by 66% and 40%, respectively [19.59].

19.2.2 Preparation and Properties of Composite Fibers

Fibers such as polyacrylonitrile (PAN) and poly(p-phenylene benzobisoxazole) (PBO) fibers are favoured over bulk polymers for many applications [19.9]. Generally, CNTs show more promising reinforcement in fibers than in bulk composites due to the possibility of improved alignment. The most important methods to fabricate polymer/CNT composite fibers include melt spinning, coagulation spinning and electrospinning.

The process for melt spinning of fibers is similar to the melt processing of bulk composite except that the dopes are extruded through a smaller nozzle and fibers are drawn further. *Kearns and Shambaugh* prepared PP/SWNT composite fibers by melt spinning [19.60]. The modulus and tensile strength were increased by 56 and 45% respectively by adding 1% of SWNTs. They also observed an increase of the elongation at break

from 19 to 27%, which is of particular significance for the composite fibers.

Coagulation spinning is a new method which was first reported by *Vigolo et al.* in 2000 [19.61]. This method disperses SWNTs using a surfactant solution and coagulates the nanotubes into a mesh by spinning it into an aqueous PVA solution. *Dalton et al.* optimized this method and prepared super tough PVA/SWNT composite fibers containing 60% of SWNTs, which had a tensile strength of 1.8 GPa, comparable to that of spider silk [19.62]. What leads to this simple method attracting much attention is the extraordinary toughness of the fiber, of 570 J/g, which is much higher than that of any existing high-performance fiber.

Electrospinning is the only method that can prepare fibers as small as several nanometers in diameter to date and it is the most effective technique to orient nanotubes in composites [19.63, 64]. In the electrospinning process, a high electric voltage is applied to a polymer solution (or melt) such that the solution is charged. When the electrostatic force overcomes the surface tension, a charged jet emanates from the nozzle, the solvent evaporates and fibers are deposited on the collector (Fig. 19.8 for a schematic diagram of the process). The nanotubes in the fibers are aligned by the strong drawing force exerted by the electric field. *Young et al.* demonstrated recently that the nanotube orientation has a dominant effect on the fiber strength [19.65]. The good orientation achieved in electrospun fibers is thus expected to enhance the strength of the fiber significantly. *Almeciya et al.* measured the mechanical properties of individual PVA/SWNT electrospun nanofibers and observed an effective modulus of 27 TPa and effective strength of 600 GPa for the nanotubes, suggesting a superb reinforcing efficiency that has never been achieved in less-aligned CNT composites [19.66]. These values are much higher than the theoretical mechanical properties of nanotubes. Nanotube-nucleated polymer ordering and crystallization might be responsible for this extraordinary reinforcement.

19.2.3 Reinforcement Mechanisms and Modelling

For composites for which the properties of the polymer matrix are unaffected by the nanotubes, mechanical reinforcement originates from stress transfer to the nanotubes. In an ideal case where long and highly aligned nanotubes are embedded in polymers, the mechanical properties of the composite can be described

Fig. 19.8 A laboratory setup for an electrospinning experiment (after [19.63])

by the simple rule of mixtures [19.67]

$$E_c = V_{\text{NT}} E_{\text{NT}} + (1 - V_{\text{NT}}) E_m, \tag{19.2}$$

$$\sigma_c = V_{\text{NT}} \sigma_{\text{NT}} + (1 - V_{\text{NT}}) \sigma_m, \tag{19.3}$$

where E_c , E_{NT} , and E_m are the modulus of the composite, nanotubes, and the polymer matrix, respectively; σ_c , σ_{NT} , and σ_m are the strength of the composite, nanotubes, and the polymer matrix, respectively; and V_{NT} is the volume fraction of nanotubes.

When all nanotubes are not aligned in the same direction and the length is too short such that the stress is nonuniform in the majority part of the nanotube, the mechanical properties of the composite are given by [19.9]

$$E_c = \eta_o \eta_L V_{\text{NT}} E_{\text{NT}} + (1 - V_{\text{NT}}) E_m, \tag{19.4}$$

$$\sigma_c = \eta_s V_{\text{NT}} \sigma_{\text{NT}} + (1 - V_{\text{NT}}) \sigma_m, \tag{19.5}$$

where η_o is the orientation efficiency factor, η_L is the length efficiency factor, and η_s is the strength efficiency factor. The effective modulus E_{eff} of nanotubes which is defined as $E_{\text{eff}} = \eta_L E_{\text{NT}}$ (similarly, σ_{eff} is defined as $\sigma_{\text{eff}} = \eta_s \sigma_{\text{NT}}$), accounts for the length and bundling effect on nanotube modulus. The effective modulus and strength allow the efficiency of mechanical reinforcement in different composite systems to be compared.

The important results for the mechanical properties of bulk composites and composite fibers reported in the literature are summarized in Tables 19.2, 19.3, respectively. The effective modulus (E_{eff}) and strength (σ_{eff}) of nanotubes which characterize the efficiency of reinforcement are back-calculated using the rule of mixtures and assuming the matrices were unaffected by nanotubes in all these cases. It is noted although nanotubes

Table 19.2 Mechanical properties of CNT-reinforced bulk composites

CNT type	Polymer	CNT (vol.%)	E_c (GPa)	E_m (GPa)	E_{eff} (GPa)	σ_{eff} (GPa)	Reference

SWNT	PBO	12	167	138	380	16	[19.76]
SWNT	PAN	0.9	1.07	0.9	730	19	[19.77]

display reinforcing effect on a range of polymers, only few of them have values of E_{eff} and σ_{eff} approaching the theoretical values for individual nanotubes (i. e. 1000 GPa for modulus and 30–100 GPa for strength). Moreover, the degree of strength improvement is less than that of the modulus improvement in most cases, which is believed to be due to the shortened length and bundling effect of nanotubes in composites. This suggests the mechanical performance of composites can be further improved. A better understanding of the structure/property relationship is needed and this requires powerful techniques to characterize the composites, which will be reviewed in the following sections.

Nanotubes can nucleate some polymers such as PVA to crystallize on their surface and the crystalline layer is much stiffer than the surrounding amorphous polymers. In this case the modulus and strength of the composites are higher than those predicted by the simple rule of mixtures, which is due to the contribution of the stiffer crystalline phase. Coleman et al. modified the rule of mixtures to calculate the composite modulus considering the contribution of the three phases [19.54]

$$E_c = \eta_o E_{eff} V_{NT} + E_a (1 - V_{NT}) + (E_\chi - E_a) \left(\frac{b^2 + 2r_t b}{r_t^2} \right) V_{NT}, \quad (19.6)$$

where E_a is the modulus of the amorphous polymer, E_χ is the modulus of the crystalline phase, b is the average thickness of the nanotube-nucleated crystalline layer and r_t is the nanotube radius.

When the nanotube induced crystallization occurs, the fracture of the composite occurs at the interface between the bulk polymer and the crystalline layer. The composite strength can be described as a sum of the strength of the bulk polymer and the interface. Coleman et al. developed another form of rule of mixtures to calculate the composite strength which is given by [19.78]

$$\sigma_c = \tau \frac{(r_t + b) l_p}{r_t^2} V_{NT} + \sigma_m \left[1 - \frac{(r_t + b) V_{NT}}{r_t^2} \right], \quad (19.7)$$

where τ is the interfacial shear strength, σ_m is the tensile strength of the polymer, and l_p is the pull out length of nanotubes. Equations (19.6) and (19.7) suggest that the crystalline layer has a significant effect on mechanical properties of the composites when b is large, and the simple rule of mixtures is not valid when the properties of polymer matrix are affected upon addition of nanotubes.

19.2.4 Fundamental Aspects of CNT Composites

Although nanotubes have exhibited their promising reinforcing effect in composites, there is still a gap between the measured and the theoretical values of modulus and strength. It is recognized that the dispersion, orientation and the interfacial adhesion have significant effect on mechanical properties of composites [19.79]. This section discusses how these factors influence the properties and how to optimize them in the composite structure.

Dispersion

The state of dispersion is probably the most important factor that determines the mechanical properties of composites and good dispersion of nanotubes is crucial for any composite. The state of dispersion of nanotubes can influence the mechanical properties of composites through the following aspects [19.79]:

1. The surface area decreases when individual nanotubes tend to aggregate into ropes (or bundles). The surface area is important for mechanical reinforcement because:
 - a) It acts as an interface for stress transfer, and larger surface area leads to higher efficiency of stress transfer.
 - b) When the nanotubes are in ropes, the load is carried mainly by the nanotube on the perimeter of each rope which is evidenced by the inter-tube sliding when subjected to external stress [19.80]. Hence, larger nanotube ropes re-

sult in smaller effective volume fraction for reinforcing fillers.

2. Nanotubes can induce polymers to crystalline on their surface. The crystalline layer, which is related to the nanotube surface area, can determine the mechanical performance for some semi-crystalline polymer composites [19.54, 78].
3. Good dispersion gives rise to a uniform distribution of stress and minimizes the stress concentration centres in the composites. Poor dispersion which results in stress concentrations consequently leads to a smaller degree of strength improvement than that of modulus improvement.
4. The mechanical properties of nanotubes bundles are much poorer than those of individual nanotubes. *Salvetat et al.* measured the modulus of nanotube ropes by bending the nanotubes with an AFM tip [19.81]. They found the modulus decreased from over 1 TPa for the nanotube rope with a diameter of 3 nm to 149 GPa for the rope with a diameter of 13.5 nm.

The aforementioned theoretical analysis of the effect of dispersion has been supported by a range of experimental works. For example, *Song and Youn* observed a greater improvement in tensile strength and elongation at break for epoxy composites with good MWNTs dispersion compared to a poorly dispersed system [19.82]. *Zhu et al.* compared the mechanical properties of epoxy composites containing untreated SWNTs (poor dispersion) and functionalized SWNTs (good dispersion), and found that the tensile strength is worse for a poorly dispersed system than the neat epoxy, whereas the modulus and strength are increased by 18 and 30% respectively for composite with good dispersion of nanotubes [19.83]. Although they claimed that the relatively better reinforcement was a consequence of the improvement of dispersion, the effect of a stronger interface, however, could not be excluded as improvements in dispersion are usually coupled with an increase of interfacial adhesion with the matrix.

Nanotube exfoliation can be accomplished by stirring, shear mixing and/or ultrasonication [19.9]. Stable and uniform dispersions of pristine nanotubes are however difficult to achieve using these techniques alone. Compared to MWNTs, SWNTs are even more difficult to disperse because they possess larger specific surface area and have a stronger tendency for aggregation. In addition, intensive mechanical agitation can induce defects and damage the sidewall structure, which consequently degrades the mechanical proper-

ties of nanotubes. Two main methods have thus been developed to facilitate the dispersion of nanotubes in polymers:

1. Dispersing nanotubes with the aid of surfactants or other dispersants. The dispersant molecule wrapping around the nanotubes can induce strong noncovalent bonding with the matrix, giving rise to stable dispersion. *Gong et al.* [19.84] prepared epoxy/CNT composites using a nonionic surfactant to assist dispersion of nanotubes. They found the elastic modulus is increased by 30% by adding 1% of nanotubes, while the incorporation of nanotubes without the surfactant has only a moderate effect on mechanical properties.
2. Introducing covalent bonding between nanotubes and the matrix by chemically functionalizing the nanotubes. This can be achieved by introducing functional groups (such as carboxyl group) or by grafting matrix polymer onto the nanotube surface through in-situ polymerization. Improving the dispersion via chemical functionalization confers extra benefit, i.e. better interfacial adhesion in the composites.

It should be pointed out however, there is a maximum volume fraction for isolated nanotubes in the polymer matrix, assuming the minimum separation between the nanotubes is the radius of a polymer molecule. For nanotubes arranged in hexagonal arrays, the separation S_{hex} between the nanotubes is given by [19.37]

$$S_{\text{hex}} = d_t \left(\sqrt{\frac{\pi}{2\sqrt{3}V_{\text{NT}}}} - 1 \right), \quad (19.8)$$

where d_t is the nanotube diameter. The typical radius for a polymer is of the order of 5 nm [19.85]. For SWNTs with an average diameter of 1 nm, more than 2.5% of nanotubes in the polymer will naturally lead to nanotube aggregation, and in the case of MWNTs with a diameter of ≈ 10 nm, the maximum volume fraction for individual nanotubes is 40%.

Orientation

Carbon nanotubes show highly anisotropic mechanical properties, e.g. the longitudinal modulus is ≈ 1000 GPa while the transverse modulus is only ≈ 15 GPa [19.86, 87]. The mechanical properties of composites are thus strongly dependent on the orientation of nanotubes and the mechanical reinforcing efficiency is lower when all nanotubes are not aligned in the same direction. A Cox

orientation efficiency factor η_o can be introduced to the rule of mixtures to take into account the effect of orientation distribution of the reinforcing fillers on properties of the composites [19.43, 88]. The parameter η_o can be considered as a summation of contribution of all fillers (nanotubes) lying at any angle Ψ with respect to the longitudinal direction of the composite

$$\eta_o = \sum_n a_n \cos^4 \Psi, \quad (19.9)$$

where a_n is the proportion of fillers lying at the angle Ψ_n and is given by $\sum_n a_n = 1$. For fillers randomly distributed in a plane (2-D distribution), η_o is an integration over the range $-\pi/2$ – $\pi/2$ and is given by

$$\eta_o = \frac{1}{\pi} \int_{-\pi/2}^{\pi/2} \cos^4 \Psi d\Psi = \frac{3}{8}, \quad (19.10)$$

while for fillers randomly distributed in three dimensions, η_o can be determined by

$$\eta_o = \frac{1}{\pi} \int_0^{\pi/2} \sin \Psi \cos^4 \Psi d\Psi = \frac{1}{5}. \quad (19.11)$$

This indicates the modulus and strength of nanotubes is 3/8 (for 2-D distribution) or 1/5 (for 3-D distribution) of those of the uniaxially-aligned nanotubes. Some reports are consistent with these theoretical values. For example, *Thostenson* and *Chou* prepared PS/SWNT composites and observed an increase of 49% in storage modulus for an aligned composite, whereas for a randomly oriented composite the modulus was increased by only 10% compared to the bulk polymer [19.89]. This means a fivefold relative increase for the aligned system over the randomly oriented system.

There are a variety of methods to align nanotubes in composites. These techniques can be generally classified into two categories:

1. Aligning nanotubes using fiber spinning techniques such as melt spinning, coagulation spinning and most efficiently, electrospinning. In the electrospinning process, there are tremendous drawing forces acting on tiny jets of the polymer solution, which leads to the rigid-rod like nanotubes rotating around their centre of gravity and orienting along the drawing direction to minimize the torque applied to them. Similarly, the shear force in a melt spinning process and the drawing force in a mechanical stretching process can also orient the nanotubes in the composites. Fiber spinning processes together with the

mechanical stretching are the most common methods to align nanotubes in composites.

2. Aligning nanotubes using magnetic or electric fields. A high magnetic field is efficient to align nanotubes along the magnetic field axis when the diamagnetic susceptibilities parallel to the nanotube axis is larger than that perpendicular to the nanotube axis. In 2002, *Kimura* et al. [19.90] firstly demonstrated the magnetic field-induced orientation of MWNTs in a PS matrix. In this process, MWNTs were dispersed in a monomer solution of unsaturated polyester, and then a constant magnetic field of 10 T was applied to align nanotubes. Polymerization under the strong magnetic field yielded good alignment of nanotubes, and this was revealed by the anisotropic properties of the composites. This procedure has been followed and modified by a number of groups to achieve good orientation.

It should be pointed out that good orientation can only be achieved when nanotubes are well separated because nanotubes bundles are often entangled during growth. Aligned nanotube arrays can be grown directly on substrates, but few examples that transfer the arrays and preserve their alignment in composites have been reported [19.91].

Interfacial Adhesion

The interfacial adhesion between the polymer matrix and nanotubes is a key factor for the properties of nanocomposites because it determines the efficiency of stress transfer from the matrix to the reinforcing filler [19.9, 10]. Adequate interfacial stress transfer from the matrix to the nanotubes is only possible when the interface has not failed during composite loading [19.92–94].

The interfacial shear strength (IFSS) is defined as the maximum shear stress before the interface fails. It governs the maximum stress transferred to the nanotube and is quite sensitive to the nanotube and matrix type, as well as the bonding type, i.e. whether it is covalent bonding or noncovalent bonding [19.9, 55]. *Liao* and *Li* found that in the absence of covalent bonding between the nanotubes and the matrix, the nanotube/matrix adhesion comes from a) electrostatic and van der Waals interactions and b) stress/deformation arising from the mismatch in the coefficients of thermal expansion between nanotubes and the polymer matrix [19.95].

There are four mechanisms for composite fracture, namely fiber fracture, fiber pull out, fiber/matrix debonding, and matrix cracking (Fig. 19.9) [19.55].

Fig. 19.9 Schematic diagram showing the fracture mechanisms of nanocomposites (after [19.55])

Which kind of fracture occurs depends on the relative strength among the polymer matrix, the interface between the bulk polymer and interfacial polymer, and the nanotube–matrix interface.

For noncovalently bonded systems, the nanotube–polymer interfacial strength is around 50 MPa, and for covalently bonded systems this value is typically of a few hundred MPa although large variation has been found in the literature [19.93]. Barber et al. found the average stress to pull out a single MWNT from a polyethylene-butene/MWNT composite is 47 MPa, which is about ten times higher than the system made up of the same polymer and carbon fibers [19.93]. They inferred that covalent bonding existed between the polymer matrix and the defects of MWNTs. Cooper et al. determined that the interfacial strength for epoxy/CNT composites ranges from 42 MPa to ≈ 300 MPa and concluded that substantial adhesion between nanotubes and the epoxy resin exists in some cases, probably related to the defects on the nanotubes [19.94]. Coleman et al. found an exceptional high IFSS of 95 MPa for their PVA/MWNT films [19.78]. They ascribed this to the nucleation effect of nanotubes which induced the polymer to form a crystalline coating around the nanotubes.

The interface can be tailored, according to the matrix type, by introducing different functional groups onto nanotube surface. Barber et al. functionalized MWNTs with carboxylic groups and found that the IFSS increased significantly from 30 MPa for epoxy/pristine-MWNT interface to 150 MPa for the chemically functionalized system [19.96]. Duncan et al. modified the MWNTs with epoxide terminated groups

which can further react with the matrix polycarbonate through thermal trans-esterification reaction [19.97]. They found the IFSS almost triples upon chemical functionalization, from the range of 5–14 MPa for untreated MWNTs to the range of 11–38 MPa for the functionalized system.

In addition to the effect of dispersion, orientation and interfacial adhesion, other factors such as the nanotube type and the preparation method of nanotubes can also influence the mechanical properties of the composites. Essentially, these factors influence the mechanical reinforcing through the more fundamental aspects, namely the dispersion, orientation and the interfacial stress transfer. For example, Chae et al. compared the reinforcing efficiency of different types of nanotubes on PAN and found a general trend of $SWNT \approx MWNT > DWNT$ [19.98]. They explained this as a result of a better dispersion and orientation of SWNTs (or MWNTs) than those of DWNTs (because the DWNTs they used were highly entangled and were difficult to align) in the composites.

The nanotube aspect ratio, however, has a more profound effect on the reinforcing efficiency. When the composite is deformed, the stress is transferred to the nanotubes through a shear mechanism and the stress in the nanotubes builds up from the ends to the midsection. The length required for the stress to build up until the nanotube has a strain equal to that of the matrix is called the stress transfer length. At a critical nanotube length l_c , the stress transferred to the nanotube is large enough to break the nanotube. If the interfacial shear stress along the nanotube is assumed to be constant (the

Fig. 19.10a–c The idealized profile of stress in nanotube composites that contain nanotubes with different lengths: **(a)** Nanotubes longer than the critical length; **(b)** nanotubes equal to the critical length; **(c)** nanotubes shorter than the critical length (after [19.97])

Kelly–Tyson model [19.37]), the critical length can be determined by [19.97]

$$l_c = \frac{d_t \sigma_{NT}}{\tau_{ave}}, \quad (19.12)$$

where σ_{NT} is the nanotube tensile strength and τ_{ave} is the average interfacial shear stress. The profiles of stress along nanotubes that possess different lengths l are shown in Fig. 19.10 and it can be seen the regions of nanotubes near the ends are less heavily stressed and nanotubes do not carry the maximum load when they are too short ($l < l_c$). Hence, the reinforcing efficiency decreases as the fiber length (or the aspect ratio) is reduced [19.67].

19.2.5 Characterization of CNT Composites

Dispersion

Despite the importance recognized unanimously of nanotube dispersion on mechanical properties of the composites, the assessment of dispersion state relies largely on qualitative and subjective interpretation of TEM and SEM images. Efforts have been made to quantify the dispersion by analysing the images. Lillehei et al. established a quantitative approach by analysing the frequency of spatial features in SEM images to evaluating the dispersion quality [19.99]. Their approach allowed the estimation of diameter of nanotube bundle, the segment length and bundle spacing. Luo et al. employed ImageJ software to measure the free-path spacing between nanotubes in TEM images and used a parameter $D_{0.1}$ to quantify the dispersion quality. This parameter is defined as the probability of the free-path distance distribution in the range of $0.9–1.1\mu$, where μ is the mean

spacing [19.100]. Figure 19.11 shows an example of the process of quantitative assessment based on TEM images.

Fluorescence spectroscopy is another useful technique for the assessment of dispersion. When a semi-conducting nanotube absorbs excitation light via an E_{22} transition, it emits the light through a $c_1 \rightarrow v_1$ transition (c_1 and v_1 are the first conduction and valence bands, respectively). The emission is quenched when the nanotubes are in bundles. Only truly debundled nanotubes can therefore be detected by fluorescence spectroscopy and this can be obtained only for an extremely low loading of nanotubes in composites. Such composites are not of particular interest for mechanical reinforcement, but are of great importance for studying the intrinsic properties and the interaction with the environment at the single nanotube level.

Other techniques such as optical microscope, UV-Vis spectroscopy, small angle neutron scattering (SANS), size exclusion chromatography (SEC) [19.101] and differential scanning calorimetry (DSC) [19.102] have also been employed to examine the dispersion quality. Fagan et al. compared the reliability of four techniques, i.e. SANS, fluorescence spectroscopy, optical absorption spectroscopy and Raman spectroscopy for evaluating the dispersion [19.103]. They demonstrated that the first two techniques both offer reliable measures due to their sensitivity to bundling or clustering of nanotubes and are more definitive than the latter two techniques. While the SANS technique is powerful in evaluating the local dispersion quality on the nanoscale (i.e. the size of individual nanotubes or nanotube bundles), it does not give information as to the distribution of bundle spacing which is a measure of the uniformity of the dispersion.

Orientation

TEM is the most common characterization technique which provides a direct view of the arrangement of nanotubes in composites. It is however difficult to image SWNTs with TEM due to the low contrast between polymers and SWNTs. This is made even more difficult when SWNTs are well separated. *Salalha et al.* used a reactive ion etching process to etch the polymer matrix so that SWNTs are exposed (Fig. 19.12) [19.104]. The processing time needs to be carefully controlled to reduce the matrix thickness without damaging the SWNTs. Characterizing the orientation using TEM requires tedious and careful sample preparation and it should be noted cutting the composites into slices using a diamond knife (a common method for TEM sample preparation) may lead to the nanotubes orient along the cutting direction, as has been demonstrated by *Ajayan et al.* in an early example [19.52].

Orientation of the nanotubes (particularly MWNTs) can also be characterized using x-ray diffraction. Figure 19.13 shows the wide angle x-ray diffraction (WAXD) pattern of PAN/MWNT composite nanofibers. The arc at $2\Phi = 26.5^\circ$ is identified as the diffraction of (002) crystal plane of MWNTs. By azimuthal scanning of the (002) diffraction arc, the average value of the angle β between the molecular axis and the fiber axis can be determined. A quantitative parameter, i. e. Herman's orientation factor f , can then be determined by

$$f = \frac{3 \langle \cos^2 \beta \rangle - 1}{2} . \quad (19.13)$$

Using this method, *Ge et al.* determined the orientation factor of both polymer molecules and nanotubes in PAN/MWNT nanofibers and found the nanotubes are better oriented than the polymer molecules [19.105].

Fig. 19.12a,b TEM images of poly(ethylene oxide) (PEO)/SWNT electrospun fibers before etching (a) and after etching showing the good orientation of SWNTs (b), bar = 50 nm (after [19.104])

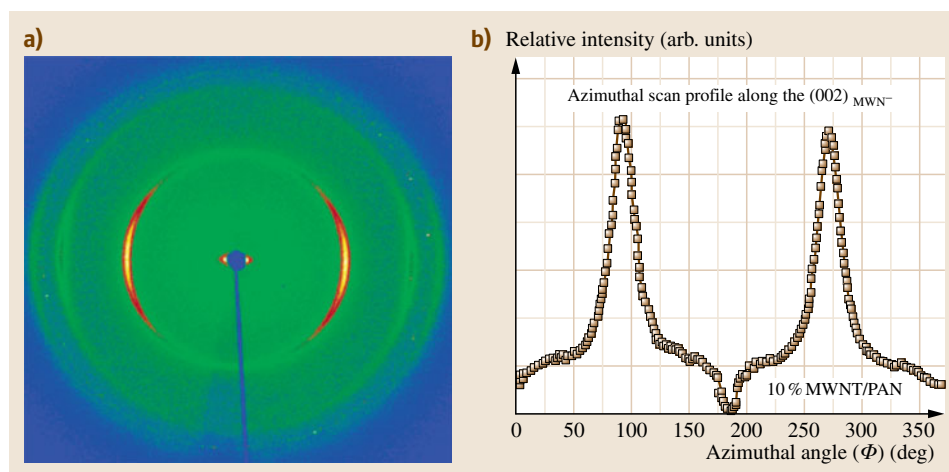

Fig. 19.13
(a) Two-dimensional WAXD pattern of PAN/MWNT composite fibers.
(b) The azimuthal scan of (002) diffraction ring from (a) (after [19.105])

However, to acquire appreciable intensity requires a relatively high loading of nanotubes in the composites, and for some type of SWNTs, there is no Bragg peak at all.

Interfacial Adhesion

The interfacial adhesion and strength can be examined qualitatively by SEM observation of the fracture surface which gives the information on the failure mechanism (i.e. whether the composite fails due to nanotube pull out, nanotube fracture or matrix failure). TEM has been used to investigate the wetting of nanotubes in polymer and crystallization of polymer on the nanotube surface. These all produce indirect information on interfacial adhesion, however.

AFM and scanning probe microscopy (SPM) tips can be utilized to apply small and accurate force to

nanotubes. Combining these tips with electron microscopy, the IFSS in nanotube composites can be determined quantitatively. Barber et al. carried out a nanopullout experiment on nanotube composites. For a typical measurement, an individual nanotube is attached to the end of an AFM tip and is then pushed into a liquid epoxy polymer. After curing of the epoxy, the nanotube is pulled away from the matrix by the tip which is driven by a cantilever (Fig. 19.14). The embedded length l_{emb} (or equivalently the pull out length l_p) can be measured using SEM (by measuring the free length of nanotube before and after pull out), TEM (by measuring the empty cylinder in the matrix upon pull out) and AFM (by measuring the depth of the hole). The pull out force applied by the cantilever can be calculated by $F_{\text{pull}} = KD$, where K is the spring constant

Fig. 19.14a,b SEM images of a MWNT before (a) and after (b) pulling out from an epoxy by an AFM tip. Bottom schematic movement of the AFM tip (after [19.96])

and D is the bending deflection of the cantilever. The average interfacial shear stress τ_{ave} is given by

$$\tau_{\text{ave}} = \frac{F_{\text{pull}}}{\pi d_t l_{\text{emb}}} \quad (19.14)$$

Using this method, Barber et al. measured the IFSS for polyethylene-butene/MWNT to be 47 MPa [19.93], for epoxy/MWNT to be 30 MPa and a much higher IFSS for epoxy/MWNT-COOH to be 150 MPa [19.96]. Cooper et al. used a SPM tip to pull nanotubes out from the epoxy matrix and found that IFSS for epoxy/MWNT ranges from 35 to 380 MPa [19.94].

19.2.6 Characterization of CNT Composites Using Raman Spectroscopy

Raman spectroscopy has becoming an important technique to characterize polymer/CNT composites. This technique shows the advantages over the other techniques in the rich information it can provide, the capability of studying the composites structure on the molecular scale and simple sample preparation. In fact, Raman spectroscopy has been employed to study almost all aspects that influence the mechanical properties of nanocomposites.

Dispersion

Raman spectroscopy provides a qualitative but convenient way to assess the dispersion of nanotubes in composites. For composites containing a single type of

nanotube (i. e. SWNTs or MWNTs), the Raman intensity is proportional to the amount of nanotubes in the laser spot for a given laser. The dispersion of nanotubes can therefore be monitored by mapping out the Raman band intensity across the composite. The spatial resolution depends on the laser spot size, which is mostly on the order of a few micrometers.

Rasheed et al. prepared poly(styrene-co-vinyl phenol) (PSVPh)/SWNT composites and examined the dispersion of nanotubes using Raman spectroscopy combined with optical microscopy. They mapped out the nanotube G-band intensity and found the oxidized nanotubes are more evenly distributed than the pristine nanotubes in the composite [19.106].

Assessment of the dispersion on the nanoscale (i. e. individual nanotubes) is a more complicated issue. When SWNTs are separated into individual ones, the Raman features including the band frequency, intensity and lineshape are different from those of nanotube bundles. For example, the RBM peaks shift to higher frequencies by $1-9 \text{ cm}^{-1}$ upon debundling, and some RBM peaks (e.g. the 267 cm^{-1} peak when excited with a 785 nm laser) seen in nanotube bundles are absent when the SWNTs are individualized [19.80].

Orientation

Raman spectroscopy is an important technique in characterising the orientation of nanotubes. It is particularly powerful in determining the orientation of individual SWNTs which is difficult to achieve using other techniques such as TEM or XRD.

The degree of alignment of SWNTs can be determined quantitatively using polarized Raman spectroscopy. This is based on the orientation dependent Raman band intensity of nanotubes: the Raman band intensity is a maximum when the nanotube axis is parallel to both the incident and scattered laser and is a minimum when the nanotube is perpendicular to the axis of laser polarization [19.107]. This orientation dependence of the Raman scattering is ascribed to the polarization behavior of nanotubes, where the absorption of the light polarized parallel to the nanotube axis is up to ≈ 20 times stronger than for perpendicularly polarized light, which in turn influences the resonance enhancement in the Raman spectra of nanotubes [19.108].

Characterization of the orientation is usually performed using a polarized Raman spectroscopy with the VV configuration where the incident light and scattered light are both parallel to the principal axis of the spectrometer, the VH configuration where the incident light is parallel and the scattered light is perpendicular to the

Fig. 19.15 (a) Variation of nanotube G-band intensity recorded using the VV configuration, as a function of the angle ϕ between the fiber axis and the laser polarization direction for an electrospun PVA/SWNT fiber. (b) G-band intensity obtained for the PVA/SWNT film rotated at different angles ϕ and using the VV configuration. The solid lines are generated for $I \propto \cos^4 \phi$ expected for perfect orientation [19.105] (after [19.109])

principal axis of the spectrometer and the HH configuration where the incident light and scattered light are both perpendicular to the principal axis of the spectrometer. An example of this is shown in Fig. 19.15 for a PVA/SWNT nanocomposite [19.109]. In the case of an electrospun fiber the intensity of the G-band decreases as the fiber is rotated relative to the axis of laser polarization. In contrast, for a nanocomposite film of the same composition the intensity of the G-band does not change as the film is rotated.

Several models describing the dependence of Raman band intensity upon the nanotube orientation have been proposed. A typical model based on the resonance theory is briefed as follows: for perfectly aligned nanotubes using a VV configuration, the dependence of scattering intensity upon the angle α between the nanotube axis and the axis of laser polarization is found to be [19.107]

$$I_{VV} \propto \cos^4 \alpha. \quad (19.15)$$

For a composite comprising nanotubes over a range of angles the total Raman band intensity can be integrated to sum the contribution from nanotubes at each angle. The Raman band intensity $I(\phi)$ at a sample angle ϕ is given by [19.107]

$$I(\phi) \propto \int_{\phi-\pi/2}^{\phi+\pi/2} F(\alpha - \phi, \Delta) \cos^4 \alpha d\alpha, \quad (19.16)$$

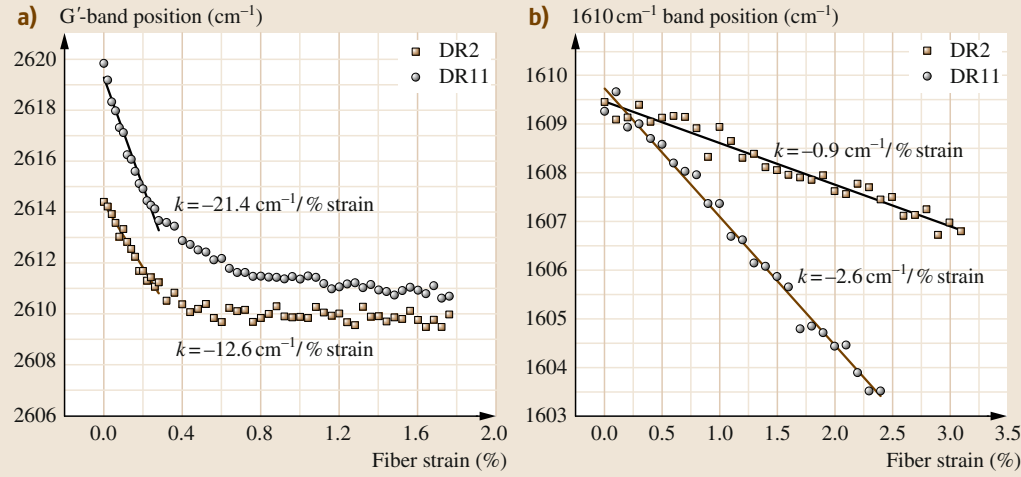

where ϕ is the composite angle with respect to the axis of laser polarization, $F(\alpha - \phi, \Delta)$ is an orientation distribution function (ODF). The degree of alignment is characterized by the parameter Δ which indicates the average orientation angle. Hwang et al. found a special Lorentzian function fitted their data well [19.107]

$$F(\alpha - \phi, \Delta) = \frac{\Delta/2\pi}{(\alpha - \phi)^2 - (\Delta/2)^2}. \quad (19.17)$$

Anglaret et al. used both Lorentzian and Gaussian functions as the ODF [19.110] and obtained slightly different results for the orientation distribution. More recently, Pérez et al. derived a Wigner function as the ODF and simplified to Legendre polynomials after symmetry considerations [19.111]. The method based on (19.16) can give the orientation factor as well as the fraction of nanotubes that make an angle Δ with respect to the sample axis. It has been used by a number of groups with a variety of samples.

Liu and Kumar proposed another model to calculate the orientation factor of nanotubes [19.112]. Considering that the Raman band intensity of SWNTs is determined by its polarizability tensor rather than the derivative of the polarizability tensor, and assuming a uniaxial orientation of the sample, the dependence of Raman band intensity on the angle is given by

$$I_{VV}(\phi) \propto \left(\cos^4 \phi - \frac{6}{7} \cos^2 \phi + \frac{3}{35} \right) \langle P_4(\cos \beta) \rangle + \left(\frac{6}{7} \cos^2 \phi - \frac{2}{7} \right) \langle P_2(\cos \beta) \rangle + \frac{1}{5}, \quad (19.18)$$

**Fig. 19.16a,b**

Variation of Raman band peak position for composite fiber with different DRs under tensile deformation: (a) nanotube G'-band and (b) PPTA 1610 cm⁻¹ peak (after [19.113])

$$I_{\text{VH}}(\phi) \propto \left(-\cos^4 \phi + \cos^2 \phi - \frac{4}{35} \right) \langle P_4(\cos \beta) \rangle + \frac{1}{21} \langle P_2(\cos \beta) \rangle + \frac{1}{15}, \quad (19.19)$$

where $\langle P_2(\cos \beta) \rangle$ and $\langle P_4(\cos \beta) \rangle$ are the second-order and fourth-order orientation parameters, respectively. Specifically, $\langle P_2(\cos \beta) \rangle$ is the Herman's orientation factor, which has a value of 1 for perfect orientation, 0 for random distribution and -0.5 for the vibration perpendicular to the main axis. The orientation factors can be determined by recording the Raman intensity at different angles and then fitting the data using (19.18) and/or (19.19). For uniaxially-oriented samples, only the VV and VH intensities at 0 and 90° are needed to determine the orientation factor accurately. This provides a simple and straightforward method for orientation determination.

Zamora-Ledezma et al. also developed a method to assess the orientation assuming that: a) the system is uniaxial and b) only the zz component (z is the coordinate along the nanotube axis) of the SWNT Raman polarization tensor is nonzero. For a 3-D orientation of the nanotubes which has a uniaxial symmetry, the orientation factor is given by [19.114]

$$f = \frac{3I_{\text{VV}} + 3I_{\text{VH}} - 4I_{\text{HH}}}{3I_{\text{VV}} + 12I_{\text{VH}} + 8I_{\text{HH}}}, \quad (19.20)$$

while for a 2-D orientation, the orientation factor is given by

$$f = \frac{I_{\text{VV}} - I_{\text{HH}}}{I_{\text{VV}} + I_{\text{VH}} + 2I_{\text{HH}}}. \quad (19.21)$$

To determine the orientation factor using Zamora-Ledezma's method does not require rotating the sample

relative to the laser polarization, as only the intensities obtained using VV, VH and HH configurations at 0° are needed. The errors brought by heterogeneities in the sample can therefore be eliminated.

It should be noted the orientation factors determined using these methods are not identical to each other due to the different assumptions made in different models. Generally, the intensity ratio $I_{\text{VV}}^0/I_{\text{VH}}^{90}$ can be used for a quick and qualitative assessment of the orientation. A higher intensity ratio corresponds to a better orientation.

Interfacial Adhesion

Raman spectroscopy can be used to probe the load transfer from the matrix to nanotubes and the interfacial slippage in the composites. This is based on the well known stress dependent Raman G-band and G'-band frequencies, where both bands shift to lower wavenumber under tensile stress and to higher wavenumber under compression.

An example of this is shown in Fig. 19.16 for the deformation of SWNT/aramid PPTA fibers of different draw ratios (DR) [19.113]. There is a large shift of the G' SWNT band with strain up until around 0.3% above which the shift rate (with respect to strain) decreases, indicating failure of the aramid-SWNT interface. In contrast the 1610 cm⁻¹ aramid (matrix) band shifts linearly with strain up to over 2% strain. The nanotube Raman band shift during deformation is an indication of stress transfer and larger shift rate (the shift rate is defined as the slope of the linear region in the Raman band frequency-strain curve) indicates higher efficiency of stress transfer and consequently higher efficiency of

Table 19.4 Factors that influence the Raman band shift rate of nanotubes in composites

Factor	Influence on the G'-band shift rate	Reference
Nanotube type	SWNTs > MWNTs	[19.43]
Preparation method	CVD CNTs > arc-discharge CNTs	[19.43]
Bonding type	Covalent bonding > noncovalent bonding	[19.115]
Dispersion state	Good dispersion > poor dispersion	[19.109]
Polymer type	Stiff polymers > elastomers	[19.113]
Nanotube orientation	Aligned > random	[19.109]

mechanical reinforcement. The Raman band shift rate depends on many factors such as the nanotube type, preparation method, state of dispersion and orientation. The factors studied in the literature that influence the shift rate are listed in Table 19.4. This is certainly not a full list, e.g. the G' shift rate for individual SWNTs is believed to be dependent on the nanotube chirality, and the aspect ratio of nanotube should also influence the Raman band shift rate during deformation, but how these factors influence the shift rate is still unclear. A systematic investigation of the effect of these factors is needed if the shift rate is to be used properly in assessing the interfacial adhesion and the efficiency of reinforcement.

While it is difficult to compare the Raman band shift rate in different composite systems, the strain at which nanotube Raman bands cease to shift during deformation is a measure of the interfacial shear strength. Roy et al. [19.115] incorporated both collagen-modified SWNTs and pristine SWNTs into PVA and observed a strain-induced shift of the nanotube G'-band in the collagen-modified system while no stress transfer was observed in the unmodified system during deformation. They determined the onset of interfacial slippage for the PVA/collagen-SWNT film is at 3.5% strain. This strain value was then used to calculate the IFSS which turned out to be 187.5 MPa [19.115]. Kannan et al. also observed a transition in the G' frequency-strain plot for the PVA/SWNT electrospun fibers, where the interface failed at 0.6% strain [19.116]. Kao and Young investigated the deformation behavior of an epoxy/SWNT composite under cyclic loading by following the nanotube G'-band [19.117]. They found the deformation is completely reversible over a low strain range (< 0.4%). When a larger strain (e.g. 1%) was released, residual compression was observed, due to friction at the damaged interface in the composite.

The stress transfer between nanotubes inside nanotube bundles and between the layers in an individual MWNT is also important because intertube sliding

in nanotube ropes or interlayer sliding in individual MWNTs are detrimental to mechanical performance of the composites. Kumar and Cronin [19.80] deformed nanotube bundles by stretching a poly(dimethyl siloxane) (PDMS) substrate on which nanotube are sitting and observed intertube slippage, based on the response of the Raman bands such as:

1. A discrete jump in the G-band frequency at certain strains.
2. The relative intensity I_D/I_G remained constant during deformation.
3. The strain-induced G-band shift rate for bundles was significantly lower than those of individual nanotubes.
4. The RBM frequency of metallic nanotubes shifted to higher-wavenumber by 4 cm^{-1} . These phenomena suggested only a fraction of the strain applied to the bundle was transferred to the individual nanotubes within the bundles and the main effect of deformation was to debundle the nanotubes [19.80].

Cui et al. studied the interlayer stress transfer in MWNTs using an epoxy/DWNT composite as a model material [19.118]. By deforming the composite using a four-point bending rig, the higher-frequency component of the G'-band which corresponds to the outer wall, shifted at a rate of $-9.2\text{ cm}^{-1}/\%$ strain, whereas the lower-frequency component which corresponds to the inner wall shifted at a much lower rate, of $-1.1\text{ cm}^{-1}/\%$ strain. This indicates the efficiency of stress transfer from the outer wall to the inner wall is rather low such that the inner wall does not carry load, which is consistent with the theoretical predictions [19.119, 120] and previous experimental findings [19.121]. They demonstrated the effective modulus of MWNTs in composites decreases as the number of walls increases, and cross-linking the walls may possibly increase the resistance of the walls to the shear process.

19.3 Graphene Composites

The preparation and properties of bulk graphene composites has been recently reviewed in detail by Kim et al. [19.33]. The vast majority of research in this area has been undertaken using graphene oxide, often in the reduced form, although this is often difficult to tell from the title of a paper, where the word *graphene* is often used to describe work upon graphene oxide. Some research has also been undertaken upon composites containing graphite nanoplatelets (GNP).

There are some attractions in employing graphene oxide rather than graphene since it is readily obtainable in large quantities, much easier to exfoliate and disperse in a polymer matrix, and has built-in functional groups that are available for bonding to a polymer matrix. The individual nanoplatelets of graphene oxide are, however, often wrinkled and graphene oxide has significantly inferior mechanical properties to graphene. In the following sections care will be taken to distinguish between research upon the different forms of graphene.

There are a number of reasons for producing graphene based composites. The addition of a filler with such impressive mechanical properties is expected to lead to a significant improvement in the mechanical properties of the host polymer matrix. It is also found, however, that changes to the mechanical properties are also accompanied by modification of functional properties such as electrical conductivity, thermal conductivity and barrier behavior. This presentation will be concerned principally with mechanical properties but a brief discussion of the effect of graphene on functional properties is also included.

19.3.1 Preparation Methods

One of the greatest challenges in the preparation of polymer-based nanocomposites is to be able to obtain a good distribution of the nano-reinforcement [19.7] and it will be demonstrated that the properties of the nanocomposites can be compromised by a poor dispersion. For example, carbon nanotubes have a tendency to form bundles which can be difficult to break down and so much of the effort in the area of nanotube-based composites has focussed upon developing methods of obtaining good distributions of nanotubes using techniques such as chemical functionalization of the nanotubes [19.122]. In the case of graphene or graphene oxide the formation of bundles is not an issue but there can still be a tendency for incomplete exfoliation to be obtained and restacking to occur.

One of the advantages of using graphite oxide is that it can be exfoliated in water and nanocomposites can readily be prepared with the use of water-soluble polymers such as poly(vinyl alcohol) [19.123] and poly(ethylene oxide) [19.124]. It is possible also to prepare nanocomposites using solution-based methods with nonwater-soluble polymers such as poly(methyl methacrylate) [19.125] and polyurethanes [19.126] by chemically modifying the graphene oxide.

In situ polymerization of the polymer matrix offers an attractive method of preparing graphene-based composites although solvents are often employed to reduce the viscosity of the dispersions. For example, intercalative polymerization of methyl methacrylate [19.127] and epoxy resins [19.128, 129] has been achieved with graphite oxide to produce nanocomposites with enhanced properties.

Melt blending offers a simple and attractive method of dispersing nanoparticles in a polymer matrix and has been used to disperse thermally-reduced graphite oxide in a number of polymers including polycarbonate [19.130] and poly(ethylene-2,6-naphthalate) [19.131]. It is possible to obtain a reasonable dispersion in these systems but the addition of the nanoparticles increases the viscosity of the polymer melt significantly and makes processing more difficult. Solid-state shear dispersion, using a modified twin-screw extruder, has been employed to produce nanocomposites of unmodified, as-received graphite dispersed in polypropylene [19.132]. Although significant property improvements were reported it was found by x-ray diffraction and electron microscopy that the composites contained graphite nanoplatelets ranging from a few to 10 nm thick and so containing up to 30 graphene layers, rather than individual graphene platelets.

19.3.2 Mechanical Properties

The effect of particulate reinforcement upon the mechanical properties of polymers has been discussed in detail in the textbook of Young and Lovell [19.5]. It is relatively easy to predict the Young's modulus of particulate-reinforced polymers, although in practice only upper and lower bounds can be determined rather than exact values. It is necessary to determine the Young's modulus for the situations where the particles and matrix (and hence the composite) are subjected to either *uniform strain* or *uniform stress*.

Mechanics of Reinforcement

In the case of uniform strain it is found that the Young's modulus E_c of the composites is given by the rule of mixtures as

$$E_c = V_p E_p + V_m E_m, \quad (19.22)$$

or

$$\frac{E_c}{E_m} = V_p \frac{E_p}{E_m} + V_m, \quad (19.23)$$

where E_p is the Young's modulus of the particles, E_m is the Young's modulus of the matrix and V_p and V_m are the volume fraction of particles and matrix respectively, within the composite (where $V_p + V_m = 1$).

In the case of uniform stress the Young's modulus of the composites is given by

$$\frac{1}{E_c} = \frac{V_p}{E_p} + \frac{V_m}{E_m} \quad (19.24)$$

which can be rearranged to give

$$\frac{E_c}{E_m} = \frac{E_p}{V_m E_p + V_p E_m}. \quad (19.25)$$

It is found that these equations give very large differences in the prediction of the Young's modulus of particulate composites, especially when $E_p \gg E_m$, and are normally taken as upper and lower bounds of the behavior. There is normally a distribution of stress in the reinforcement such that the particles are subjected to neither uniform stress nor uniform strain and the Young's modulus normally lies between the two predictions which can be considered to be upper (uniform strain) and lower (uniform stress) bounds of composite Young's modulus.

There have been a number of attempts to produce more appropriate predictions of the Young's modulus of particulate reinforced composites without having to have widely-separated bounds [19.133–136]. *Halpin* and *Kardos* developed an approach based upon the self-consistent micromechanics method of *Hill* which enabled them to predict the elastic behavior of a variety of both fiber and particulate geometries [19.133]. This approach was employed by *Halpin* and *Thomas* [19.136] to predict the behavior of ribbon-shaped reinforcements which is clearly relevant to graphene-based composites. The theory predicts that in the case of aligned reinforcement, the ratio of the Young's modulus of the composite to that of the matrix is given by

$$\frac{E_c}{E_m} = \frac{1 + \xi \eta V_p}{1 - \eta V_p}, \quad (19.26)$$

where

$$\eta = \frac{E_p/E_m - 1}{E_p/E_m + \xi}. \quad (19.27)$$

The parameter ξ is a measure of reinforcement geometry which depends upon the loading conditions and is essentially a parameter controlled by the aspect ratio of the reinforcement. The limiting values of ξ are $\xi = 0$ and $\xi = \infty$ and for the prediction of the longitudinal modulus of reinforcement by a ribbon of length l and thickness t , the value of ξ can be taken as $2l/t$ [19.133]. Equation (19.26) tends to the lower, uniform stress, bound (19.25) as $\xi \rightarrow 0$ and to the upper, uniform strain, bound (19.23) as the aspect ratio of the reinforcement increases and $\xi \rightarrow \infty$. There are a number of other approaches that can be employed to model the reinforcement by nanoparticles [19.134,135], but the *Halpin–Tsai* approach for aligned reinforcement [19.133] produces relatively-simple equations that will be used next to account for the measured levels of reinforcement found in graphene-based nanocomposites.

Measured Levels of Reinforcement

The simplest way of assessing the level of reinforcement imparted upon a polymer matrix by a filler is to plot the ratio of the Young's modulus of the composites to that of the matrix E_c/E_m against the volume fraction of filler particles, V_p as shown in Fig. 19.17. The widely-spaced upper and lower bounds, given by (19.25) and (19.23) for uniform strain and uniform stress respectively, are indicated. The expected behavior for a ribbon-shaped reinforcement is given by (19.26) but the form of this relationship depends upon both the aspect ratio ξ and the ratio of the Young's modulus of the filler to that of the matrix, (E_p/E_m) through the parameter η . In order to compare the behavior of different systems it is necessary therefore to make different plots for families of materials with different ratios of E_p/E_m and values of ξ .

Most of the published research upon the mechanical properties of graphene-reinforced polymers is concerned with either rigid polymers (both glassy and semi-crystalline) for which $E_p/E_m \approx 10^3$, taking the Young's modulus of graphene as around 1 TPa or elastomers for which $E_p/E_m \approx 10^6$, since most elastomers have a Young's modulus of the order of 1 MPa. It is therefore possible to produce general plots for the two types of matrix materials with a series of lines for different values of ξ . Experimentally-determined values of E_p/E_m as a function of V_p for nanocomposites with

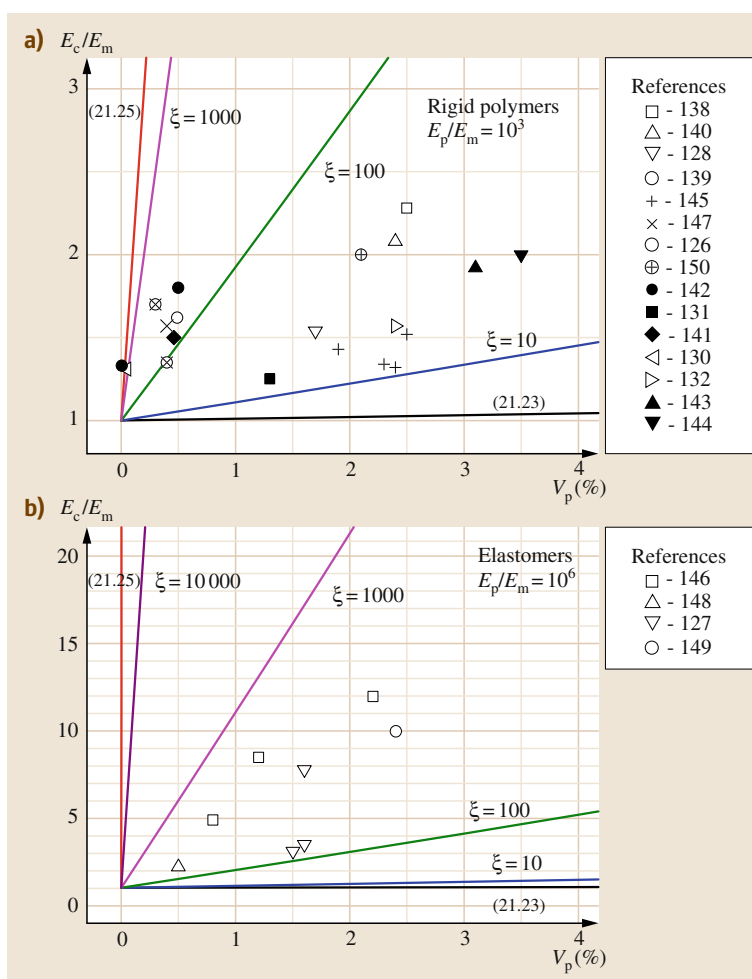

Fig. 19.17a,b Predicted and measured variation of E_c/E_m with volume fraction of graphene filler particles for (a) rigid polymers and (b) glassy polymers

either rigid [19.125, 127, 129–131, 137–146] or elastomeric [19.126, 147–149] matrices are also plotted. Since some of the data in the literature are given in terms of the weight fraction of filler, it is necessary to convert this to volume fraction using the density of the filler and matrix. Where this has not been given, a filler density of 2280 kg/m³ has been assumed for the data in Fig. 19.17.

It is instructive to examine the relationship between the experimental data and theoretical predictions. It would be expected that in the case of fully-exfoliated graphene or graphene oxide the parameter ξ ($= 2l/t$) would be of the order of at least 1000 and that if the particles were providing good reinforcement, the experimental data should lie above the line for $\xi = 1000$. It can be seen that in the case of the rigid reinforcement

(Fig. 19.17a) the data lie close to the line for $\xi = 1000$ only at very low volume fractions ($< 0.1\%$) and then fall in the range $1000 < \xi < 100$ for volume fractions up to around 0.5%. Above volume fractions of 1% the data points lie in the region in which $100 < \xi < 10$. In the case of the limited data available for elastomeric matrices, it can be seen in Fig. 19.17b that the data all fall in the range $1000 < \xi < 100$.

It appears therefore that the level of reinforcement measured experimentally is less than the theoretical value for graphene except at very low volume fractions. There are a number of possible reasons why this might be the case:

1. Equations (19.25) and (19.26) are strictly valid only for aligned platelets and the values of E_p/E_m

will be lower in the case of randomly oriented platelets [19.129, 150, 151]. Waviness of the reinforcing flakes that is found particularly in the case of thermally-reduced graphite oxide will contribute further to the reduction of modulus [19.129, 144].

2. The majority of the reports are concerned with graphene oxide rather than pristine graphene and it is known that defects and holes in the material reduce the modulus of the reinforcement to around 250 GPa [19.38].
3. In many cases the length of the flakes is relatively short and reinforcing material is not completely exfoliated [19.131] making the appropriate value of ξ significantly less than 1000.
4. There may be a poor dispersion of the reinforcement, especially at higher volume fractions, leading to clustering – a similar problem to that encountered with nanotubes [19.7].
5. The interface between the platelets and the matrix may not be particularly strong leading to poor stress transfer. The presence of the functional groups on the surface of graphene oxide may help to provide a stronger interface with a polymer matrix than in the case of graphene or graphite nanoplatelets. Recent work has also shown that an improvement in Young's modulus of the nanocomposites can be obtained through the use of coupling agents [19.152].

Overall it can be concluded that the levels of reinforcement achieved so far in graphene-based composites have been disappointing but there is considerable scope to overcome some of the problems listed above and produce nanocomposites with greatly improved properties.

Although the discussion outlined above has been concerned solely with enhancement of Young's modulus there are other important mechanical properties that need to be considered. The increase in modulus encountered in graphene-based nanocomposites is often accompanied by a reduction in elongation to failure and sometimes lower failure strength. There are reports, however, of ductility being maintained along with an increase in modulus and strength for poly(vinyl alcohol)/graphene oxide nanocomposites [19.137]. Other mechanical property improvements of note on the addition of graphite oxide to polymers include increases in hardness [19.125, 149], fracture toughness and fatigue crack growth resistance [19.129].

19.3.3 Functional Properties

It is possible to make polymers *electrically conductive* by the addition of graphene in a similar way to what is done using other nanofillers [19.153] such as carbon black [19.154, 155] and carbon nanotubes [19.7, 156]. The presence of the graphene can lead to percolation pathways through which the electrical charge can pass and this will occur if there is a good distribution of the graphene. It is possible, in fact, to use the conductivity of the nanocomposite to monitor the quality of the filler distribution. It has been found that it is possible to make a number of different polymers conductive by the addition of graphite nanoplatelets [19.21, 22] and different forms of graphene [19.126, 127, 131, 132, 144, 147, 157, 158]. An important factor is the amount of filler needed to render the polymer conductive – the percolation threshold – which depends strongly upon the shape and distribution of the filler particles. This has been found to be of the order of 0.1% by volume of chemically-reduced graphene oxide in polystyrene [19.159] which is approaching the best values obtained for carbon nanotubes [19.156]. The thresholds for percolation of graphene in a number of different polymers have been reviewed by Kim et al. and they are found to vary from 0.1 to over 2% depending upon the matrix polymer, form of graphene and processing method [19.33].

Since it was found that a monolayer graphene membrane is impermeable to common gases including helium [19.160] it was anticipated that graphene-based polymer nanocomposites should have good *gas barrier properties*. Kalaitzidou et al. [19.161] showed that the incorporation of appropriately-aligned graphite nanoplatelets into polypropylene could increase the oxygen barrier of the material more efficiently than other nanofiller particles. The gas permeation data for a series of different polymer nanocomposites has been reviewed and summarized by Kim et al. [19.33]. Reductions of diffusion rate for a variety of common gases for loadings of around 1.5–2.2% graphite oxide or reduced graphite oxide in a number of different polymers are found to be in the range 30–90% [19.126, 131, 132, 147].

The addition of graphene to polymers can have a significant effect upon their thermal properties. It has been found that the addition of graphene nanoplatelets to polymers can improve the *thermal conductivity* of polymer by over 3000% when particles with a high aspect ratio (≈ 200) are used [19.162]. This enhancement is found to be superior to that found with nanotubes although a synergistic effect has been reported with

a mixture of single-walled nanotubes and graphene nanoplatelets out-performing composites made using the pure nanofillers [19.163]. Polymers generally have high *thermal expansion coefficients* and the addition of aligned graphene nanoplatelets to polypropylene has been shown to reduce the thermal expansion coefficient in two directions rather than one in the case of aligned fibers [19.161]. A similar reduction in the thermal expansion coefficient of an epoxy resin has been found with the use of graphene oxide [19.128]. Finally, it is found that the addition of graphene-based nanofillers to a polymer can increase *thermal stability* [19.164, 165]. This effect has been attributed to the suppression of the mobility of polymer segments at the filler–polymer interface [19.164]. Based upon experience with nanotube-based nanocomposites [19.166] it has been suggested that graphene-based polymer nanocomposites may also have good *flame-retardant* properties [19.33].

19.3.4 Nanomechanics

The mechanical behavior of a graphene monolayer in a matrix can be modeled using shear lag theory in which it is assumed that the graphene is a mechanical continuum and surrounded by a layer of elastic resin as shown in Fig. 19.18. It is predicted [19.47] from shear-lag analysis that for a given level of matrix strain e_m the variation of strain in the graphene monolayer e_f with

Fig. 19.18 Model of a graphene monolayer within a resin used in shear-lag theory. The shear stress τ acts at a distance z from the center of the monolayer

position x across the monolayer will be of the form

$$e_f = e_m \left(1 - \frac{\cosh\left(\frac{nsx}{T}\right)}{\cosh\left(\frac{ns}{2}\right)} \right), \quad (19.28)$$

where

$$n = \sqrt{\frac{2G_m}{E_p}} \left(\frac{t}{T} \right) \quad (19.29)$$

and G_m is the matrix shear modulus, E_p is the Young's modulus of the graphene monolayer, l is the length of the graphene monolayer in the x direction, t is the thickness of the graphene, T is the total resin thickness and s is the aspect ratio of the graphene (l/t) in the x direction. In composite micromechanics [19.5] the parameter n is accepted widely as an effective measure of the interfacial stress transfer efficiency, so ns depends on both the morphology of the graphene monolayer and the degree of interaction it has with the matrix.

Moreover, the variation of shear stress τ_i at the polymer–graphene interface is given by [19.47]

$$\tau_i = nE_p e_m \frac{\sinh\left(\frac{nsx}{T}\right)}{\cosh\left(\frac{ns}{2}\right)}. \quad (19.30)$$

It can be seen that the graphene monolayer is most highly stressed, i. e. the most efficient platelet reinforcement is obtained, when the product ns is high. This implies that a high aspect ratio s is desirable along with a high value of n . This analysis relies on the assumption that both the graphene monolayer and polymer behave as linear elastic continua.

19.3.5 Model Graphene Monolayer Composites

Gong et al. [19.47] used Raman spectroscopy to monitor stress transfer in a model graphene composite consisting of a thin polymer matrix layer and a mechanically-cleaved single graphene monolayer using the stress-sensitivity of the graphene G' band [19.44–50]. A schematic diagram of their specimen is shown in Fig. 19.19 where an approximately diamond-shaped graphene monolayer is sandwiched between thin layers of transparent polymer.

Mapping the local strain along a carbon fiber in a polymer matrix allows the level of adhesion between the fiber and matrix to be evaluated [19.167, 168]. In a similar way mapping the strain across the graphene monolayer enables stress transfer from the polymer to the graphene to be followed. Figure 19.20 shows the local variation of strain across the graphene monolayer

Fig. 19.19 Schematic diagram (not to scale) of a section through a single monolayer graphene composite

determined from the stress-induced Raman band shifts at 0.4% matrix strain. The laser beam in the spectrometer was focused to a spot around $2\ \mu\text{m}$ which allows a spatial resolution of the order of $1\ \mu\text{m}$ on the monolayer by taking overlapping measurements.

Figure 19.20 shows the variation of axial strain across the monolayer in the direction, x , parallel to the strain axis. It can be seen that the strain builds up from the edges and is constant across the middle of the monolayer where the strain in the monolayer equals the applied matrix strain (0.4%). This is completely analogous to the situation of a single discontinuous fiber in a model composite when there is good bonding between the fiber and matrix [19.167, 168] which has been analyzed using the well-established shear-lag theory [19.5, 37, 169]. The experimental data are fitted to (19.28) in Fig. 19.20 and it can be seen that the fits of the theoretical shear-lag curves to the strain distribution are sensitive to the value of ns chosen with the best fit being for $ns = 20$.

Deformation of the graphene monolayer composite to higher axial strain led to breakdown of the graphene polymer interface at an interfacial shear stress of the order of around 1 MPa and a different shape of strain distribution [19.47]. The quality of fiber reinforcement is often described in terms of the *critical length* l_c – the parameter is small for strong interfaces and is defined as $2 \times$ the distance over which the strain rises from the fiber ends to the plateau level [19.5, 37]. It can be seen from Fig. 19.20 that the strain rises to about 90% of the plateau value over about $1.5\ \mu\text{m}$ from the edge of the flake making the critical length of this graphene reinforcement of the order of $3\ \mu\text{m}$. It is generally thought that in order to obtain good fiber reinforcement the fiber length should be $\approx 10l_c$. Hence, relatively large graphene flakes ($> 30\ \mu\text{m}$) will be needed before efficient reinforcement can take place. Processes for exfoliating graphene to single layers efficiently reported recently produce monolayers of no larger than a few micrometers across [19.23, 170]. The relatively poor

Fig. 19.20 Distribution of strain in the graphene in the direction of the tensile axis across a single monolayer at 0.4% strain. The curves were calculated from (19.28) using different values of ns

level of adhesion between the graphene and polymer matrix is also reflected in the low level of interfacial shear stress, τ_i , determined – carbon fibers composites have values of $\tau_i \approx 20\text{--}40\ \text{MPa}$, an order of magnitude higher [19.167, 168]. The efficiency of reinforcement is also reflected in the value of the parameter ns ($= 20$) in the shear lag analysis used to fit the experimental data. Since the graphene is so thin, the aspect ratio s will be large (in this case, $12\ \mu\text{m}/0.35\ \text{nm} = 3.5 \times 10^4$) making n small ($\approx 6 \times 10^{-4}$) compared to carbon fibers.

This study of Gong et al. [19.47] has important significance for the use of graphene as reinforcement in composites. It appears that the continuum mechanics approach is also valid at the atomic level – a question widely asked in the field of nanocomposites – and that the composite micromechanics developed for the case of fiber reinforcement is also valid at the atomic level for graphene monolayers.

19.4 Conclusions

It is clear that there is a great deal of interest in preparing composites reinforced with different forms of nanocarbons, although a number of major challenges still exist. As yet the full potential of these high-modulus fillers is yet to be realized in the mechanical behavior of the nanocomposites. One of the main reasons for this is that it is difficult to obtain good distributions of the nano-reinforcement at levels of loading that would be expected to lead to significant improvements in mechanical behavior. Fibrous reinforcements such as nanotubes are difficult to disperse and lead to a rise in the viscosity of the polymer system, making processing

very much more difficult. In the case of graphene, it is found that procedures that are needed to produce good exfoliation of the nanoplatelets tend to either oxidize or damage the material.

It has been shown clearly that the use of Raman spectroscopy enables stress transfer from the matrix to the nano-reinforcement to be followed in these systems with a great deal of precision and it is likely that this technique will find increasing use in the characterization of polymer nanocomposites reinforced with carbon nanotubes and graphene in the future.

Nanoparticle

20. Nanoparticle Dispersions

Krisztián Kordás, Jarmo Kukkola, Géza Tóth, Heli Jantunen, Mária Szabó, András Sápi, Ákos Kukovecz, Zoltán Kónya, Jyri-Pekka Mikkola

This chapter aims to provide an insight into the physics and chemistry of nanoparticle–liquid systems. The first part of the chapter discusses parameters and effects that influence dispersion stability (Sect. 20.1), including particle size and shape as well as the interactions at the interface between the solid and liquid phases. Section 20.2 summarizes the practical aspects of making a dispersion, collecting and listing hundreds of examples from contemporary literature. Because of the broad spectrum of materials in question, the survey is limited to dispersions of inorganic nanoparticles including metals, their oxides/sulfides, some (compound) semiconductors, as well as nanostructured carbon particles such as fullerenes, nanotubes, and graphene/graphite (Sect. 20.3). Dispersions of polymers of either synthetic or biological origin lie beyond the scope of this work. Since a very large fraction of applications are related to various surface coatings using dispersions as the source of nanoparticles,

Sect. 20.4 is devoted to drying phenomena and particle self-ordering.

Dispersions of various particles have been made since prehistoric times, at that time applied mainly as paints and inks. The oldest cave paintings, made of various kinds of dyestuff such as hematite, charcoal, manganese oxide, and red and yellow ochre, are more than 30 000 years old [20.1]. These paints (i. e., dispersions) were made by grinding the solid followed by mixing in water, grease, and sometimes with blood. Later, many ancient cultures discovered their own inks for writing and drawing. The basic recipes were quite similar. Soot collected from the smoke of burning wood or lamp oil was mixed with oils or grease. To change the smell, color, and probably drying and sticking behavior of the inks, usually some additives such as gelatin extracted from animal skin, honey, powdered minerals,

and natural dyes of plants were applied as well [20.2–5]. Milled particles of a number of different minerals such as calcite, gypsum, lime, hematite, goethite, cuprorivaite, azurite, cinnabar, red lead, etc. were utilized to tune color [20.6–8]. Water-based inks of lampblack or charcoal were made with the help of added gum and sugar. For coloration, natural dyes but also powders of silver and gold were applied [20.9]. In 1450, Gutenberg developed oil-based inks of carbon black and metal particles (Cu, Pb, Ti) that properly wetted the lead-based alloy types in his printing press [20.10, 11]. Paints similar to those used in prehistoric times still have practical importance today. Ochre mixed with seal oil (North America) or linseed oil (Scandinavia) has been the traditional paint of wooden houses [20.12].

Conscious synthesis and use of micro- and nanoparticle dispersions other than for inks and paints probably started with the advent of colloid chemistry in the middle of the 19th century. Recognizing that the surface properties of particles are of key importance in preparing and storing dispersions shifted the trial-and-error experimental work towards more scientific approaches. The previously accumulated empirical knowledge combined with understanding of particulate–solvent interactions finally resulted in the birth of the fascinating world of colloid chemistry – the science of multiphase systems with large interfacial surface areas. Today, several in-

dustries utilize and are still developing further knowhow of making dispersions tailored for particular applications. Apart from paints and coatings, sub-micrometer-size particles suspended in liquids are employed in medicine, biotechnologies, electronics, optoelectronics, materials processing, and mechanical and civil engineering, just to mention a few. Though a large selection of various nanoparticle dispersions are commercially available from several vendors, the continuously increasing number of novel nanomaterials and the need for engineered nanoparticle–liquid systems for a particular end-use sustain and inspire research in the field.

20.1 Stabilization of Nanoparticle Dispersions

The suspension and then stabilization of nanoparticles in a liquid is a function of a number of different variables. The shape, size, material, concentration, and surface chemistry of the nanoparticles, the nature of the solvent, the mixing technique applied, and external parameters such as the temperature and directing fields are all important to consider when designing and synthesizing nanoparticle dispersions. Both theoretical and practical aspects of nanoparticle stabilization are discussed in this section.

20.1.1 Shape of Nanoparticles

Nanoparticles differ from their bulk counterparts – amongst many other aspects – in their shape. When using the prefix *nano* it is assumed that the size along at least one direction is small (by convention, shorter than 100 nm). If the structure is confined to planar geometry, we refer to a two-dimensional (2-D) structure such as nanoflakes, nanosheets, or thin plates. Having small extension in two perpendicular dimensions, we obtain one-dimensional (1-D) structures called nanowires, nanorods, nanofibers, and (with a hollow interior) nanotubes. Continuing this train of thought, small dimensions along all three coordinates results in zero-dimensional (0-D) objects such as spherical and polygon-shaped nanoparticles – often called quantum dots in the case of semiconducting materials. The shape of nanoparticles has some effects on the properties of their dispersions. The viscosity, stability, and even the optical behavior are all influenced depending on whether nanoparticles, nanowires/tubes/rods, or particles of lamellar/sheet-like shape are present in the liquid. The nanoparticles are

in continuous movement in the dispersion (Brownian motion), thus drag forces, which depend on the shape of the moving particles, are different, causing for instance higher viscosity and slower sedimentation for elongated and lamellar nanoparticle dispersions than for those consisting of spherical nanoparticles of similar volume. On the other hand, the shape of the primary particles also determines how these particles agglomerate to form secondary particles, thus indirectly influencing the rheological properties of the dispersion (0-D particles usually form clusters, chains, and branches thereof, 1-D particles form elongated bundles but also may tangle into bigger clumps, while 2-D particles often agglomerate as lamellar stacks) [20.13].

20.1.2 Sedimentation, Ordering, and Coarsening of Nanoparticles in Liquid Dispersions

In dispersions, the spatial distribution and – in certain applications – also the orientation of the nanoparticles are probably the most important measures. The system is homogeneous if the concentration of particles is the same throughout the whole volume. The medium is heterogeneous when the solid phase is separated from the solvent. Between these two extremes, we talk about diffuse dispersions; i.e., slight concentration gradients may be present. From a practical point of view, homogeneous nanoparticle inks are preferred; however, diffuse dispersions may be useful as well, provided the concentration gradients in the inks are minimized by stirring, shaking, or ultrasonic agitation immediately before application of the medium [20.13].

External fields exerting forces on dispersed nanoparticles may result in sedimentation, separation, as well as orientation/ordering of the nanoparticles in reference to the liquid. The efficiency of particle migration and rotation depends on whether the driving forces can overcome the disorder caused by Brownian motion.

In a gravitational field, the drift of particles (i. e., velocity with respect to the liquid phase, or terminal velocity) is determined by the buoyancy and drag forces and can be expressed as

$$v_d = \frac{2r^2(\rho - \rho_0)g}{9\eta},$$

where r is the radius and ρ is the density of the particle, ρ_0 is the density of the liquid, g is the acceleration, and η is the viscosity of the liquid. It is important to note that the equation is only valid for spherical particles that are not interacting with each other. In the case of 1-D or 2-D particles, a sphere with equivalent radius may be calculated to enable reasonable approximations. Furthermore, the particles are assumed to be wetted by the surrounding medium (viz. the momentum transfer is taking place at the interface of the adsorption layer and liquid) [20.14]. When the terminal velocity becomes higher than the rms speed along to gravitational axis of particles due to thermal motion

$$v_t = \left(\frac{k_B T}{m} \right)^{1/2},$$

sedimentation of the particles occurs (k_B is Boltzmann's constant, T is the thermodynamic temperature, and m is the mass of the particle). The rms displacement of a particle within a time interval t due to thermal diffusion is

$$\Delta = (2Dt)^{1/2},$$

where $D = k_B T / (6\pi\eta r)$ is the diffusivity at temperature T of a spherical particle having r radius, in a fluid with viscosity η . To demonstrate the importance of the role played by diffusion when talking about nanoparticle–liquid systems, let us consider a dispersion of nanoparticles with diameter 20 nm and density 4 g/cm^3 in water ($\eta = 10^{-3} \text{ N s/m}^2$) and estimate the diffusion length within 1 s period of time and compare it with the sedimentation height within the same time. Substituting the materials parameters into the above equations, we get $\Delta \approx 6.6 \mu\text{m}$ and $v_d \cdot 1 \text{ s} \approx 0.7 \text{ nm}$, suggesting that such a colloidal system is supposed to remain homogeneously dispersed for several years. On

the other hand, when the nanoparticles are agglomerated in larger clusters, with diameter of say 500 nm, the corresponding length values become comparable (≈ 1.3 and $\approx 0.4 \mu\text{m}$), indicating very rapid sedimentation of the large agglomerates.

Since v_d is a quadratic function of the particle radius, decreasing the size of the particles to be dispersed helps to avoid their sedimentation. In the case of polydisperse systems, separation of the solid particles having the largest size takes place first. This effect is frequently utilized in practice when separating nanoparticles that are chemically similar but with different sizes simply by speeding up the sedimentation process using high acceleration in centrifuges (up to several tens of thousands of g) and ultracentrifuges (up to $10^6 g$). Besides the application of smaller particles, a good strategy for disabling sedimentation can be the use of liquids having density close to that of the nanoparticles, since then $\rho - \rho_0 \approx 0$, leading to $v_d \approx 0$. Increasing the viscosity may also help in maintaining the homogeneity of the dispersions, as $v_d \propto \eta^{-1}$.

Charged particles can be separated in electrostatic fields (electrophoresis). The process is very similar to the previously discussed sedimentation, but besides gravity, also Coulomb forces proportional to the electrical field and the charge of the particles are exerted on the particles. Particles with a dipole moment can only be rotated and oriented in a uniform electric field (liquid-crystal displays); however, when applying a field gradient, movement of dipole particles is enabled in dispersions (as in optical tweezers).

Nanoparticles having a magnetic momentum can be manipulated in magnetic fields. In a uniform field, only rotation occurs, while in the presence of field gradients a magnetic force is exerted and moves the particles. This latter effect is frequently applied in separating ferromagnetic nanoparticles from dia- and paramagnetic phases. As the viscosity of aligned nanoparticles in a dispersion is higher than in a random (or disordered) system, such magnetic colloids (ferrofluids) are very often used in mechanical vibration damping. In practice, ferromagnetic or antiferromagnetic materials are applied in various inks and pastes to enable use of low magnetic fields below 1 T, e.g., with ferrites and rare-earth magnets or with ordinary electromagnets. In the case of paramagnetic nanomaterials, magnetic fields above 10 T are required for efficient manipulation, thus the applicability of such nanomaterials is mainly limited to laboratory experiments.

Until this point, only individual nanoparticles have been considered; i. e., any interaction between the

nanoparticles has been neglected. Though this enabled a very simple discussion of the spatial distribution and orientation of nanoparticles in dispersions, in reality, the picture is much more complex than this, since the particles interact with the liquids as well as with each other.

The surface energies of solid nanoparticles (in J/m²) are usually very different from the surface tension of solvents. From the point of view of thermodynamics, such dispersions cannot be assumed to be stable and thus will undergo coagulation to minimize the Gibbs energy of the system. Coagulation takes place as the particles in (thermal) motion collide and then adhere together, resulting in agglomeration of the primary nanoparticles into larger, secondary particles. In some cases, also irreversible merging (recrystallization) of the particles that are in intimate contact may occur [20.13, 15].

The particle-size- or surface-curvature-dependent solubility of materials known as Ostwald ripening is another reason for coarsening of nanoparticles in dispersions. As derived by Ostwald, the solubility of particles L_r increases exponentially with decreasing radius r as

$$L_r = L e^{\frac{2\gamma M}{rKT\rho}},$$

where L is the solubility of a particle with infinite radius (i.e., the conventional solubility of a macroscopic bulk material), γ is the surface tension, ρ is the density, and M is the molecular weight of the solute. Accordingly, polydisperse systems cannot be in equilibrium, since the smaller particles dissolve and the dissolved moieties then deposit on the larger particles, thus continuously increasing the average particle size (a process also called isotherm distillation) [20.13, 16–18].

20.1.3 Electrolytes and the DLVO Theory

It was observed long ago that some particles form stable dispersions in certain solvents while others require additional substances to achieve stability. As we will see, the structure of the solid–liquid interface and the interactions between the particles and the medium strongly determine the stability of the corresponding dispersions. Accordingly, we have to take a look at various scenarios of how a nanoparticle is actually situated in liquids and what sort of solid–liquid interfaces may form in dispersions [20.13, 15].

Very often, stable sols are obtained when dispersing nanoparticles in electrolytes. In such cases, an electric double layer forms at the solid–liquid interface, which helps in the separation of the nanoparticles due to the

repulsive electrostatic forces exerted among them. This phenomenon is described by the Derjaguin–Landau–Verwey–Overbeek (DLVO) theory, named after the scientists who developed its fundamentals. The surface of solid particles in a liquid may dissociate and/or adsorb ions, resulting in a surface charge buildup, which then attracts ions of the opposite charge (counterions) from the surrounding solution and repels ions with charge of the same sign (co-ions). The region of ions and balancing counterions is called the electrical double layer (EDL). According to the DLVO theory, the interaction between two particles is described by a potential function V (Fig. 20.1), which is a sum of the attractive and repulsive potentials (V_a and V_r , respectively), both being dependent on the interparticle distance d . Note that Born repulsion is typically neglected; however, at distances below 0.2 nm, this interaction is to be considered, as it becomes the dominant force that prevents the electron clouds of atoms from approaching each other arbitrarily closely [20.19, 20].

The attractive potential (van der Waals attraction) [20.15] between two spheres of the same radius r is

$$V_a = -\frac{rA}{12d},$$

where A denotes the Hamaker constant (accounting for the energy of interactions among the atoms of adjacent nanoparticles). The Hamaker constants for various materials of different size and shape can be measured with good accuracy using, e.g., atomic force microscopy and electrophoresis, or can be calculated, e.g., by the Lifshitz theory or the Tabor–Winterton approximation [20.13, 15]. The typical Hamaker constants for ceramic materials in water are in the range $\approx 10^{-21}$ – 10^{-19} J, while in vacuum the values are somewhat higher, in the range $\approx 5 \times 10^{-20}$ – 5×10^{-19} J [20.21, 22]. For common metals (such as Au, Ag, and Cu), $A \approx 5 \times 10^{-20}$ – 3×10^{-19} J in both water and vacuum [20.14, 23, 24]. For TiO₂ nanoparticles of 20 nm diameter at spacing of 1 nm in water, considering $A \approx 6 \times 10^{-20}$ J, the energy of van der Waals attraction is $V_a \approx -5 \times 10^{-20}$ J, which is about an order of magnitude higher than the thermal energy of particles at room temperature, meaning that thermal motion without other repulsive interactions would not be enough to separate such particles. The force exerted on such particles due to van der Waals attraction is

$$F_a = -\frac{rA}{12d^2} \approx -5 \times 10^{-11} \text{ N}.$$

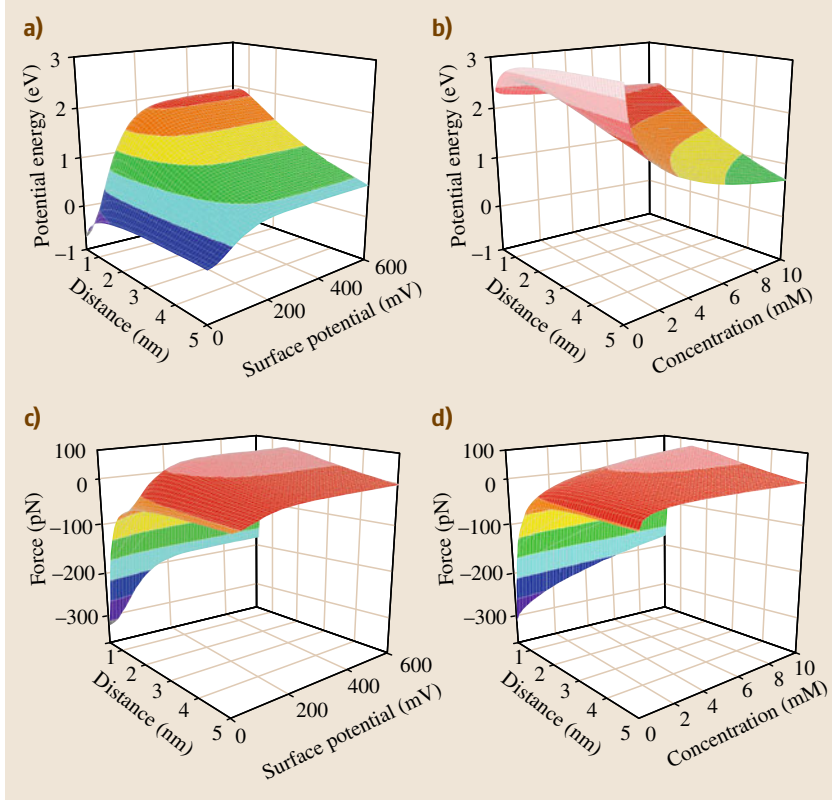

Fig. 20.1a–d Calculated attractive and repulsive potentials considering interparticle distance, electrolyte concentration, and surface charge. Interparticle-distance-dependent potential energy between two TiO_2 nanoparticles as a function of (a) surface potential at 10 mM electrolyte concentration and as a function of (b) electrolyte concentration at constant 500 mV surface potential. Panels (c) and (d) show the respective force between the nanoparticles

The repulsive potential [20.15], assuming that $r \gg d$, is

$$V_r = \frac{r}{2} Z e^{-\kappa d},$$

where

$$\kappa^{-1} = \left(\frac{\varepsilon \varepsilon_0 k_B T}{e^2 N_A \sum_i z_i^2 M_i} \right)^{1/2}$$

is the Debye length and

$$Z = 64\pi\varepsilon\varepsilon_0 \left(\frac{k_B T}{e} \right)^2 \tanh^2 \left[\frac{ze\psi_0}{4k_B T} \right],$$

where ε is the dielectric permittivity of the electrolyte, ε_0 is the vacuum permittivity, ψ_0 is the surface potential, N_A is the Avogadro number, e is the elementary charge, z_i is the valency, and M_i is the concentration of ions ($\frac{1}{2} \sum_i z_i^2 M_i$ representing the ionic strength of the electrolyte). While the Debye length depends on the electrolyte and indicates the thickness of the diffuse ionic layer, Z is determined by the surface charge. In aqueous electrolytes, the Debye length is below $1 \mu\text{m}$ (pure water) and decreases with the square root

of the ionic strength (e.g., $\kappa^{-1} \approx 30 \text{ nm}$ for 10^{-4} M and $\approx 3 \text{ nm}$ for 10^{-2} M KCl solution but $\approx 15 \text{ nm}$ for 10^{-4} M and $\approx 1.5 \text{ nm}$ for 10^{-2} M MgSO_4 solutions). As we see, the repulsive potential decays exponentially with the distance between particles and with the ionic strength of the electrolyte. An example value for the repulsive potential, assuming similar nanoparticles as previously when calculating the van der Waals potential (particles of radius 10 nm each with separation of 1 nm) but having 500 mV surface potential in 10^{-2} M KCl solution, is $V_r \approx 3 \times 10^{-19} \text{ J}$ with a corresponding force of $F_r = \kappa \frac{r}{2} Z e^{-\kappa d} \approx 11 \times 10^{-11} \text{ N}$. The obtained repulsive force F_r is thus larger than the van der Waals attraction calculated earlier ($F_a \approx -5 \times 10^{-11} \text{ N}$), meaning that the particles have not crossed the energy barrier to emerge as one cluster. Allowing d to vary, one gets $|F_a| = |F_r|$ at $d \approx 0.6 \text{ nm}$ particle spacing. Accordingly, if the nanoparticles reach separation below 0.6 nm, the attractive van der Waals force binds the nanoparticles together, leading to agglomeration.

Nanoparticles of silicates and clays form stable dispersions in pure water without addition of any elec-

trolytes to the system. In such cases, partial surface dissociation results in the appearance of ionic species both on the solid surface and in the liquid phase, leading to the formation of an electric double layer similar to that found in ordinary electrolyte-stabilized dispersions [20.25–31].

20.1.4 Steric (Nonelectric) Stabilization

Although the DLVO theory gives a quite reliable account of the interactions between nanoparticles in electrolytes, it cannot explain the stability of dispersions without electric double layers. In a number of different dispersions, a thin adsorbed layer of the solvent forms on the surface of nanoparticles. A good example is dispersion of carbonaceous particles with apolar behavior in organic solvents. Their stabilization is based on the entropy production (and thus decreased overall Gibbs energy) as the particles separate from each other in the solvent. Earlier, soot and other carbonaceous particles were stabilized in oils. In contemporary scientific works – due to their potential in future electronics – pristine (nonfunctionalized) carbon nanotubes and graphenes have been studied and found to be dispersible reasonably well in *N*-methyl-pyrrolidone (NMP), dimethylformamide (DMF), γ -butyrolactone (GBL), dimethylacetamide (DMA), or benzene. In the case of graphene in DMF, the interaction is so strong that, under ultrasonic agitation, the graphene layers of graphite could be separated (exfoliation) [20.32–35].

Dispersion stabilization with surfactants and macromolecules is another approach to establish a gradual transition between particles and solvents of dissimilar nature [20.13, 36, 37]. As we all well know from daily experiences (e.g., when cleaning surfaces or washing clothes), hydrophobic surfaces are immiscible in polar solvents. The reason is the strong interaction between the polar solvent molecules (van der Waals forces and hydrogen bonding), which cannot be disrupted by

a hydrophobic surface, thus such systems remain phase-separated. Although the dipoles of the solvent might induce a weak dipole moment on the surface of particles, such interactions are weak and the overall Gibbs energy of the mixture will be higher than the phase-separated one, thus considerable mixing cannot occur. The picture is very similar for hydrophilic surfaces in nonpolar solvents, but here the strong attraction between particles is responsible for the immiscibility. To mix hydrophobic and hydrophilic materials, a very convenient approach is to apply amphiphiles (surfactants, i. e., molecules having both hydrophilic and hydrophobic parts) which can mediate the dissimilarities of the two different phases. The hydrophilic part of the molecule (an anionic, cationic, zwitterionic or a noncharged but polar group) is solvated by the polar solvent or adsorbed on the hydrophilic nanoparticle surface, while the hydrophobic part (hydrocarbon chain or ring) is attracted to the molecules of apolar solvents or to the apolar surface of nanoparticles (for a comprehensive set of various types of surfactants, see [20.38]). Since the surfactant molecules typically form an oriented interface between the two phases, the separation between two nanoparticles in such a dispersion is at least twice the length of the apolar hydrocarbon group of the surfactant molecule (the size of the polar part being negligible). Accordingly, nanoparticles stabilized, for instance, with oleyl alcohol ($C_{18}H_{36}O$) or with stearyl alcohol ($C_{18}H_{38}O$) will be separated (sterically) by a distance of at least ≈ 2 or ≈ 4 nm, respectively. In this case, it is assumed that the surfactant molecules adsorbed on the two adjacent nanoparticles cannot be pushed into each other. Within such a distance, the van der Waals potential drops considerably, resulting in small attractive forces, thus avoiding the particles sticking together. For TiO_2 nanoparticles, similar to those discussed above, the van der Waals potential energies at 2 and 4 nm are -0.16 and -0.08 eV, respectively.

20.2 Nanoparticle Dispersion in Practice

Direct dispersion of nanoparticles in ordinary solvents is possible only very seldom. As we have seen in Sect. 20.1.3, the attractive van der Waals forces between nanoparticles is to be compensated for by electrostatic stabilization or to be reduced by steric hindrance through addition of molecules that can adsorb onto the nanoparticles, forming spacer units between the primary particles.

Metals and metal oxides are often stabilized in electrolytes of NaCl, Na_2SO_4 , $HClO_4$, ascorbic acid, and citrates [20.38, 39].

Application of surfactants and various capping agents is probably the most widespread method used to disperse virtually any type of nanoparticle in a large selection of different solvents. Surfactants and capping

agents adhere to the particles by van der Waals forces (dipole–dipole, induced dipole) or electrostatic attraction (e.g., ions on a partially dissolved surface with ionic surfactants of opposite charge). Because of the large variety of polar and ionic groups linked to the apolar part of the molecules, it is relatively easy to find the optimal one for a particular type of nanoparticle–solvent system [20.40].

The application of either ionic or nonionic conventional surfactants (such as sodium dodecyl sulfate (SDS), oleic acid, cetyltrimethylammonium bromide (CTAB) or polyethylene ethers, Triton X) offers a quite generic route to suspend nanoparticles [20.40, 46, 57–62]. The disadvantage of this method is the difficulty in getting rid of the excess surfactant molecules, which might be disadvantageous in several applications (e.g., in electrical devices or in catalysis).

Capping agents (alkyl thiols, polyvinyl pyrrolidone (PVP), trioctylphosphine oxide (TOPO), amines or dendrimers) have a reactive head group that can strongly coordinate to the surface of the particle, while the hydrophobic tails (for example, an alkane chain) help

to keep the particle suspended. Because of the crystal facet-dependent chemisorption of capping agents, both the particle size and shape of the forming particles can be tuned when they are applied during growth [20.63–77].

Thiol-containing molecules are an especially attractive choice, as the sulfur of the thiol can form a strong coordinative covalent bond with several metals (e.g., Au, Ag, Cu, and Pt). With proper choice or further modification of the hydrophobic tail, again many solvents can be applied to stabilize thiol-functionalized nanoparticles [20.68, 71–73, 75, 77–89].

Steric stabilization by coating the particles is also a popular approach. Some parts of the polymer chain bond to the surface of the particle, while the other parts are solvated by the solvent, forming a spacing layer around the nanoparticles [20.90–96].

Table 20.1 presents details of various nanoparticle dispersions. The *Preparation* column contains information about the synthesis of the nanoparticles. Details about the solvents, and the stabilization or surface modification of the particles are also collected.

Ag	Chemical reduction (from AgNO ₃ as metal precursor using hydrazine in DMF as reducing agent)	Ethanol Ethanol, water	PVP PVP		[20.41, 42] [20.43, 44]
Au	Wet chemical method (using HAuCl ₄ in a replacement reaction of Ag nanoparticles) Reduction of HAuCl ₄	Water Ethanol	Sodium citrate CTAB	Surface-enhanced Raman spectroscopy applications	[20.45] [20.46]
MnO ₂	Wet chemical method (calcination of the mixture of KOH and Mn ₂ O ₃ ; or hydrothermal treatment of the precipitate of Mn(NO ₃) ₂ , NaOH, and H ₂ O ₂)	Water	Tetramethylammonium for making stable suspensions, chitosan coating for biological application	Energy storage, solar cell application, H ₂ O ₂ sensor	[20.47–50]
1-D					
Ag	Polyol process (AgNO ₃ as precursor) Template-assisted method (the nanorods were deposited in the pores of a polycarbonate filtering membrane)	Water Hexafluoro-2-propanol or CHCl ₃	PVP PVP	Transparent electrodes, ink	[20.51–54] [20.55]
Ag/Au core/shell	Wet chemical method (Ag from aqueous solution of AgNO ₃ was deposited on the surface of Au nanorods)	Water	PVP		[20.56]

Table 20.1 (continued)

NP	Preparation	Solvent	Stabilization/ functionalization	Application	References
Au	Electrochemical method (in a two-electrode type cell, Au plate as anode)	Water	C ₁₆ TAB	Nanoelectronic applications	[20.97,98]
	Template-assisted method (the nanorods were deposited in the pores of a polycarbonate filtering membrane)	Hexafluoro-2-propanol or CHCl ₃	PVP		[20.55]
	Electrodeposition in nanoporous alumina	NaOH solution	PVP		[20.99]
	Chemical reduction (of HAuCl ₄)	Hexane	Oleic acid and oleylamine		[20.57, 100]
	Photochemical synthesis (HAuCl ₄ solution was irradiated with 254 nm UV light)	Water	CTAB, tetradodecyl-ammonium bromide (TDABr)		[20.58]
	Seed-mediated growth method (seeds from HAuCl ₄ and NaBH ₄ , then in the second step ascorbic acid was used)	Water	CTAB, benzyldimethyl-ammoniumchloride (BDAC)		[20.101]
Ni	Decomposition of bis(cyclooctadiene)nickel(0) (Ni(cod) ₂) with hexadecylamine (HDA)	Pentane	TOPO		[20.66]
Si	One-dimensional growth via a vapor–liquid–solid (VLS) bis(cyclooctadiene)nickel(0)	Ethanol		Nanoelectronic devices	[20.102, 103]
CdS	Microwave-assisted method (from cadmium ethylxanthate)	Toluene	HDA, octadecylamine (ODA)		[20.104]
CdSe	Microwave-assisted method (from cadmium acetate and selenourea)	Toluene	HDA, ODA		[20.104]
	Precipitation method (from dimethylcadmium and tri- <i>n</i> -butylphosphine in a glovebox)	Chloroform, toluene	TOPO, hexylphosphonic acid (HPA)		[20.105, 106]
CdSe/CdS core/shell	Seed growth approach	Toluene	–	Lasers	[20.107, 108]
CoP	Thermal decomposition of cobalt acetylacetonate (Co(acac) ₂) and tetradecylphosphonic acid (TDPA)	Organic solvents	TOPO, HDA	Anodes, catalyst, magnetic sensing	[20.109]
TiO ₂	Hydrolysis of titanium tetraisopropoxide (TTIP)	CHCl ₃ , hexane	Oleic acid stabilizes the particles, but the ligands can be easily replaced by adding alkyl phosphonic acids	Cancer treatment, antimicrobial applications	[20.110–112]
ZnS	Microwave-assisted method (from zinc ethylxanthate)	Toluene	HDA, ODA		[20.104]
ZnSe	Microwave-assisted method (from zinc acetate and selenourea)	Toluene	HDA, ODA		[20.104]
Al ₂ O ₃	Carbothermal procedure (from Al powder)	DMF			[20.113, 114]

Table 20.1 (continued)

NP	Preparation	Solvent	Stabilization/ functionalization	Application	References
0-D					
Ag	Solvothermal method from AgNO ₃	Toluene	Dodecylamine	Printing, fabrication of silver wires	[20.67]
	Polyol process from AgNO ₃	Ethylene glycol	PVP	Photonics, catalysis, and surface enhanced raman spectroscopy (SERS)-based sensing	[20.115, 116]
	solvated metal atom dispersion (SMAD) followed by digestive ripening	<i>t</i> -Butyl toluene	Synthesis with 2-butanone as stabilizing agent followed by functionalization with dodecane thiol and trioctyl phosphine		[20.79]
	γ-Irradiation from AgNO ₃	Water/ethanol	SDS		[20.117]
	Chemical reduction (of usually AgNO ₃)	Aceton/chloroform	Polydimethylsiloxane (PDMS)	Microwire fabrication	[20.118]
		Hexane	Oleic acid		[20.59]
		Water	Mercaptoacetic acid	SERS-active substrate	[20.119]
		Water	Dodecanethiol		[20.68, 75, 76]
		Water	Bis(11-trimethyl-ammonio-undecanoyl-aminoethyl) disulfide dibromide		[20.120]
		Water	Na-citrate as reducing and stabilizing agent		[20.121]
		DMF	3-Aminopropyltri-methoxysilane		[20.122]
		Methanol, ethanol, acetone	Dodecanethiol		[20.69]
		Water	Polyvinyl alcohol (PVA)		[20.80]
		Diethylene glycol/water	PVP	Inkjet printing for electronic devices	
		Water	PVP	SERS-active substrate, microinterconnects antimicrobial application	[20.123–125]
		Formamide	PVP, colloidal silica		[20.126]
		Water	Dendrimers, amphilic block copolymers, citrate quaternary ammonium disulfide	Water-based inkjet ink	[20.70, 127–130]
Ag/CaCO ₃ composite	Flame spray synthesis (Ag-octanoate and Ca-2-ethyl-hexanoate as precursors)	Water	Disperbyk 190	Fabrication of membranes for filtering	[20.131]

Table 20.1 (continued)

NP	Preparation	Solvent	Stabilization/ functionalization	Application	References
Au	Chemical reduction (usually from HAuCl ₄)	Water	Thiocyanuric acid	Chemiresistor sensors	[20.132]
		Water	PVA		[20.80]
		Water	Place exchange and amide-forming coupling modification of tiopro- nin-protected particles		[20.133]
		Dichloro- methane and methanol solution	Surface modification of alkylthiolate- protected particles by coupling reactions		[20.133, 134]
		Ethanol	Thiol-capped nanoparticles		[20.71, 72]
		Water	Thiol-capped nanoparticles		[20.81, 82]
		Organic solvents	Capping with alkyl thiols and further functionalization of the alkyl chain		[20.78, 83–87]
		Organic solvents	Place exchange reactions of monolayer-protected nanoparticles		[20.135–139]
		Organic solvents	Modification of the surface of dodecanethiol-protected particles by atom transfer radical (ATR) polymerization		[20.88]
		Organic solvents	didecyldimethylammonium bromide (DDAB)		[20.140]
		Organic solvents	<i>p</i> -Mercaptophenol		[20.141]
		Formamide	PVP		[20.74]
		TOPO	TOPO/ODA		[20.142]
		Toluene/ water	Linear alkylamine, triphenyl phosphine, dendrimers		[20.143–146]
		Water	Na ₂ SO ₄ , NaCl, SDS, amino acid, PVP, tiopronin and coenzyme A, poly(meth- acrylic) acid, polystyrene		[20.147–151]
		Water/ toluene	Dodecanethiol		[20.75, 152–154]
	Citrate reduction	Butyl acetate, water	Citrate ions, <i>comb</i> stabilizer, sodium 3-mercaptopropionate, sulfur ligands, lysine, amine, thiols, dendrimer, amphiphilic block copolymers	Coatings, electronic devices, catalytic sur- faces, sugar sensors, biodiagnostics, bio- logical application	[20.130, 155–173]
	Brust–Schiffrin method	Toluene	Thiols, poly(methyl metha- crylate), 5-(<i>N</i> -pyrrolyl)pentane- thiol		[20.174–178]

Table 20.1 (continued)

NP	Preparation	Solvent	Stabilization/ functionalization	Application	References
	Reduction with ascorbic acid	Water	PVP/PVA, sodium citrate Dodecanethiol Dodecanethiol, dodecylamine, octadecyl silane, trioctyl phosphine, dodecyl bromide, dodecyl iodide, dodecanol, and decane Dendrimers	Laser	[20.179]
	Reduction with tetrakis(hydroxymethyl)phosphonium chloride (THPC)	Water			[20.76, 180–182]
	γ -Irradiation	Water			[20.183–185]
	Seed growth method	Water/ toluene			[20.77]
	SMAD and digestive ripening	Toluene			[20.186, 187]
Au-Pd alloy	Displacement reaction	Water	SDS		[20.188]
	Sonochemical method (from aqueous solution of $\text{NaAuCl}_4 \cdot 2\text{H}_2\text{O}$ and $\text{PdCl}_2 \cdot 2\text{NaCl} \cdot 3\text{H}_2\text{O}$)	Water			[20.60]
Au-coated magnetite	Wet chemical method (gold coating from the reduction of HAuCl_4)	Ethanol	Surface modification by carboxylation	DNA sensor	[20.189]
Co	Wet chemical method (reduction of CoCl_2 or decomposition of dicobalt octacarbonyl)	Organic solvents, toluene	Oleic acid, methylmethacrylate-ethylacrylate-vinyl pyrrolidone terpolymer $\text{Al}(\text{C}_8\text{H}_{17})_3$	Catalyst	[20.190–196]
	Sonochemical method (ultrasonic decomposition of $\text{Co}(\text{NO})(\text{CO})_3$)	Decane	Oleic acid		[20.197]
	Reduction of cobalt acetate tetrahydrate	Water	SDS		[20.61]
	γ -Irradiation of $\text{Co}(\text{ClO}_4)_2$ solution in the presence of Na-formiate	Water	Polyacrylate, poly(vinylsulfate)		[20.198]
	Microemulsion method [reduction of CoCl_2 or cobalt bis(2 ethyl-hexyl) sulfosuccinate in the micelles]	Toluene	DDAB		[20.199–201]
Co-ferrite	Wet chemical method (coprecipitation from cobalt and iron dodecylsulfate solutions)	Water	Dodecyl sulfate	Magnetic fluid	[20.202, 203]
	Microemulsion method (from CoCl_2 and FeCl_2)	Water/ toluene	SDS		[20.204, 205]

	Commercial	Acetylacetonate Water	Stabilization with p(MAA/nBA) (copolymer of metacrylic acid and <i>n</i> -butyl acrylate), lactic acid, and stearate	Cancer treatment Ceramics patterning by inkjet printing, antimicrobial appli- cations	[20.343, 344] [20.94, 345, 346]
		Organic solvents Span 60 Water	Functionalization with Sodium polyacrylates as stabilizing agent	Photovoltaic cells	[20.347, 348] [20.95]
	Hydrolysis of TiCl ₄ , titanium <i>n</i> -butoxide or titanium(IV) isopropoxide	Water or organic solvents	Surface modification with <i>n</i> -aliphatic carboxylic acids and acetylacetone	Photocatalytic appli- cations	[20.349–355]
	Microwave-assisted precipi- tation method (from TiCl ₄)	Water	Glycolic acid, citric acid, glycine, L-alanine, β-alanine as capping agents		[20.356]
	Precipitation method from TiCl ₄	Water			[20.356]
WO ₃	Wet chemical method (from WCl ₆ , Na ₂ WO ₄ , phospho- tungstic acid hydrate)	Toluene	Dispersing polymer		[20.357]
		Water	PVA	Oxygen generation, gas sensing	[20.358, 359]
	Thermal decomposition of W(CO) ₆	Hexane	Oleic acid and TOPO		[20.360]
ZnO	Commercial	Ethyl acetate	Silquat J15	For fabricating super- hydrophobic surface	[20.361]
	Hydrothermal method from Zn(NO ₃) ₂	Water Water	Ammonium polymethacrylate Oleic acid	Coolant application	[20.96] [20.362]
ZnS	Wet chemical method (re- action of ZnSO ₄ and Na ₂ S)	Water	Surface modification with cystein		[20.363]
Alumina	Commercial	DMF, ethylene glycol monomethyl ether (MCS) : dipropylene glycol monomethylether, (PM) = 3 : 1 water, ethylene glycol	HCl	Fabrication of alum- ina-resin hybrid films by inkjet printing, heat transfer applica- tions	[20.364–372]

20.3 Dispersions of Carbon Nanomaterials

As shown in the previous sections, apart from their size, mainly the surface chemistry of nanoparticles plays

the most decisive role in their stabilization in liquids. The surfaces of pristine carbon nanomaterials such as

Fig. 20.2 Photograph of single-walled carbon nanotube dispersions each ultrasonicated for 1 h then centrifuged for 10 min at 3000 rpm. Vial A: 0.5 mg SWCNTs in 15 ml water; vial B: 0.5 mg SWCNT in 15 ml 1% Triton X-100 in water; vial C: 0.5 mg SWCNT-COOH in 15 ml water

fullerenes, nanotubes, and graphene/graphite are composed of sp^2 -hybridized C atoms, which are chemically quite unreactive. The equivalent chemical bonds between adjacent C atoms make these materials apolar, thus direct dispersion or – in the cases of fullerenes – dissolution in liquids is limited to a few organic solvents only. To enable preparation of dispersions in a large variety of solvents, the surfaces must be modified, i. e., chemically functionalized, in order to stick various *easy-to-disperse* groups onto the surface (Fig. 20.2). Functionalization of carbon surfaces may be accomplished by a large variety of methods including covalent chemical bond formation as well as noncovalent adsorption/wrapping of molecules.

Creating strong first-order covalent bonds is typically achieved under harsh conditions. Using strong oxidizing acids to create defects and form hydroxyl, carbonyl, and carboxylic moieties on the surface is one approach to generate the starting points for subsequent synthetic construction of virtually any side-groups via, e.g., esterification or amidation. Since carboxyl-functionalized nanotubes and graphite/graphene can be simply dispersed in water, these products are often sufficient for applications without further modification. It is worth pointing out that various halogenation, cycloaddition, and radical-addition reactions are also often used to enable side-wall functionalization and dispersion in a large variety of solvents [20.373–376].

Noncovalent adsorption of molecules having delocalized electrons may take place on sp^2 -hybridized carbon surfaces due to the overlapping of π -electrons

between the two molecules. Such interaction can be very useful and attractive in practice. If the adsorbing moiety has some polar groups, the nanocomposite structure becomes dispersible in various polar solvents without altering the original structure of the host material [20.377–379].

Surfactants adsorbed on the surface as well as polymers wrapping nanoparticles offer further options for exfoliating and stabilizing nanotubes and graphene flakes in solvents. In practice, sodium dodecyl sulfate (SDS), sodium dodecylbenzene sulfonate (NaDBS), and Triton X-100 are the most frequently applied amphiphiles enabling reasonably high carbon concentrations in aqueous dispersions ($> 0.1 \text{ mg/cm}^3$) (Fig. 20.2). Both synthetic and biopolymers have been demonstrated to establish strong molecular interactions by wrapping carbon nanotubes. The process is widely utilized to synthesize polymer-nanotube composites with added electrical and/or mechanical features [20.380, 381] and lately has been shown to be a powerful tool for separating carbon nanotubes according to their chirality. Selective wrapping of nanotubes has been demonstrated by several groups using DNA [20.382] and also various synthetic polymers [20.383]. Highly selective separation of near-armchair chiralities has been shown in toluene suspensions with poly(9,9-di-*n*-octylfluorenyl-2,7-diyl). In the separated suspensions, 90% of the carbon nanotubes (CNTs) had (9,7) chirality when applying laser-grown nanotubes, while for the HiPCo nanotubes the dispersions were composed of mainly (7,5), (7,6), and (8,6) chiralities (50, 25, and 20%, respectively) [20.384, 385].

Tables 20.2–20.4 collect some of the most frequently used nanostructured carbon materials and their derivatives, which are applied in forms of solutions and dispersions. Fullerenes dissolve quite well in organic solvents such as toluene, xylene, benzene, 1-methylnaphthalene, and *N*-methyl-2-pyrrolidinone. However, direct dispersion in polar solvents is very limited; when a solution of fullerenes with apolar solvents is mixed with polar organic solvents (acetonitrile, ethanol, acetone), precipitates of stable colloidal fullerene clusters appear in the polar phase. Similar phenomena also occur when saturated solutions of fullerenes in tetrahydrofuran (THF) are injected into water. The stability of the colloidal particles has been explained by the negatively charged surface [20.386–391]. Dispersions in water by complexing fullerenes with cyclodextrin or by anchoring carboxyl groups on the surface offer direct applications in biology

Table 20.2 Fullerene solutions/dispersions and their applications

Fullerene/funtionalization	Solvent/dispergant	Application	Notes	References
C ₆₀ , C ₇₀	Toluene, xylene, benzene, 1-methyl-naphthalene, <i>N</i> -methyl-2-pyrrolidinone	Preparation of colloidal agglomerates of fullerenes	The fullerenes dissolved in apolar solvents, then mixed with polar organic solvents (acetonitrile, ethanol, or acetone) to get precipitates	[20.386]
C ₆₀ , C ₇₀	1,2-Dichloro-benzene, 1,2-dimethyl-benzene, bromo-benzene, iodo-benzene, and toluene			[20.387]
C ₆₀ , C ₇₀	Toluene, water	Because of water as solvent, biochemical-biophysical studies are suggested	200 mg/dm ³ fullerenes dissolved in toluene. Water added then sonicated and toluene evaporated resulting in ≈ 5 mg/dm ³ aqueous dispersion of fullerene nanocrystals	[20.388]
C ₆₀ , C ₇₀	THF, water	Because of water as solvent, biological uses or medical applications would be enabled as suggested by the authors	1.3×10^{-5} and 2.7×10^{-5} mol/dm ³ negatively charged stable fullerene clathrates form after injecting the THF solution into water	[20.389]
C ₆₀	Toluene, water, THF	Studying bacterial response to nano-C ₆₀ under both aerobic and anaerobic conditions in various media	Nanocrystals of C ₆₀ remain stable in solution at or below ionic strengths of 0.05 <i>I</i> for months	[20.390]
C ₆₀	Toluene, acetonitrile	Nanostructured SnO ₂ films for enhanced photocurrent generation	Nanoparticles of fullerene clusters are made by precipitating a toluene solution in acetonitrile	[20.391]
C ₆₀ complexed in γ -cyclodextrin	Water		8×10^{-5} mol/dm ³	[20.392]
C ₆₃ ((COOH) ₂) ₃	Water	Neuroprotective agent		[20.393]
Carboxylic acid derivatives of C ₆₀ , C ₃ C ₆₀ , and D ₃ C ₆₀	Water	Use as antioxidants preventing lipids from radical-initiated peroxidation of membrane		[20.394]
Gd@C ₆₀ [C(COOH) ₂] ₁₀ and Gd@C ₆₀ [C(COOCH ₂ CH ₃) ₂] ₁₀	Water	MRI contrast agent		[20.395]
Fluorinated derivatives of C ₆₀ , C ₆₀ F ₃₀ , C ₆₀ F ₃₆ , C ₆₀ F ₅₂	Benzene, toluene, THF, acetone	Contact angle measurements with water hold promise of lubricating applications	Thin films may be prepared by sublimation or spin-coating from solution	[20.396]
Amphiphilic C ₆₀ derivatives	Water	Langmuir–Blodgett films		[20.397]

Table 20.3 Carbon nanotube (CNT) solutions/dispersions and their applications

CNT/ funtionalization	Solvent/dispergant	Application	Notes	References
SWCNTs (single- walled CNTs)	Cyclohexylpyrrolidone (CHP) and 1-benzyl-2-pyrrolidinone (NBenP)		Concentrations up to 3.5 and 0.2 mg/cm ³ for CHP and NBenP, respectively	[20.401]
SWCNTs	N-Methyl-pyrrolidone		Concentrations up to 0.03 mg/cm ³	[20.402]
SWCNTs	Toluene	Chirality- and diameter-selective dispersion of nanotubes (i. e., separation) using polymers such as poly[9,9-dioctylfluorenyl-2,7- diyl] (PFO), poly[9,9-dihexyl- fluorenyl-2,7-diyl], (PFH), poly[(9,9-dioctylfluorenyl-2,7- diyl)-co-(1,4-phenylene)] (PFO-P), poly[(9,9-dioctyl- fluorenyl-2,7-diyl)-alt-co-(1,4- benzo-2,10,3-thiadiazole)] (PFO-BT)	5 mg SWNT, 6 mg polymer, and 10 cm ³ solvent homogenized in a sonic bath then centrifuged	[20.383]
SWCNTs	Dimethylformamide (DMF), dimethylacetamide (DMA)	Polymer composite reinforce- ment		[20.403]
SWCNTs	N,N-Dimethylformamide (DMF), N-methylpyrrolidone (NMP), hexamethylphosphoramide, cyclopentanone, tetramethyl- ene sulfoxide, and ε-capro- lactone			[20.404]
SWCNTs	N-Methyl-2-pyrrolidone (NMP)	Inkjet printing of field-effect transistors	Ink concentrations after ultra- sonic treatment and centrifuging are ≈ 0.012 mg/cm ³	[20.405]
MWCNTs (multiwalled CNTs)	Epoxy polymer	Electrically conductive polymer composites	Studied up to 0.15 wt % nanotube loading	[20.406]
SWCNTs	Gum arabic (0.5–15 wt %) dissolved in water	Authors suggest applications of the gum arabic–nanotube composites in adhesion promo- ters at interfaces between indi- vidual tubes and polymeric matrix	CNT powder (0.2–3 wt %) sonicated (50 W, 43 kHz) for 15–20 min in the polymeric solutions	[20.407]

Table 20.3 (continued)

CNT/ functionalization	Solvent/dispersant	Application	Notes	References
SWCNTs	1 wt % SDS in water	Wrapping the dispersed nanotubes with polymers such as polyvinyl pyrrolidone (PVP), polystyrene sulfonate (PSS), poly(1-vinyl pyrrolidone-co-vinyl acetate), poly(1-vinyl pyrrolidone-co-acrylic acid), poly(1-vinyl pyrrolidone-co-dimethylaminoethyl methacrylate), polyvinyl sulfate, poly-(sodium styrenesulfonic acid-co-maleic acid), dextran, dextran sulfate, and bovine serum albumin	Concentration of PVP-wrapped CNTs is 1.4 g/dm ³ . Wrapping with poly(methyl methacrylate-co-ethyl acrylate), polyvinyl alcohol, polyethylene glycol, or polyallyl amine was unsuccessful	[20.408]
SWCNTs	Sodium dodecylbenzene sulfonate (NaDDBS), sodium octylbenzene sulfonate (NaOBS), sodiumbutylbenzene sulfonate (NaBBS), sodium benzoate, sodium dodecyl sulfate (SDS), Triton X-100, dodecyl-trimethylammonium bromide (DTAB), dextrin, poly(styrene)-poly-(ethylene oxide) (PS-PEO) diblock copolymer	Highest dispersion concentrations are: NaDDBS (20 mg/cm ³); NaOBS (8 mg/cm ³); SDS (0.1 mg/cm ³); Triton X-100 (0.5 mg/cm ³); sodium benzoate (0.01 mg/cm ³); NaBBS (0.1 mg/cm ³); dextrin (0.05 mg/cm ³); DTAB (0.1 mg/cm ³); PS-PEO diblocks (0.1 mg/cm ³)		[20.409]
SWCNTs	1 wt % aqueous SDS in deionized water	Inkjet printing of supercapacitors	Ink concentration of 0.2 mg/cm ³	[20.410]
Octadodecylamine-functionalized SWCNTs (ODA-SWCNTs)	Chloroform, dichloromethane, benzene, toluene, chlorobenzene, 1,2-dichlorobenzene, CS ₂	Authors suggest applications related to polymer composite with mechanical reinforcement and new electrical properties as well as metal complexation	Solubility in 1,2-dichlorobenzene and CS ₂ is > 1 g/dm ³	[20.411]
DWCNTs and amino-functionalized DWCNTs	Epoxy resin with an amine curing agent	Mechanical reinforcing of epoxy polymer	Up to 1 wt % CNT load was tested	[20.412]
Pyrene carboxylic acid (PCA) functionalized SWCNTs	Water or tetrahydrofuran (THF)	Improvement of dispersion and adhesion of SWCNTs in polycarbonate matrix	Up to 1 wt % CNT load was tested	[20.413]
Carboxylic-functionalized MWCNTs (MWCNT-COOH)	Water	Printing inks, electrically conductive pattern and gas sensor printing, optical polarizer	Stable dispersions with concentration up to ≈ 0.26 mg/cm ³	[20.414, 415]

Table 20.3 (continued)

CNT/ functionalization	Solvent/dispergant	Application	Notes	References
Carboxylic-functionalized CNTs (SWCNT-COOH and MWCNT-COOH)	Water	Dispersions for drop casting, electrically conductive film, and gas sensor applications		[20.416]
SWCNT-COOH	Water	Printing inks, electrically conductive pattern, and field-effect transistor printing	Stable dispersions with concentration up to $\approx 0.1 \text{ mg/cm}^3$	[20.417–419]
Amide-, polyethylene glycol (PEG)-, and polyaminobenzene sulfonic acid (PABS)-functionalized SWCNTs	Water	Printing inks, electrically conductive pattern, and field-effect transistor printing	Stable dispersions with concentrations up to $\approx 0.046 \text{ mg/cm}^3$ (amide), 0.035 mg/cm^3 (PEG), and 0.038 mg/cm^3 (PABS)	[20.419]
Acid-treated MWCNTs	Water with added surfactant (S27000)	Inkjet printing of conductive patterns	Ink concentration up 0.4 wt %	[20.420]

Table 20.4 Graphene–graphite solutions/dispersions and their applications

Graphene–graphite and funtionalization	Solvent/dispergant	Application	Notes	References
Graphene	<i>N</i> -Methylpyrrolidone (NMP), <i>N,N</i> -dimethylacetamide (DMA), γ -butyrolactone (GBL), 1,3-dimethyl-2-imidazolidinone (DMEU)	The authors suggest spray coating, vacuum filtration or drop casting to deposit graphene flakes on surfaces and potential applications in sensors, transparent electrodes, and conductive composites	Concentrations up to 0.01 mg/cm^3	[20.32]
Graphite platelets	THF	Mechanical reinforcing of PMMA		[20.421]
Graphene (4–5 layers)	DMF	Transparent conductive coatings	Concentration: 0.7 mg/cm^3	[20.422]
Graphite	Sodium cholate (SC) 2% w/v in water	Dispersions for density gradient ultracentrifugation (for separating graphene fractions of various thicknesses). Fabrication of transparent conductive films	After sonication, the exfoliated graphene layers are surrounded with the amphiphilic SC with solid contents up to 0.09 mg/cm^3	[20.423]
Graphite oxide	Water	Solar cell electrode fabrication by spin coating deposition of graphene oxide followed by reduction in hydrazine	$\approx 15 \text{ mg/cm}^3$ exfoliated graphite oxide in water	[20.424]
Graphite oxide	Water	Self-assembled multilayer thin films of graphite oxide with poly(diallyldimethylammoniumchloride)	1 mg/cm^3 dispersion is applied	[20.425]

Table 20.4 (continued)

Graphene–graphite and functionalization	Solvent/dispersant	Application	Notes	References
Graphite oxide	Water films	Production of large-area graphene	0.05 wt % GO is exfoliated by ultrasonic treatment to obtain graphene oxide dispersions	[20.426]
Graphite oxide	Water	Graphene film production for thin-film transistor manufacturing	Graphite oxide slurry with a concentration of 49 mg/cm ³ is diluted with water, then sonicated to exfoliate graphene oxide	[20.427]
Graphite oxide	Hydrazine	Thin-film transistors after spin coating and annealing hydrazinium graphene	Stable dispersions of hydrazinium graphene (HG) shown with a concentration of 1.5 mg/cm ³	[20.428]
Graphite oxide	DMF	Electrically conductive composites with polystyrene	1 mg/cm ³ dispersion for further processing	[20.429]
Graphene functionalized with Congo Red (π – π stacking)	DMF, methanol, Dimethyl sulfoxide (DMSO), ethanol, water	Synthesis of Au nanoparticle composites with graphene	The functionalized graphene was also partially dispersed in other organic solvents such as NMP and 1,4-dioxane	[20.430]
Graphene oxide – MWCNT composite (π – π stacking)	Water			[20.431]

and medicine [20.392–395]. Other derivatives suitable for both polar and apolar solvents hold promise in thin-film applications in tribology as well as in electronics [20.396–400].

Pristine carbon nanotubes can be dispersed reasonably well in various organic solvents such as *N,N*-dimethylformamide (DMF), *N*-methylpyrrolidone (NMP), cyclohexylpyrrolidone (CHP) [20.383, 401–

405], in polymers [20.406, 407], and also in water when using surfactants [20.408–410]. CNTs with functional side-groups may be suspended in various solvents determined by the nature of the functional groups [20.32, 411–420].

Dispersions of graphene sheets and thin graphite flakes can be made by vigorous ultrasonic treatment of microscopic graphitic particles in NMP, DMA, DMF,

Fig. 20.3 Photographs of graphite oxide dispersions in water and 13 organic solvents by ultrasonic agitation (1 h). *Top*: freshly prepared dispersions. *Bottom*: after 3 weeks of storage (after [20.432])

GBL, 1,3-dimethyl-2-imidazolidinone (DMEU), and THF [20.32, 326, 421, 422], but also in water if surfactants are added [20.423]. Anyhow, the most common method of graphene dispersion preparation is based on graphite oxide, which is obtained by partial oxidation of graphite particles in strong oxidizing acids. Graphite oxide is suspended and exfoliated in water or DMF by ultrasonic agitation to yield graphene oxide (Fig. 20.3) and annealed or reduced in hydrazine to

get graphene [20.424–428]. Exfoliation directly in hydrazine has been also reported [20.429]. Noncovalent functionalization of pristine graphene by π – π stacking of Congo Red molecules on the surface has been proven to be efficient to disperse the hybrid nanoparticles in a large variety of solvents [20.430]. In a similar vein, nanocomposites of carbon nanotubes with graphene oxide adsorbed on their surface could be suspended in aqueous media [20.431].

20.4 Drying Dispersions on Surfaces

A considerably large fraction of nanoparticle dispersion applications aim at deposition of the particles on solid as well as soft surfaces for use as decorative, electrical, or optical functional coatings and patterns and so forth. The surface morphology of the deposits is important in all cases, thus understanding the transformation of the dispersion to solid nanoparticles – i. e., the drying process – is of key importance. When a dispersion is brought into contact with a surface, new interfaces appear at the substrate–dispersion and substrate–dispersion–air contact regions, breaking the continuity of the bulk of the liquid. As long as the surface is chemically inert, not electrostatically charged, and not magnetized, and temperature differences are not introduced, the new system remains stable until considerable evaporation of the solvent. When that happens, the dispersion stability conditions may change but also various fluxes can start in the bulk of the liquid, giving rise to the formation of a large variety of surface structures/morphologies during the drying process. This section discusses the formation of various surface deposit morphologies upon drying associated with solvent evaporation, contact-line pinning, particle–solvent flow fluxes, and self-ordering phenomena.

20.4.1 Ring-Stain Effect

As we often see in our daily life, drying droplets of liquids in which solid particles are present leave stains on surfaces along the perimeter of the droplet. A similar effect is observed when depositing and drying nanoparticle inks on surfaces. For most solute–solvent–surface systems, the deposited nanoparticles do not form a film with ideal flat-top surface profile, but rather a thick pattern at the perimeter of the droplet and a thin inner area with smaller amounts of solid particles. Such an effect might seem to be disturbing when applying nanoparticle

dispersions on various surfaces; however, under optimized conditions, good spatial homogeneity of solid nanoparticle deposits has been demonstrated for a large variety of materials and solvents. On the other hand, ring-shaped stains or other narrow patterns forming at the contact lines enable the generation of self-assembled narrow features made of nanoparticles.

Based on a simplified model constructed by Deegan and coworkers [20.433], the primary reasons for such ring-stain formation (often referred to as the coffee-ring effect) are the pinned contact line, i. e., the perimeter of droplet at the substrate, and the surface-curvature-dependent solvent evaporation rate [20.433]. Because of the smaller curvature radius at the contact-line region, evaporation of solvent takes place faster there than on the top of the droplet. To ensure pinning of the contact line (and avoid shrinking of the droplet), a radial flow of fluid starts, which compensates for the amount of evaporated solvent. The dispersed solid particles are carried outwards by the radial flow, and they sediment at the sharp apex of the contact line. Although the model gives a reasonable explanation for the formation of solid particle deposits at the contact line, it lacks a number of different effects which may contribute to other solute–solvent fluxes in the drying droplet. The previously mentioned curvature-dependent evaporation rate of the solvent inherently generates concentration gradients in the droplet and results in solute diffusion [20.434] from the zone of the contact line towards the center of the droplet. Temperature gradients may form as well due to the different solvent evaporation rates to induce Marangoni flows [20.435, 436]. Electrostatic (DLVO) interactions and van der Waals forces may also modify the particle deposition process [20.435]. High solvent viscosity can influence the deposition by decreasing the diffusivity of nanoparticles and limiting the flow of the solvent itself [20.433].

Applying surfactants to change the contact angle may change the surface pinning conditions of the contact line and consequently the overall spatial particle distribution of the nanoparticles in the deposits after solvent evaporation [20.437].

Shen et al. proposed that ring-shaped stains can be avoided by applying small enough droplets (typically $D_c \approx 5\text{--}50\text{ }\mu\text{m}$), since in small droplets, the solvent can evaporate before the solid particles can diffuse to form the ring-shaped deposits [20.438]. Thus, the maximum (or critical) droplet diameter D_c is a function of the liquid evaporation rate, the diffusive particle transport within the droplet, and the contact angle as

$$D_c = L_m \left[\frac{32 D_v (c_0 - c_\infty)}{\rho_L \pi (\theta_{\text{initial}} - \theta_{\text{receding}}) D_p} \right]^{1/2},$$

where L_m is the mean distance between two particles within the liquid droplet, D_v is the molecular diffusion

coefficient of the vapor in air, c_0 and c_∞ are the densities of the saturated vapor at the liquid–air interface and the ambient vapor, respectively, ρ_L is the liquid density, θ_{initial} and θ_{receding} are the initial and receding contact angles of the colloidal droplet, and D_p is the particle diffusivity in the solvent (Fig. 20.4).

Heating of the substrate – frequently utilized in inkjet printing applications – to induce efficient evaporation of the solvent makes the deposits uniform as well [20.440–444]. Applying solvents with different boiling points (or different vapor pressure at a given temperature) allows tuning of the surface morphology of the deposits [20.439]. The concentration of solute in dispersions gives another degree of freedom to alter the deposit morphology. With increasing solute concentration the width of the dried pattern increases and eventually may form fairly uniform disks as well as hill-shaped dots (Fig. 20.5) [20.445].

Fig. 20.4 Scanning electron microscopy (SEM) images of nanoparticle deposits on hydrophilic Pt structures of differing size (3–100 μm). Two different size regimes of the deposit patterns – either avoiding or causing ring formation – can be distinguished (after [20.438])

Fig. 20.5 (a) Sub-millimeter-size ring stains of SiO_2 nanoparticles deposited on a hydrophilic Si surface by a drop-on-demand inkjet printer from water/formamide-based inks of different solid concentration (images after [20.439]). (b) Macroscopic ring-shape stains of TiO_2 nanoparticles deposited on a gold surface from aqueous dispersions of different concentrations (each droplet is $\approx 0.5\text{ }\mu\text{l}$)

Fig. 20.6 Drops (2.4 μl) of alumina powder dispersion [20 vol. %, average particle size of 480 nm dispersed in water with the help of 0.75 wt % ammonium poly(methacrylic acid)] on silicone release paper (after [20.446])

Under extremely high nanoparticle concentrations, complex three-dimensional surface features have been demonstrated [20.446]. As an interesting feature, the morphology of the three-dimensional stains could be altered by depositing droplets of alumina suspension close to each other (Fig. 20.6). Since the evaporation of solvent is less favored in the volume between two droplets (viz. because the ambient in such regions becomes easily saturated with solvent vapor), concentration gradients of the solvent vapor occur, influencing the evaporation rates at different surface locations and giving rise to Marangoni flows in the droplets.

Having nonuniform pattern morphologies of the nanoparticles is usually undesirable in applications for optics and electronics, therefore special attention is paid to avoid ring-stain formation by optimizing solvent viscosities, vapor pressure, processing temperature, droplet size, nanoparticle concentration, and substrate wetting behavior [20.447–453]. On the other hand, having narrow rings, lines, or other patterns caused by the coffee-ring effect can indeed be very advantageous when the goal is to generate narrow and thin patterns of various types of nanoparticles. Normally, lithographic methods are applied to make such patterns; however, taking advantage of the self-ordering and alignment of nanoparticles at the contact line [20.454, 455], one may avoid the tedious multistep lithography process to prepare narrow patterns of nanoparticles on a large variety of surfaces (Fig. 20.7).

One particularly interesting and practically relevant application of ring-shaped stains has been identified in

the fabrication of transparent conductive coatings with metal nanoparticle dispersions (Fig. 20.8) [20.456, 457]. In such coatings, the substrate is covered with a two-dimensional network of metal rings composed of metal nanoparticles. Since only a minor fraction of the surface area is coated with optically nontransparent thick metal, the overall optical transmittance of the deposited layer can be high. As demonstrated lately by Magdassi and coworkers [20.457], sheet resistivity down to $\rho = 4.0 \pm 0.5 \Omega/\square$ could be achieved while having optical transparency of 95% when inkjet printing silver nanoparticle rings onto transparent surfaces from a dispersion of 0.5 wt % Ag nanoparticles stabilized in water with poly(acrylic acid). Such two-dimensional networks of metallic rings might eventually be competitors of other transparent conductive coatings such as indium-tin oxide (ITO) [20.458] ($\rho_{\text{ITO}} \approx 0.1 \text{ k}\Omega/\square$ at 90% transmittance) and emerging solution-processed carbon nanotube [20.459, 460] as well as graphene [20.461, 462] films ($\rho_{\text{SWCNT}} \approx 0.3 \text{ k}\Omega/\square$ and $\rho_{\text{graphene}} \approx 10 \text{ k}\Omega/\square$ at $T = 90\%$).

In analogy with the ring-shaped stains at the contact line of a drying droplet, deposition of nanoparticles may also occur at the meniscus formed between a solid surface and a (partially) wetting dispersion as the solvent evaporates [20.463–465]. For planar substrates, the geometry of the deposits is a line (which is curved at the proximity of the substrate edge). Furthermore, parallel lines can be deposited by pulling the surface out from the liquid, ensuring that the pinned contact line is detaching, sliding, and then pinning again parallel in a location under the previous line (stick–slip phenomenon). To be able to detach the contact line, a threshold force $F_c = \gamma (\cos \theta_r - \cos \theta_{\text{eq}})$ has to be exceeded, where γ is the surface tension of the liquid, and θ_r and θ_{eq} are the contact angles for the receding and equilibrium contact lines [20.463]. Applying the stick–slip process, Huang and coworkers deposited electrically conductive parallel line patterns of Ag nanowires on oxygen-plasma-treated SiO_2 as well as on glass surfaces from methylene chloride suspensions [20.466]. The thickness of the deposits could be controlled well by the duration of contact-line sticking, while the spacing of adjacent lines was adjusted by the pulling velocity. Using a similar process – but with drying-induced slip of the contact line – microscopic parallel lines of single-walled carbon nanotubes (SWCNT) were deposited on Si/ SiO_2 chips from aqueous dispersions (1% SDS), and used as channels of field-effect transistors [20.467]. It is worth pointing out that, in both experiments, the nanowires as well as the

Fig. 20.7 (a) Optical image of periodic parallel line-shaped deposits of SiO_2 nanoparticles (10 wt % in water) on glass surface based on the contact-line stick-slip mechanism (contact-line velocity of $6.2 \mu\text{m/s}$). (b) Atomic force microscopy (AFM) image of a contact-line deposit (contact-line velocity of $1 \mu\text{m/s}$). The AFM scan area is $100 \mu\text{m} \times 50 \mu\text{m}$, and the height of the deposit is $1.45 \mu\text{m}$ (after [20.464])

Fig. 20.8 (a–c) Scanning electron microscopy images taken from of ring-shaped deposit of silver nanoparticles. (d) Plot of height profile across a ring stain. (e) Ring-shaped stains of Ag nanoparticles forming an electrically conductive, two-dimensional network (after [20.457])

nanotubes were also aligned parallel within each microscopic line along the axis of the pattern.

20.4.2 Self-Organized Structures

After drying, particles of similar shape and size tend to be organized in a periodic uniform fashion just like atoms in a crystal lattice, but instead of atoms the nanoparticles now form superlattices. The common name for this process is self-assembly; however, the term “directed self-assembly” is also frequently used when the assembly is perturbed/modulated by external fields (electrical, magnetic, flow), capillary forces, or by surface topology inducing spatial confinement of the particles to certain surface areas or enabled volumes [20.469].

The symmetry of the superlattice depends on the particle–particle and substrate–particle interactions, and particle confinement within surface structures, while the range of ordering is a function of the particle size uniformity [20.470]. The simplest structures are composed of uniform spherical particles which typically form two-dimensional layers with hexagonal symmetry (Fig. 20.9) and close-packed (face-centered cubic (fcc), body-centered cubic (bcc), and hexagonal close-packed (hcp)) structures in three dimensions [20.471–474].

During the past few years, template-assisted self-assembly (TASA) has received much attention because of its direct applications in photonics [20.475–479] and nanoelectronics [20.480, 481]. Surfaces having three-

dimensional topology features (cavities, channels, or tiny capillaries) can spatially confine the nanoparticles, which – after evaporation of the solvent – form microscopic patterns that are self-similar to the geometry of the three-dimensional surface features [20.482–487]. Another approach to accomplish constrained geometries on chemically functionalized surfaces that are patterned, e.g., by means of photolithography, is to generate surface areas with different wetting/electrostatic behavior, thus forcing the deposited dispersions to cover only the desired locations of the surface [20.488, 489]. TASA has been recognized as a powerful technology for creating patterned assemblies of micro- and nanoparticles. Lines but also micropatterns of arbitrary shape composed of ordered micro- and nanoparticles have been demonstrated. What makes the process even more fascinating is that the confinement itself enables the symmetry of the superlattices to be tuned simply by adjusting the particle size and the template feature geometry (diameter/shape of cavities, channels, width/spacing of functionalized surface patterns).

Further complexity may be brought into the deposited structures by applying nanoparticles of bimodal size distribution – provided that the diameters of the smaller as well as the larger nanoparticles are uniform (Fig. 20.10). Spontaneous assembly of bimodal decanethiol-functionalized Au nanoparticles into hexagonal and pseudohexagonal lattices, and binary mixtures of nanoparticles – such as Fe_2O_3 , PbSe, PbS,

Fig. 20.9 (a) Micrograph of a gold nanoparticle monolayer (dodecanethiol-ligated nanocrystals of 6 nm diameter) and its fast Fourier-transformed (FFT) pattern in the lower right inset. A schematic arrangement of two adjacent nanoparticles of the monolayer is shown in the upper left inset. (b) Image of a compact nanocrystal monolayer on the top surface of a thin liquid droplet extending completely across a $3 \times 4 \text{ mm}^2$ Si_3N_4 substrate (after [20.468])

Fig. 20.10a–i Transmission electron microscopy (TEM) images of binary structures made of CdSe and PbSe nanoparticles (each *scale bar* denotes 20 nm). Panels (a)–(c) show an AB₂ structure (0001) plane, the corresponding FFT pattern, and model structure, respectively; (d) cub-AB₁₃ (100) plane with the corresponding FFT image (e) and schematic structure (f); (g) cub-AB₁₃ with the (110)PbSe terminated with the corresponding FFT image (h) and schematic structure (i) (after [20.494]) ►

CdSe, Pd, Ag, Au – into various types of superlattices have been reported [20.490–494].

20.4.3 Inkjet Printing of Nanoparticle Dispersions

Inkjet printing as a cost-effective, rapid, and – for many applications – reasonably precise technology for depositing films and patterns of various materials on virtually any substrate has emerged and found use in diverse fields. With the rapid development of silicon microelectromechanical systems (Si-MEMS) technology, very accurate but still robust piezoelectric printing heads became possible to fabricate at low cost and very high throughput, offering a feasible platform for printing head production. Today's printers enable adjustment of printing parameters (piezo voltage, waveform, frequency), and if needed the process may be run by applying individual nozzles (drop-on-demand). These features may be extremely useful in process optimization and in laboratory-scale experiments to explore new ink formulations designed for a specific nanoparticle, substrate, or end-use application. State-of-the-art printers can eject droplets as small as of 1 pL in volume, corresponding to lateral print resolution of $\approx 10 \mu\text{m}/\text{pixel}$ on smooth unstructured surfaces. Surface confinement of the deposited droplets in microscopic or even sub-micrometer-size topographic and/or chemically modulated features – similar to that in directed self-assembly – can help in further enhancing the resolution. Apart from press/printing industry, inkjet deposition of nanoparticles is clearly becoming an important enabling technology in electronics and optoelectronics sectors. Electrodes and electrical interconnects deposited from metal, carbon nanotube, and graphene dispersions have been demonstrated by several research groups. Inkjet-printed patterns of semiconducting nanomaterials are of great importance too, due to their potential in cost-effective large-scale fab-

rication of field-effect transistor channels as well as emitting layers in light-emitting diodes [20.405, 414, 416–420, 439, 442–444, 447–453, 495–501].

Fig. 20.11 (a) Optical micrograph of an entire inkjet-printed carbon nanotube-based field-effect transistor. (b) Schematic drawing of the structure and (c) source-drain current-voltage and gate-transfer curves of a transistor with p-channel behavior (after [20.419])

20.5 Concluding Remarks

The long history of making dispersions is not over. In fact, the continuously evolving new nanoparticles of various functionalities synthesized today necessitate well-engineered dispersion formulations, thus giving rise to a renaissance of the discipline. Considering the shape, size, composition, and surface chemistry of the solid particles along with the composition of the liquid-phase dispersion medium, the number of possible variations of dispersions is enormous, offering a rich pool of materials for applications in diverse fields. To be able to exploit nanoparticles in wet chemical/physical processes fully, some

basic principles of dispersion-making need to be followed. In this chapter, we have discussed the parameters influencing dispersion stability and summarized the practical aspects of dispersion-making by compiling hundreds of examples from contemporary literature for nanoparticles of semiconductors, metals, their oxides/sulfides, as well as nanostructured carbon particles such as fullerenes, nanotubes, and graphene/graphite. As a considerable fraction of the applications are related to surface coatings, drying phenomena and self-ordering of the particles have also been discussed.

Nanoporous

21. Nanoporous Metals

Yi Ding, Zhonghua Zhang

In this chapter, we mainly describe the fabrication, properties, and potential applications of nanoporous metals (NPMs) with random porous structure. Nanoporous metals represent an interesting type of nanostructured material with nanosized porosity and ultrahigh specific surface area, and thus possess unique mechanical, physical, and chemical properties associated with their nanoporous structure. Based upon the porosity distribution, nanoporous metals can be classified into two categories: one has a random porous structure, and the other has a regular pore distribution. Nanoporous metals with random porous structure can be synthesized by the dealloying strategy, whereas template methods are normally used to fabricate nanoporous metals with more regular pore distribution. Nanoporous metals date back to the days of Raney (1920s) when high specific surface metal catalysts were prepared by dealloying Al-based alloys in alkaline solutions. In the new century, monolithic nanoporous metals received renewed attention due to the observation of a series of very intriguing structural properties. Nanoporous metals made by dealloying exhibit a three-dimensional bicontinuous interpenetrating ligament (metal)–channel (void) structure with a length scale of several nanometers to hundreds of nanometers, and the characteristic size can be modulated to as large as several microns by treatments such as thermal annealing. In contrast, the template technique can precisely control the pore size and microstructure of nanoporous metals, but dynamic modulation of the dominant length scale is virtually impossible. In addition, nanoporous metals are different from metallic foams, which

have a length scale of several microns to more than 1 cm, and are normally used as damping and acoustic materials. Here, we mainly focus on dealloyed nanoporous metals. Firstly, the dealloying method and formation mechanism of nanoporous metals are reviewed based upon previous experimental observations and computer simulation. Secondly, we summarize recent knowledge on microstructures of nanoporous metals and their unique properties (catalytic, electrocatalytic, mechanical, sensing, optical, etc.). Finally, potential applications of nanoporous metals are discussed in the fields of fuel cells, catalysis, sensors, actuators, etc.

21.1 Preparation of Nanoporous Metals

Many routes have been reported to prepare nanoporous metals, including transmetallation (galvanic replace-

ment) reaction [21.1–3], the combination of block-copolymer template with deposition [21.4], chem-

ical reduction of metal ions [21.5, 6], hydrothermal synthesis method [21.7–11], ballistic deposition [21.12], powder metallurgy [21.13], filter casting [21.14], potential-controlled anodization [21.15, 16], electroplating [21.17], electrodeposition [21.18–20], potential-controlled displacement [21.21], surfactant emulsion template [21.22], catalytic chemical deposition method [21.23], one-step square-wave potential pulse treatment [21.24], inkjet printing–sintering technique [21.25], template-printing method [21.26], and wet-chemical strategy [21.27]. However, the dealloying strategy is at present the most popular method to prepare nanoporous metals with random porous structure. Dealloying refers to selective dissolution of one or more components out of an alloy. In fact, dealloying is an ancient process and has a long history. Indians of pre-Columbian Central America had invented such a technique (also named depletion gilding) for coloration of castings prepared from copper–gold alloys. A very closely related process for coloration of silver–gold alloys, known as cementation, is known to have been used by European and Near Eastern goldsmiths before the early Middle Ages [21.28]. At that time, however, people did not know about the formation of nanoporous structures during the dealloying or depletion gilding process.

Historically, dealloying has received significant attention in the context of corrosion, including stress corrosion cracking (SCC) and corrosion fatigue, such as dezincification of brass [21.29–40]; for example, dealloying was found to be a common feature of both intergranular and transgranular cracking during stress corrosion of Cu–Zn and Cu–Zn–Ni alloys [21.29]. Raney catalysts, named after their inventor Murray Raney, were well known throughout most of the last century [21.41]. They are formed by selective dissolution (usually by alkali) of an active metal (usually aluminum) from an alloy, leaving a noble metal residue which is an active hydrogenation catalyst [21.42]. Recently, dealloying has received renewed attention due to the fact that certain systems exhibit nanoporosity evolution upon dealloying. As early as the 1960s, *Pickering* and *Swann* [21.43, 44] used gold alloys as model systems to study their electrochemical behavior, and were also the first to use transmission electron microscopy (TEM) to characterize the resulting structures, which confirmed a nanoporous structure with feature size of ≈ 10 nm. In 1979, *Forty* [21.28] presented electron micrographs for a free-standing nanoporous gold (NPG) membrane material, which had pore size of approximately 20 nm and was made by etching an Ag–

Au alloy film in HNO_3 . Since the 1980s, *Sieradzki* and *Newman* and others have systematically investigated the corrosion process of Ag–Au alloys [21.45–47]. With advanced electrochemical techniques, such as electrochemical scanning tunneling microscopy, they discussed in great detail two key parameters associated with dealloying: the parting limit and the critical potential, where the parting limit defines the concentration of noble metal in an alloy above which dealloying does not occur, while the critical potential is empirically defined as a voltage threshold above which the dissolution current rises dramatically, resulting in substantial dealloying. At the very beginning of this century, *Erlebacher* et al. [21.48] further clarified the underlying physical mechanism of dealloying of Ag–Au alloys using experiments and computer simulation. After that, *Ding* and *Erlebacher* [21.49–52] continued to pay more attention to the microstructural morphology of NPG by dealloying commercial Ag–Au leaves. In the past 10 years, increasing interest has been paid to nanoporous metals made by dealloying, as well as their microstructures, unique properties, and potential applications.

21.1.1 Alloy Design of Precursors Suitable for Dealloying

Alloy systems that form porosity upon dealloying share a number of characteristics, and there are four basic common characteristics that an alloy typically possesses if it has a chance of becoming nanoporous during dealloying:

1. The difference in potential required to dissolve the alloy component in its pure form must be a few hundred millivolts, with one element being more noble (MN) and the other less noble (LN).
2. The composition is usually rich in the less noble component (the content of the more noble element is below its parting limit).
3. The alloy must be homogeneous with no phase separation prior to dissolution. Porosity evolution thus forms dynamically during dissolution and is not due to one phase simply being excavated from a two-phase material.
4. Diffusion of more noble atoms at the alloy/electrolyte interface must be sufficiently fast [21.53].

The prototypical alloy system for dealloying is Ag–Au, which has single-phase solid solubility across all compositions. Until now, dealloying has been observed in many binary alloy systems including Cu-based alloys (Cu–Au, Ag, Pt, Mn, Zr, Ni, etc.) [21.54–59],

Al-based alloys (Al-Au, Ag, Pt, Pd, Cu, etc.) [21.60,61], Mg-based alloys (Mg-Ag, Cu, etc.) [21.62, 63], Zn-based alloys (Zn-Pt, Au, Ag, Cu, etc.) [21.64–67], etc. These binary systems are composed of a single-phase solid solution, or a single-phase intermetallic compound or a combination of solid solution and/or intermetallic phase [21.68–70]. Accordingly, nanoporous metals such as Au, Ag, Pd, Pt, Cu, etc. can be fabricated through chemical or electrochemical dealloying of these binary precursors. Figure 21.1 shows typical scanning electron microscopy (SEM) micrographs of NPG obtained by dealloying Ag-Au leaf in nitric acid [21.51], and optical images before and after dealloying are also included.

Besides binary systems, dealloying can also be realized in ternary or multicomponent precursors [21.71, 72]. Dealloying of ternary or multicomponent precursors is more complicated than that of binary systems, but they also provide the opportunity to tune the microstructure of the as-obtained nanoporous metals and to fabricate nanoporous alloy materials. Other than crystalline precursors, some amorphous alloys (metallic glasses) can also be dealloyed to form corresponding nanoporous metals [21.73, 74]. In comparison with crystalline alloys, multicomponent metallic glasses are monolithic in phase with homogeneous composition and structure down to subnanoscale. In addition, the shapes of precursors are also diverse, and films, ribbons, powders, nanoparticles, nanowires, and even bulk form have been reported.

It is well established that the composition, structure, and phase constitution of precursors have a significant influence on the dealloying process and the formation of nanoporous metals. It has been reported that electrochemical dealloying of nanocrystalline 62Cu-38Zr films results in formation of porous copper with uniform diameter of approximately 500 nm. In contrast, no porous copper could be obtained from coarse-grained 62Cu-38Zr alloys under the same conditions [21.70]. The following routes are normally used to prepare precursors: melt casting, rapid solidification, rolling, surface alloying, template-assisted electrodeposition, vapor deposition, sputtering deposition, etc. It is obvious that one can control the dealloying process by adopting a proper processing method of precursors.

21.1.2 Formation Mechanisms of Nanoporous Metals by Dealloying

In 1967, *Pickering* and *Wagner* [21.75] argued that, when one metal is preferentially dissolved, it may be

Fig. 21.1 (a–b) Optical and (c–e) SEM images of white gold leaf before and after dealloying in nitric acid for 15 min. The inset image in (c) shows a region where a slid grain boundary is located. Very thin gold ligaments with diameter smaller than 2 nm are often observed. Examples are marked with arrows in (e) (after [21.51])

assumed that one or more of the following three mechanisms operate:

1. Both metals ionize followed by redeposition of the more noble metal.
2. Only the less noble metal ionizes and enters the solution, while the atoms of the more noble metal aggregate by surface diffusion.
3. Only the less noble metal ionizes and enters the solution, and atoms of both metals move in the solid phase by volume diffusion.

Later, *Forty* et al. [21.28, 76, 77] thought that the formation of the island–channel structure during dealloying of Ag-Au alloys can be explained in terms of a corrosion disordering/diffusion reordering model in which corrosion proceeds by selective dissolution of the less noble component, thereby creating a disordered surface layer which subsequently reorders by surface diffusion of gold adatoms. In 1989, *Sieradzki* et al. [21.78] developed a new model to account for all the known features of dealloying based upon percolation theory. Their Monte Carlo simulation results could reproduce many of the features usually associated with dealloying in real binary noble–metal alloy sys-

tems, including the porous morphology of the dealloyed residue, coarsening of this porosity, sharp dealloying thresholds or parting limits, and the development of intermediate compositions.

In 2001, *Erlebach* et al. [21.48] proposed a continuum model that is fully consistent with experiments and theoretical simulations of alloy dissolution, and demonstrated that nanoporosity in metals is due to an intrinsic dynamical pattern formation process; that is, pores form because the more noble atoms are chemically driven to aggregate into two-dimensional clusters by a phase separation process (spinodal decomposition) at the solid/electrolyte interface, and the surface area continuously increases owing to etching. Figure 21.2 clearly shows the simulated nanoporosity evolution during dealloying. Moreover, the nanoporous structure of NPG can be well modeled by their simulations. In 2004, *Erlebach* [21.53] further described the micro-

scopic details of porosity formation during dealloying as illuminated by a kinetic Monte Carlo model incorporating site coordination-dependent surface diffusion of all alloy components, and site coordination-dependent dissolution of the less noble atoms. Their simulation model can reproduce many of the characteristics of dealloying, particularly the observation of porosity evolution and reproduction of the classical phenomenology of a parting limit and a composition-dependent critical potential.

Below the dealloying critical potential, passivation normally occurs, but its origin is still unclear. Recently, *Renner* et al. [21.79] revealed the microscopic structural changes associated with a general passivation phenomenon on the atomic scale by in situ x-ray diffraction with picometer-scale resolution. They observed the formation of a gold-enriched single-crystal layer that is two to three monolayers thick and has an unexpected inverted (CBA-) stacking sequence. At higher potentials, the protective passivation layer dewets and pure gold islands are formed; such structures form the templates for the growth of nanoporous metals.

It is known that, for most systems, the critical dealloying potential E_c is determined by a balance between dissolution-induced surface roughening and surface-diffusion-induced smoothing. Below the critical potential, the current density is surface diffusion limited and is typically less than $1 \mu\text{A}/\text{cm}^2$. The conventional view of morphology evolution in the region below the critical potential is that the alloy surface maintains a stable planar interface while enriching in the more noble constituent. The current decay is believed to be correlated with the B (MN element) enrichment, but the current never drops identically to zero. *Wagner* et al. [21.80] studied in detail the dealloying behavior below the critical potential, and found the existence of different regimes of power-law current decay behavior at potentials below the critical potential. The initial current decay displays t^{-1} behavior, which their modeling has shown to be consistent with the exhaustion of sites available for dissolution. When the current from this process falls to a low enough level, the power law adopts an exponent indicative of one of three mechanisms dominating in the surface-vacancy diffusion process. The current resulting from the surface-diffusion-controlled process can follow $t^{-5/8}$, $t^{-1/2}$, and $t^{-1/4}$ behaviors, respectively, for surface-vacancy-controlled periphery diffusion, terrace diffusion, and evaporation–condensation.

It is well recognized that the formation of nanoporous metals by dealloying involves selective

Fig. 21.2a–d Simulated evolution of an artificial pit in $\text{Au}_{10\%}\text{--Ag}_{90\%}$ (at.%), $f = 1.8 \text{ eV}$. Cross-sections along the $(11\bar{1})$ plane defined by the yellow line in (a) are shown below each plan view. (a) The initial condition is a surface fully passivated with gold except within a circular region (the artificial pit). (b) After 1 s, the pit has penetrated a few monolayers into the bulk. We note how there are fewer gold clusters near the side wall than at the center of the pit. (c) After 10 s, a gold cluster has nucleated in the center of the pit. (d) At 100 s, the pit has split into multiple pits; each will continue to propagate into the bulk to form a porous structure (after [21.48])

dissolution of the less noble element coupled with coarsening of the more noble element by surface diffusion. However, minor dissolution of the more noble element is also possible during dealloying, especially when the electrolyte contains Cl^- . During dealloying of brass in aqueous sodium chloride, Cu dissolves into the solution to form Cu(I) and Cu(II) complex ions [21.31]. At appropriately high dealloying potentials, relatively steady chloride compound or chloride complexes can form between chloride ions and the more noble metals included, such as soluble $[\text{AuCl}_4]^-$, PdCl_2 , $[\text{AgCl}_2]^-$, $[\text{CuCl}_2]^-$, and insoluble AgCl and CuCl during the electrochemical dealloying of Al-based alloys [21.61]. Eventually, the dissolution of Cu to form soluble $[\text{CuCl}_2]^-$ complex plays a key role in the dealloying of MgCu_2 and the formation of nanoporous copper [21.81]. Moreover, inductively coupled plasma (ICP) measurements also verify the existence of minor Ag ions in the electrolyte after chemical dealloying of Mg-Ag-Pd alloys [21.71]. In addition, the electrochemical dealloying mechanism of Al_2Au in neutral NaCl solution can be explained based upon the Pourbaix diagram and chloride ion effect [21.82]. During the dealloying process, a self-acidifying effect is triggered due to the dissolution and instant hydrolysis of Al^{3+}/Al , which is assisted by chloride ions in the electrolyte (Fig. 21.3). The self-acidifying effect accelerates the dealloying process of the Al-Au alloys and thus the formation of NPG.

If multiple phases exist in the alloy, Pugh et al. [21.55] argued that porosity formation of any individual phase would follow the same requirement for a single phase, and hence typically only the A-rich phase would dealloy (here A is the less noble element). In this case, dealloying would be isolated to only surface grains unless a mechanism existed for penetration of the electrolyte throughout the alloy; for example, the A-rich grains form a percolating path through the alloy. As for a two-phase alloy, we have found that the dealloying process depends upon the composition, activity, and electrochemical properties of each phase in the alloy. According to the reactions (being excavated, dealloyed, or retained) of the constitutive phases in a biphasic alloy during dealloying, six types of dealloying are classified, and four typical dealloying scenarios can be identified from the viewpoint of nanoporosity evolution during dealloying [21.61]. Moreover, it is interesting to note that dealloying of the less noble phase has a promoting effect on dealloying of the more noble phase (for example, Al-Ag alloys containing Al and Ag_2Al) [21.83]. In addition, the promoting effect

in eutectic structures is stronger than that in peritectic structures, the effect of a solid solution as the less noble phase is stronger than that of an intermetallic phase, and the higher the diffusivity and the lower the equilibrium potential of the more noble element in the electrolyte, the more substantial the promoting effect is.

Most recently, the chemical dealloying mechanism of bimetallic Pt-Co nanoparticles (NPs) has been investigated on a fundamental level by the combination of x-ray absorption spectroscopy (XAS) and aberration-corrected scanning transmission electron microscopy (STEM) [21.84]. Structural parameters, such as coordination numbers, alloy extent, and the unfilled d states of Pt atoms, are derived from the XAS spectra, together with the compositional variation analyzed by line-scanning energy-dispersive x-ray spectroscopy (EDX) on an atomic scale, to gain new insights into the dealloying process of bimetallic Pt-Co NPs. The XAS results on acid-treated Pt-Co/C NPs reveal that the Co-Co bonding in the bimetallic NPs dissolves first, and the remaining morphology gradually transforms to a Pt skin structure. Furthermore, it is observed that such an imperfect Pt skin surface feature will collapse due to penetration of electrolyte into layers underneath and cause further dissolution of Co and the loss of Pt. The electrocatalytic activity decreases accordingly, if the dealloying process lasts for 4 h.

Fig. 21.3 Schematic illustration of pore evolution and hydrogen bubble emergence during electrochemical dealloying of Al_2Au in 10 wt % NaCl aqueous solution (after [21.82])

Normally, a minor residue of the less noble element is inevitable in the resultant nanoporous metals formed by dealloying, but less attention has been paid to the retention of the less noble element during dealloying. Recently, *Liu et al.* [21.85] investigated factors controlling retention of the less noble metal in nanoporous structures processed by electrochemical dealloying, taking Ag-Au as an example. It has been found that, while the dealloying critical potential is generally independent of pH, the dissolution rate is strongly affected by the solution acidity. pH substantially affects Ag retention in both the oxide and alloy forms. To discriminate between the retention forms, two different approaches employed for removing the Ag oxide from freshly dealloyed samples are: (i) oxide dissolution in 1 M HClO₄, and (ii) oxide reduction to elemental Ag followed by subsequent electrochemical oxidation to Ag⁺ ions. Critical analysis of the experimental results suggests that the pH and dissolution rate affect more significantly the amount of Ag retained in the form of oxide, while the dealloying potential has a stronger impact on Ag trapping. In addition, the Ag retained as oxide is determined to be predominantly AgO. Their findings could enable the development of strategies for structural and compositional control in electrochemically processed metallic nanoporous materials.

21.1.3 Control over Structures of Nanoporous Metals

It is known that the properties of nanoporous metals are closely related to their microstructure and especially the characteristic length scale of ligaments/channels. It is of great importance to control the microstructures of nanoporous metals. Some factors including the microstructure of precursors, the kind and type

of electrolytes, the applied dealloying potential, and the dealloying temperature and time will affect the dealloying process and thus the formation/structure of nanoporous metals. At the same time, formation of nanoporous metals by dealloying is a self-organization process by surface diffusion of the more noble element along the alloy/solution interface, and the surface diffusivity of the more noble element has a significant influence on the length scale of the ligaments/channels of nanoporous metals. We can tune the microstructure of nanoporous metals by adjusting the dealloying parameters, especially by control of the surface diffusivity of the more noble element.

Pt has a value of surface diffusivity ($< 10^{-19}$ cm²/s) that is at least 3–4 orders of magnitude lower than that ($< 10^{-15}$ – 10^{-16} cm²/s) of Au under their respective electrochemical environment. Therefore, nanoporous Pt normally shows a ligament–channel structure with a length scale of only a few nanometers through dealloying of Cu-Pt and Al-Pt alloys [21.55, 60, 86]. Figure 21.4 shows TEM and high-resolution TEM (HRTEM) images of nanoporous Pt obtained by chemical dealloying of Al₈₈Pt₁₂ alloy in 20 wt % NaOH solution [21.60]. The corresponding selected-area electron diffraction (SAED) pattern and the HRTEM image confirm that the as-obtained nanoporous Pt is composed of randomly oriented face-centered cubic (fcc) nanocrystals. For a given dealloying solution, the length scale of the ligaments/channels in the resulting nanoporous metal is associated with surface diffusion of more noble atoms, and increases with increasing diffusion coefficients in the sequence: Pt/Pd < Au < Ag < Cu [21.60].

Antoniou et al. [21.87] reported synthesis of nanoporous platinum (np-Pt) through electrochemical dealloying in aqueous HF from cosputtered Pt_xSi_{1-x}

Fig. 21.4 (a) TEM image of nanoporous Pt obtained by chemical dealloying of Al₈₈Pt₁₂ alloy in 20 wt % NaOH solution. (Inset) Corresponding SAED pattern. Scale bar, 20 nm. (b) HRTEM image of nanoporous Pt. Scale bar, 2 nm (after [21.60])

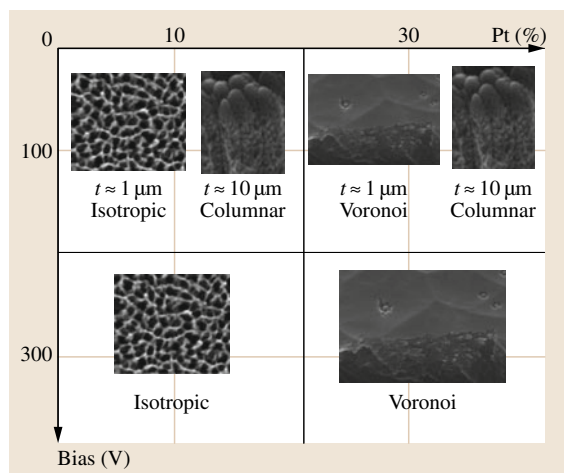

Fig. 21.5 Schematic of the possible np-Pt foam morphologies as a function of cosputtering parameters, initial alloy composition, and thickness (after [21.87])

amorphous films for different initial compositions and sputter bias conditions. They found that, in addition to the expected isotropic open-cell np-Pt foam, anisotropic columnar and Voronoi np-Pt is obtained. There are two levels of anisotropy: On the micron scale, 100 nm columns or 1 μm Voronoi polygons form, whereas inside the columnar and Voronoi hyperstructures, the ligaments and pores are anisotropic, ranging from 5 to 25 nm. The ligament diameter and grain size were 5 nm for all reported structures. A processing–structure map was developed to correlate np-Pt structure to the processing conditions (Fig. 21.5).

Monolithic nanoporous copper can be synthesized by dealloying $\text{Mn}_{0.7}\text{Cu}_{0.3}$ by two distinct methods: potentiostatically driven dealloying and free corrosion [21.57]. Both the ligament size and morphology were found to be highly dependent on the dealloying methods and conditions; for example, ligaments of 16 or 125 nm were obtained by dealloying either electrochemically or by free corrosion, respectively. Optimization of the starting Mn-Cu alloy microstructure allowed generation of uniform porous structures. *Seker et al.* [21.88] reported that thermal treatment of Ag-Au films can reduce microscale void formation in blanket nanoporous gold films. *Okman et al.* [21.89] found that the ramped potential increase gave better NPG film uniformity than stepped potential increase during potentiostatic dealloying of Ag-Au films. *Li and Balk* [21.90] reported effects of substrate curvature on dealloying of cosputtered Au-Pd-Ag alloy films. They found that ligament morphology, film cracking, and

composition were significantly different for np-AuPd in concave versus convex film regions. Convex substrate curvature led to extensive film cracking, wide and high-aspect-ratio ligaments, and low residual Ag content. A more tensile stress state is believed to enhance the dissolution rate of Ag. *Li et al.* [21.91] reported that the microstructure of precursors has a significant influence on the dealloying of ternary amorphous Si-Pt-Ni precursors, and the ligament patterns and mechanical properties of the resulting nanoporous Pt-Ni alloys.

Snyder et al. [21.92] investigated dealloying behaviors of Ag-Au alloys in neutral silver nitrate solution. A small-pore (5 nm) NPG can be formed over a potential range of 1.3–2.0 V versus normal hydrogen electrode. They explained the observations in terms of residual surface oxides passivating the pores behind the dissolution front, which is itself acidified and thus corrosive due to accumulation of protons associated with oxide formation and water dissociation. Their method of fabricating NPG has the advantages of simplicity and safety. Linear relationships have been observed between the dealloying potential and the size of ligaments and pores [21.93]. Moreover, at low dealloying potential the pore size is larger than the ligament diameter, whereas at high dealloying potential they are comparable. *Li and Balk* [21.94] found that the pore and ligament dimensions of nanoporous palladium nickel (np-PdNi) were reduced by 50% when surfactants were added to the sulfuric acid etching solution. Ultrasonic agitation was also used to enhance dealloying and shortened the time required from 5 to 1 h, while retaining pore/ligament size of 5 nm.

During dealloying, adsorption of anions (such as Cl^-) from the electrolyte can accelerate surface diffusion of the more noble element. *Dursun et al.* [21.95] studied dealloying of $\text{Ag}_{0.7}\text{Au}_{0.3}$ and $\text{Ag}_{0.65}\text{Au}_{0.35}$ alloys in 0.1 M HClO_4 with addition of either 0.1 M KCl, 0.1 M KBr, or 0.1 M KI. They found that the critical overpotential decreases with addition of halides, with KI having the largest potential reduction of almost 50%. This decrease can be rationalized according to competition between the rates of increase of Au surface diffusivity and Ag exchange current density with halide addition. The size scale of porosity produced during dealloying of $\text{Ag}_{0.65}\text{Au}_{0.35}$ was found to increase with addition of halides. Also, it has been found that the length scale of ligaments/channels of nanoporous metals can be modulated by simply changing the dealloying solution (from HCl to NaOH) [21.60].

Low-temperature dealloying treatment is an effective method to tailor the characteristic length scale of

nanoporous gold. By systematically investigating the kinetics of nanopore formation during free corrosion, *Qian and Chen* [21.96] experimentally demonstrated that the dealloying process is controlled by diffusion of gold atoms at alloy/electrolyte interfaces, which strongly relies on the reaction temperatures. Low dealloying temperatures significantly reduce the interfacial diffusivity of gold atoms and result in ultrafine nanoporous structure. NPG with ultrafine ligaments/channels (less than 10 nm) can be obtained by dealloying of Al_2Au in alkaline solution at low temperature. The surface diffusivity of Au adatoms was evaluated as 2.1×10^{-23} , 2.3×10^{-21} , and $1.6 \times 10^{-19} \text{ m}^2/\text{s}$ for dealloying at 253, 298, and 368 K, respectively. Measurement of the activation energy demonstrates that formation and coarsening of NPG are governed by Au diffusion at alloy/solution interfaces, regardless of the dealloying medium [21.97].

Addition of elements with low surface diffusivity into precursors can effectively refine the ligaments and channels of nanoporous metals (or alloys). In addition, as is well known, the noble metals Pt and Pd are widely used in the field of fuel cells as electrocatalysts and exhibit excellent catalytic activities for oxidation of small organic molecules. Introduction of Pt or/and Pd into nanoporous metals (such as NPG) can also generate a kind of novel bi-/trimetallic nanoporous functionalized alloys. Addition of Pt to precursor Ag/Au alloys was, upon dealloying, found to stabilize the morphology of the porous metal formed, to refine its pore size to nearly atomic dimensions, and to stabilize its morphology even in harsh chemical and thermal environments [21.99]. As Pt possesses much slower surface diffusion rates than Au, during dissolution, Pt embedded in exposed terraces should segregate to the edges of the growing vacancy island step edges,

Fig. 21.6 SEM, TEM, and HRTEM images of nanoporous Au/Pt alloys obtained by dealloying (a–c) $\text{Au}_{10}\text{Pt}_{10}\text{Cu}_{80}$, (d–f) $\text{Au}_4\text{Pt}_{16}\text{Cu}_{80}$, and (g–i) $\text{Au}_{16}\text{Pt}_4\text{Cu}_{80}$ alloys, respectively (after [21.98])

stabilizing them and ultimately reducing the scale of porosity as well as leading to a Pt-rich shell. Selective etching of Cu from Au/Pt/Cu alloy precursors results in the formation of three-dimensional bicontinuous porous network structures with uniform pores and ligaments less than 10 nm (Fig. 21.6) [21.98]. Moreover, nanoporous Au/Pt alloys have a single-phase cubic structure with relatively uniform composition across the samples. The addition of the third element Pd into Mg-Ag results in the formation of an ultrafine nanoporous $\text{Ag}_{80}\text{Pd}_{20}$ alloy which exhibits superior catalytic activity towards electrooxidation of ethanol [21.71]. It has been found that elemental doping has no influence on the phase constitution of rapidly solidified Al-Au-Pt, Al-Au-Pd, and Al-Au-Pt-Pd alloys, and all these precursor alloys are composed of a single Al_2Au -type intermetallic compound ($\text{Al}_2(\text{Au,Pt})$, $\text{Al}_2(\text{Au,Pd})$, and $\text{Al}_2(\text{Au,Pt,Pd})$). Ultrafine nanoporous gold alloys with ligaments/channels less than 10 nm can be facily fabricated through dealloying these rapidly solidified Al_2Au -based precursors under free corrosion conditions. When performing dealloying in 20 wt % NaOH solution, a certain amount of Pt or/and Pd addition exhibits a superior refining effect, and the length scale of the ligaments/channels in the as-obtained np-Au alloys can reach ≈ 3 nm for Pt doping or Pt/Pd codoping. When performing dealloying in 5 wt % HCl solution, the anticoarsening capacity of Pt doping is more remarkable than that of Pd doping. In addition, the amount of doping can significantly affect the anticoarsening ability of ligaments/channels in thus-obtained np-Au alloys [21.72].

Generally, the structure of nanoporous metals can be coarsened to larger length scales (up to micrometers) at elevated temperatures and has been shown to coarsen at room temperature as a function of the applied voltage and electrolyte composition; for example, fast surface diffusion of gold in electrolyte gives NPG leaf the unique ability to have its porosity adjusted using simple room-temperature acid-induced postprocessing (Fig. 21.7) [21.51]. *Hakamada* and *Mabuchi* [21.100] reported a simple and spontaneous synthesis of a nanoporous gold prism microassembly with highly dense skins, which was achieved just by immersing nanoporous gold into concentrated hydrochloric acid. Coarsening of the porous structure can be attributed to the rapid surface diffusion of gold accelerated by Cl^- . Moreover, the morphology of the nanoporous gold prism microassembly was significantly different from that of annealed nanoporous gold.

Through combination with other routes such as template methods, galvanic replacement reactions, and underpotential deposition electroless plating, dealloying can be used to further tailor the morphology, microstructure, and properties of nanoporous metals. *Ji* and *Searson* [21.101] reported fabrication of nanoporous nanowires with high surface area and well-defined pore morphology (Fig. 21.8). The nanoporous nanowires were formed in a two-step process involving electrochemical deposition of a single-phase, two-component A_xB_{1-x} alloy into a nanoporous template (AAO), with subsequent chemical etching of one component from the alloy after removal from the template. Moreover, nonporous segments can be incorporated into

Fig. 21.7a–f Plan-view and cross-sectional SEM images of NPG leaf samples showing significant structure coarsening upon continued immersion in acid for extended times after the leaf is completely dealloyed (dealloying is usually complete after 5 min) (after [21.51])

(d) EDS analysis indicates a gradual structure transition from Pt/NPG to NMP (after [21.52])

multisegment nanowires. *Chen et al.* [21.102] reported synthesis of a novel gold-decorated nanoporous copper (Au at NPC) core-shell composite. Thin gold shells with controllable thickness are homogeneously deposited onto the internal surfaces of three-dimensional (3-D) nanoporous copper via a spontaneous displacement reaction, while nanoporous copper is utilized as a reduction agent as well as 3-D template and substrate. *Ding et al.* reported the design and fabrication of nanotubular mesoporous platinum (NMP), a new material that can be described as a network of platinum nanotubes with diameter of about 15 nm and walls 1 nm thick that interconnect to form an open, doubly bicontinuous structure that may possess the highest surface-area to-volume ratio known for a macroscopic sample of metal (Fig. 21.9) [21.52]. Nanotubular mesoporous platinum can be synthesized by epitaxial casting using nanoporous gold membrane molds (dealloying-plating-dealloying). They further

investigated the structure evolution of a novel electrocatalyst, Pt-decorated nanoporous gold (Pt-NPG), during thermal annealing at relatively low temperatures [21.103]. Pt-NPG was made by plating a thin layer of Pt over NPG substrate during an electroless plating process that generated epitaxial Pt nanoislands loaded on the NPG surface. In comparison with Pt's very high melting point, thermal annealing at temperatures as low as 100 °C was found to significantly change the structure and surface chemistry of these nanomaterials. While Pt-NPG preserved very well its initial porous morphology, the deposited Pt islands collapsed to form a thin Au-Pt alloy layer coating on the NPG surface upon heating. This structure change results in severe modulation of the electronic structure and surface reactivity of Pt, as proved by the markedly different behaviors in electrocatalytic reactions such as formic acid electrooxidation and CO stripping.

21.2 Properties of Nanoporous Metals

The phase constitution, microstructure, and composition of nanoporous metals can be characterized using XRD, SEM, TEM, HRTEM, x-ray photoelectron spectroscopy (XPS), energy-dispersive x-ray (EDX) analysis, atomic force microscopy (AFM), scanning tunneling microscopy (STM), small-angle neutron scattering (SANS), x-ray absorption spectroscopy (XAS), high-angle annular dark-field scanning transmission electron microscopy (HAADF-STEM), and many other techniques.

21.2.1 Structure and Morphology

Characterization Methods

Corcoran [21.104] explored the use of small-angle neutron scattering and scanning tunneling microscopy as potential tools for determining the mechanisms involved in porosity formation. The average pore size and distribution were found to depend upon the electrolyte composition, dealloying rate, applied potential, and time. Figure 21.10 shows in situ scattering data for spontaneous corrosion of $\text{Ag}_{0.7}\text{Au}_{0.3}$ in concentrated HNO_3 . The length scale of nanopores can be evaluated from the characteristic peak position. *Fujita and Chen* [21.105] proposed a method derived from the fast Fourier transform (FFT) process to measure the characteristic length scale of bicontinuous nanoporous

structures. By rotationally averaging the FFT power spectrum of a nanoporous micrograph from SEM or TEM, a significant peak in the power spectrum can be obtained, which reflects the characteristic length scale

Fig. 21.10 In situ scattering data for spontaneous corrosion of $\text{Ag}_{0.7}\text{Au}_{0.3}$ in concentrated HNO_3 . The dealloying time associated with each curve is indicated (after [21.104])

of the quasiperiodic structure. This method is valid for the bicontinuous morphology that is frequently observed in nanoporous metals prepared by chemical or electrochemical dealloying.

Renner et al. [21.107] presented an in situ x-ray diffraction study of the initial steps of potential-controlled, selective dissolution of Cu from a Cu_3Au (111) single-crystal surface immersed in 0.1 M H_2SO_4 . They found structural evolution of an ultrathin Au-rich metallic passivation layer at low overpotentials toward thicker, pure Au islands at elevated overpotentials below the critical potential. The thickness of the ultrathin layer grows from two hexagonal close-packed (hcp) monolayers to several fcc-stacked monolayers. The epitaxial Au-rich layer, which exhibits a reversed stacking with regard to the single-crystal substrate, passivates the Cu_3Au (111) surface. Complementary ex situ AFM images showed at elevated overpotentials a surface completely covered with islands of a homogeneous size distribution, which agrees well with the findings from the x-ray experiments. The Au islands are found to be weakly hexagonally correlated.

Rösner et al. [21.108] developed a method to reconstruct a nanoporous metal (taking NPG as an example) in three dimensions from TEM images. Normally, the small feature sizes of NPG prevent characterization using many established techniques such as optical microscopy serial sectioning or x-ray tomography. The most important observations obtained using TEM tomography are:

1. The structure represents a contiguous network of branched ligaments.
2. The structure is quite inhomogeneous, with a broad distribution of ligament and pore diameters and shapes.

3. As a consequence, the specific surface area is larger than what would be estimated based on the characteristic ligament size.
4. In spite of the many saddle-point-like features, the average mean curvature is positive and close to what would be expected for convex objects of a size corresponding to the ligament diameter.
5. Encased voids are observed within the ligaments; there is no obvious explanation for the formation of these features.

This information contributes to establishing a basic description of the topology and local structure of nanoporous metals prepared by dealloying, which may form the basis for future models leading to predictive understanding of their properties, such as strength, surface induced strain, or transport properties.

Fujita et al. [21.106] reported transmission electron tomography of nanoporous gold fabricated by chemically dealloying $\text{Au}_{35}\text{Ag}_{65}$ films. A number of algorithms were employed to quantitatively characterize the complex three-dimensional nanoporous structure. It was found that gold ligaments and nanopore channels are topologically and morphologically equivalent; i.e., they are inverses of each other in three-dimensional space. Statistical analysis reveals that this bicontinuous nanostructured material is actually quasiperiodic and has, on average, near-zero surface curvature. Figure 21.11 shows corresponding 3-D tomographic reconstruction of nanoporous gold. These quantitative measurements will help in understanding the structural stability of nanoporous gold and in modeling its physical and chemical performance.

Petegem et al. [21.109] studied the evolution of the grain structure, internal strain, and lattice misori-

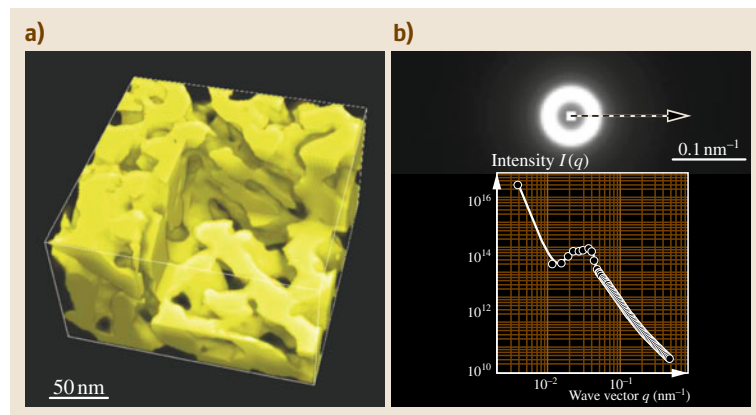

Fig. 21.11a,b 3-D tomographic reconstruction of nanoporous gold. (a) Magnified 3-D image revealing the internal bicontinuous structure of nanoporous gold. The inserted intensity profile was taken along the dashed arrow in the Fourier-transform pattern (after [21.106])

entation of nanoporous gold during dealloying of bulk (3-D) Ag-Au alloy samples by various in situ and ex situ x-ray diffraction techniques including powder and Laue diffraction (Fig. 21.12a). Their experiments revealed that the dealloying process preserves the original crystallographic structure but leads to a small spread in orientations within individual grains. Initially, most grains develop in-plane tensile stresses, which are partly released during further dealloying. Simultaneously, the feature size of the developing nanoporous structure increases with increasing dealloying time. Finally, microdiffraction experiments on dealloyed micron-sized nanoporous pillars revealed significant surface damage introduced by focused ion beam milling. Figure 21.12b shows a two-dimensional (2-D) x-ray microdiffraction image of a nanoporous gold pillar. The inset displays a 3-D image of a part of the (111) ring.

Thin films of nanoporous gold, with ligaments and pores of the order of 10-nm diameter, offer a highly constrained geometry for deformation and thus provide an opportunity to study the role of defects such as dislocations in the plasticity of nanomaterials. Sun et al. [21.110] studied the mechanical behavior of nanoporous gold by using in situ nanoindentation in a transmission electron microscope. They found that dislocations were generated and moved along ligament axes, after which they interacted with other dislocations at the nodes of the porous network. For thicker films, the load–displacement curves exhibited load drops at regular intervals. Additionally, they also investigated the effect of the indenter displacement rate on the mechanical response of these gold films with nanoscale porosity. There appears to be a kinetic factor related to dislocation nucleation, where slower displacement rates cause load drops to occur at shorter distance intervals and over longer time intervals.

Liu et al. [21.111] developed an inexpensive, fast, selective, and sensitive technique for surface area measurement of metallic nanoporous materials (MNPM). Their approach is based on underpotential deposition (UPD) of metals on foreign substrates. In their work, Pb UPD on Au was chosen to illustrate the applicability, and revealed the advantages and limitations, of the proposed method. They measured the surface area of NPG electrodes with pore sizes in the range of 5–15 nm, prepared by electrochemical dealloying of single-phase AuAg. A critical comparison with Brunauer–Emmett–Teller (BET) analysis reveals important advantages of the method developed for surface area measurement in MNPM specimens.

Microstructure and Morphology

Through design of precursors and control over the dealloying process, nanoporous metals with diverse structures and morphologies can be fabricated, such as homogeneous structure, bimodal pore distribution, composite structure, ultrafine porous structure, etc. Moreover, both nanostructures (nanowires, nanotubes) and monolithic forms (films, ribbons, bulk samples) can be obtained. In addition, as well as pure metals, nanoporous alloys can also be produced.

Normally, larger-sized pores (hundreds of nm) are useful in microfluidic flow control, whereas very small pores (tens of nm) are useful for increasing device surface area as required for sensor applications. For microfluidic-based sensors, a bimodal pore size distribution composed of large porosity channels with highly porous channel walls is desirable to

Fig. 21.13a,b A 2-D/3-D hybrid NPG structure, where the dimension of the unit structure in 2-D ($1\text{--}2\text{ }\mu\text{m}$) is two orders of magnitude larger than that in 3-D substructure ($\approx 8\text{ nm}$). Here, 100 nm-thick gold leaf was used, and the second-stage annealing was carried out at $500\text{ }^{\circ}\text{C}$ for 8 h (after [21.49])

achieve fast response time and high sensitivity. Ding and Erlebacher [21.49] reported a two-step dealloying

(dealloying–plating–annealing–dealloying) strategy to create nanoporous gold with multimodal pore size distributions. Figure 21.13 shows a 2-D/3-D hybrid NPG structure. In addition, NPG ribbons with bimodal channel size distributions can also be fabricated by chemical dealloying of Al–Au alloys composed of Al and Al_2Au phases [21.68]. The as-obtained NPG ribbons are composed of large-sized channels (hundreds of nanometers) with highly porous channel walls (tens of nanometers). Both large- and small-sized channels are 3-D, open, and bicontinuous. Moreover, the length scales of the large-sized channels can be modulated by changing the alloy composition, while those of the small ligaments/channels in the channel walls can be tuned by changing the dealloying solution.

Yoo and Park [21.113] reported that ultrathin, platinum-coated, nanoporous nanorod arrays can be synthesized by electrodepositing gold and silver ions into porous alumina membranes, followed by selective dealloying and copper-UPD redox exchange reactions. Using a similar strategy, Shin et al. [21.114] synthesized hollow nanotubes (pore $d > 100\text{ nm}$) with nanoporous walls (pore $d < 10\text{ nm}$).

Metallic nanostructures with hollow interiors or tailored porosity represent a special class of attractive materials with intriguing chemophysical properties. Gu et al. [21.112] recently reported the fabrication of a new type of metallic nanoporous nanotube structure based on a facile and effective combination of nanocrystal growth and surface modification. By controlling the individual steps involved in this process, such as nanowire growth, surface modification, thermal diffusion, and dealloying, one-dimensional (1-D) Ag–Au alloy nanoporous nanotubes (NPNTs) could be prepared with tailored structural features and predesigned functionalities. Figure 21.14a schematically shows the

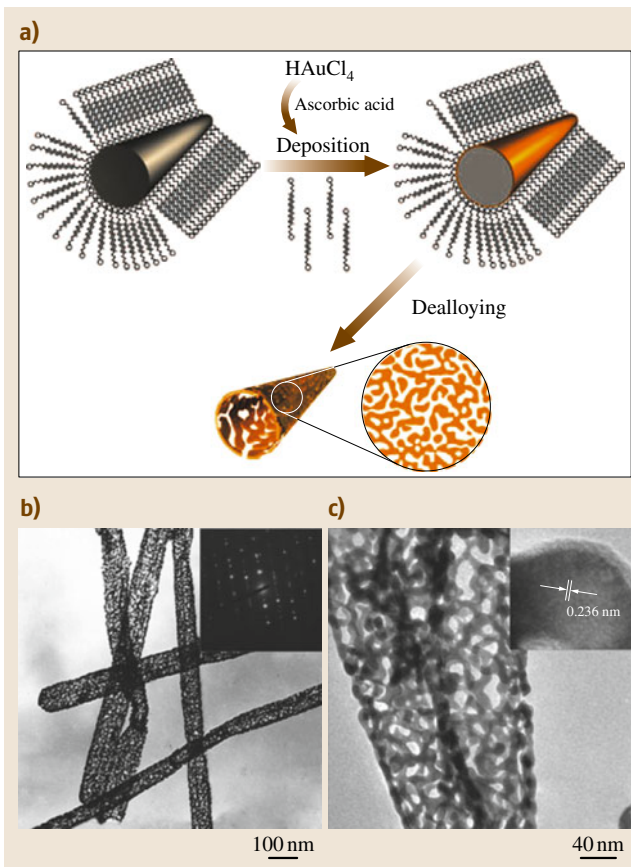

Fig. 21.14 (a) Schematic illustration of the synthesis process of Au–Ag alloy NPNTs. (b–c) TEM images of Au–Ag alloy NPNTs (after [21.112])

synthesis process of Au-Ag alloy NPNTs, and the corresponding microstructures are presented in Fig. 21.14b,c.

We have found that high-surface-area Ag nanostructures can be used as novel effective template materials for construction of nanotubular mesoporous Pt/Ag and Pd/Ag alloy structures (Fig. 21.15), which are realized via room-temperature galvanic replacement reactions with H_2PtCl_6 and K_2PdCl_4 solutions by adding a high concentration of Cl^- ions as a coordinating agent [21.115]. Moreover, electrochemical measurements indicate that the resulting hollow and porous bimetallic nanostructures show enhanced electrocatalytic activities and CO tolerance with better durability toward methanol and formic acid oxidation due to alloying with Ag.

Due to the difference in dealloying between individual phases, a two-phase alloy can be dealloyed to form nanoporous metal composites. Nanoporous gold composites (NPGCs) can be produced through chemical dealloying of two-phase Al-Au alloys comprising Al_2Au and AlAu intermetallic compounds under free

corrosion conditions [21.69]. The dealloying of Al_2Au and AlAu proceeds separately, resulting in the formation of the NPGCs. The microstructures of the NPGCs are composed of intracellular and intercellular areas which exhibit two kinds of nanoporous structures with different length scales of ligaments/channels. The nanoporous structure of the intracellular areas forms due to the dealloying of Al_2Au , while that of the intercellular areas forms owing to the dealloying of AlAu . Moreover, the proportion of the intercellular areas in the NPGCs increases with increasing Au content in the starting Al-Au alloys. Nanoporous palladium composites with second-phase embeddings can be fabricated through chemical dealloying of a rapidly solidified $\text{Al}_{70}\text{Pd}_{30}$ alloy in alkaline or acidic solutions under free corrosion conditions [21.116]. The experimental results show that the precursor alloy is composed of Al_3Pd and Al_3Pd_2 intermetallic compounds, and the resultant composites comprise the nanoporous palladium matrix dealloyed from Al_3Pd and the undealloyed Al_3Pd_2 embeddings.

In addition, bulk nanoporous Cu ribbons, rods, and slices (of centimeter scale) can be fabricated by dealloying of Al-Cu alloys under free corrosion conditions (Fig. 21.16) [21.117]. These nanoporous Cu ribbons and bulk rods/slices can serve as model materials to investigate the mechanical, physical (for example, electrical resistivity), and chemical properties associated with the random porous structure of nanoporous solids.

21.2.2 Catalytic Properties

Due to their very high specific surface area and nano-sized ligaments, nanoporous metals show excellent catalytic properties for a series of important heterogeneous reactions.

Despite the general inertness of gold, finely dispersed gold nanoparticles on suitable oxide supports can

demonstrate remarkable catalytic activity for propene epoxidation or CO oxidation. Gold-based catalysts have potential applications in automotive emission control, because unlike platinum or palladium catalysts, they remain active at low temperatures (room temperature). Zielasek et al. [21.119] first pointed out that nanoporous gold is a promising material for catalytic applications, because it is self-supporting, thermally and mechanically stable, and shapeable; as a thin foil it could possibly find use as a membrane catalyst. Almost at the same time, Xu et al. reported that unsupported nanoporous gold could show extraordinary properties in low-temperature CO oxidation (-30°C) [21.118]. Figure 21.17 shows the catalytic performance of a-NPG at different temperatures. It was believed that the curved shape of the ligaments could accommodate a high density of low-coordinated surface sites, such as step and kink atoms, which are responsible for the observed catalytic activity. More detailed studies have been carried out on this new catalytic system, including discussion of the active sites of catalysts, the reaction kinetics, and the dependence of the activity on space velocity and temperature [21.120]. The results show strong evidence that metallic gold atoms on NPG are the intrinsic active sites at which the reaction of CO with O_2 occurs. The kinetic study found that the reaction rate of CO oxidation on unsupported NPG depends significantly on the

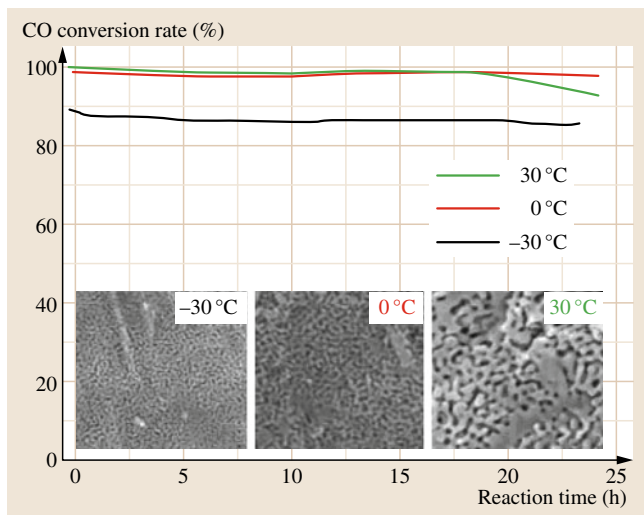

Fig. 21.17 Catalytic performance of a-NPG at different temperatures. In each experiment, 50 mg NPG catalyst and a gas mixture of 1% CO, 10% O_2 , and 89% N_2 were used with flow rate of 66.7 ml/min, corresponding to space velocity of 80 040 ml/h gcat. The turnover frequency (TOF) was measured to be about 0.034 s^{-1} . Insets are SEM images of NPG samples after catalytic reactions. Scale bars: 100 nm (after [21.118]) ◀

CO concentration but only slightly on the O₂ concentration, suggesting that CO adsorption plays a decisive role in CO oxidation on NPG as the rate-limiting step.

Wittstock et al. [21.122] recently reported that nanoporous Au can catalyze selective oxidative coupling of methanol to methyl formate with selectivity above 97% and high turnover frequencies at temperatures below 80 °C. Because the overall catalytic characteristics of nanoporous Au are in agreement with studies on Au single crystals, they deduced that the selective surface chemistry of Au is unaltered but that O₂ can be readily activated with this material. Residual silver is shown to regulate the availability of reactive oxygen.

Recently, Han et al. found that nanoporous gold catalysts made by dealloying could be applied in gas-phase selective oxidation of benzyl alcohol to benzaldehyde, delivering good catalytic activity with high selectivity under ambient reaction conditions (Fig. 21.18) [21.121]. By increasing the concentration of oxygen in the gas mixture, the conversion increased greatly, accompanied by a slight decline in selectivity. By using pure oxygen, over 61% conversion with 95% selectivity was achieved at 240 °C. Interestingly, after the catalysts were pretreated with NaOH, the catalytic activity was promoted considerably. The dependence on residual Ag of the performance of NPG catalysts was tested, and in general, higher Ag content did not seem improve the activity and selectivity of NPG for benzyl alcohol oxidation. However, this study cannot rule out the possibility that low levels of Ag may contribute as a promoter to improve the selectivity.

As to the unsupported nature of NPG, however, there is still controversy. Haruta [21.123] classified the hypotheses for the active states of gold proposed so far as follows, in order of decreasing size of the gold catalyst:

1. Unsupported gold
2. Junction perimeter between gold and the metal-oxide supports
3. Specific size or thickness of gold clusters or thin layers
4. Cationic gold

He argued that gold nanoporous foams, the surfaces of which might be substantially contaminated by Ag₂O fine particles or patches, are highly active at temperatures even below 0 °C without water and OH⁻ ions. Actually, the catalysts can be regarded as inversely supported gold catalysts, and the junction perimeters between gold and Ag₂O can account for the

Fig. 21.18 NPG shows high selectivity and conversion for gas-phase selective oxidation of benzyl alcohol to benzaldehyde (after [21.121])

high catalytic activity, as in the cases of TiO₂, Fe₂O₃, Co₃O₄, NiO, and CeO₂ supports (hypothesis 2). Wittstock et al. [21.124] investigated NPG with respect to its morphology, surface composition, and catalytic properties. In particular, they studied the reaction kinetics for low-temperature CO oxidation in detail, taking the mass transport limitation due to the porous structure of the material into account. Their results revealed that Ag, even if removed almost completely from the bulk, would segregate to the surface, resulting in surface concentrations of up to 10 at. %. While no Ag₂O was observed, they believed that Ag plays a significant role in activating molecular oxygen. Therefore, they thought that NPG should be more appropriately considered as an unsupported bimetallic catalyst rather than a pure Au catalyst.

Most recently, Moskaleva et al. [21.125] investigated the catalytic properties of nanoporous gold foams via CO and oxygen adsorption/coadsorption. They analyzed experimental results using theoretical models representing flat Au(111) and kinked Au(321) slabs with Ag impurities. Their results show that Ag atoms incorporated into gold surfaces can facilitate the adsorption and dissociation of molecular oxygen on them. CO adsorbed on top of six-fold-coordinated Au atoms can in turn be stabilized by coadsorbed atomic oxygen by up to 0.2 eV with respect to the clean, unsubstituted gold surface. These experiments suggest a link between the most strongly bound CO adsorption state and the catalytic activity of np-Au. Thus, they believed that their results shed light on the role of silver admixtures in the striking catalytic activity of unsupported gold nanostructures.

NPG catalysts made by dealloying Ag/Au alloys were found to be novel unsupported Au nanocatalysts that exhibited effective catalytic activity and high selectivity ($\approx 99\%$) for aerobic oxidation of D-glucose to D-gluconic acid under mild conditions [21.126]. The activity dependence as functions of pH value, temperature, NPG ligament size, reaction active sites, and reaction kinetics was discussed in great detail. The pos-

Fig. 21.19 Schematic illustration of a possible mechanism for methanol photoelectrocatalysis on the TiO_2/NPG electrode under UV illumination (after [21.127])

sible contribution from the residual Ag atoms trapped in the **NPG** ligaments was also discussed, which turned out to be unfavorable for glucose oxidation. The unexpected observation of catalytic activity of **NPG** with ligament size as large as 60 nm indicated that low-coordinated surface Au atoms should be the reaction active sites for glucose oxidation.

Recently, *Jia et al.* found that commercial TiO_2 nanoparticles can be assembled on the surface of **NPG** to fabricate novel TiO_2/NPG nanocomposite electrodes [21.127]. Large photocurrent and nearly reversible voltammetric responses were observed for methanol photoelectrocatalysis under ultraviolet (UV) radiation, indicating effective elimination of gold surface passivation due to a pronounced synergistic effect between TiO_2 and **NPG**. A possible mechanism was proposed to elucidate such a synergistic effect, based on the reaction of photogenerated reactive intermediates on the surface of **NPG** (Fig. 21.19). Kinetic studies showed that the coupling of TiO_2 with **NPG** in the system could lead to about a 30% decrease of apparent activation energy for methanol electrooxidation. In addition, porous AgCl/Ag nanocomposites show enhanced visible-light photocatalytic properties for degradation of methyl orange (MO) dye [21.128].

Asao et al. [21.129] recently discovered that nanoporous gold exhibited remarkable catalytic activity for oxidation of organosilane compounds with water. The catalyst was easily recoverable and could be used at least five times without leaching or loss of activity. The observed excellent durability of the catalyst was also confirmed by SEM images. Indeed, the nanoporous structure of the catalyst did not change, even after five uses for oxidation of dimethylphenylsilane.

21.2.3 Electrocatalytic Properties

Nanoporous metals represent a new class of high-surface-area nanostructures, where the interconnected interstices and channels extending in all three dimensions allow unblocked transport of medium molecules and electrons, which is particularly desirable for catalysis. In addition, made by dealloying in aqueous solutions, nanoporous metals have extremely clean surfaces, readily available for surface electrode reactions. Being support free and particle free, nanoporous metals completely eliminate the support corrosion problem and particle aggregation/sintering problem. It is thus interesting to explore their electrocatalytic performance by evaluating their potential in important energy con-

version applications, such as as anode catalysts in fuel cell technology.

NPG made by dealloying Au-Ag has been investigated as a novel electrode material for methanol electrooxidation [21.130]. Compared with bulk Au electrode, oxidation and subsequent reduction of **NPG** occur at significantly negative potentials in both acid and alkaline solutions. **NPG** shows great catalytic activity for methanol electrooxidation, but the structure quickly coarsens upon long-time potential cycling. Interestingly, after surface modification with only a tiny amount of platinum, **NPG** exhibits greatly enhanced electrocatalytic activity toward methanol oxidation in alkaline solution, which is exemplified by a broad and high anodic peak during the positive scan and two secondary oxidation peaks in the subsequent reverse scan. At the same time, **SEM** observation and long-time potential cycling both prove that Pt-**NPG** has greatly enhanced structure stability as compared with bare **NPG**. Yu et al. [21.131] also reported that self-supported nanoporous gold film electrodes show high catalytic activity and stability in direct electrooxidation of methanol.

Ge et al. investigated an ultralow-platinum-loading electrocatalyst based on a novel nanoporous membrane metal (**NPG** leaf), and its excellent performance toward methanol and **CO** electrooxidation [21.132]. Although it is widely accepted that the highest Pt utilization can be achieved only on monolayer (or submonolayer) type structures, to which these **NPG**-based nanostructures are close, the most important characteristic of Pt-**NPG**-type structures is the easy accessibility to almost all surface precious atoms by target molecules, which the current fabrication protocol based on physical mixing of nanoparticles can hardly achieve. This can explain why 0.5 min Pt-**NPG** samples exhibit much better performance than commercial Pt/C, although they have similar platinum utilization values. Considering the structure flexibility of **NPG** and the strong synergistic effect between Pt and Au, Pt-**NPG** may represent an alternative ultralow precious-metal loading catalyst to traditional ones with promising performance in important green energy technologies, such as direct methanol fuel cells (**DMFC**). Furthermore, by effectively enhancing the Pt utilization and providing a unique surface structure, electrooxidation of formic acid on Pt-**NPG** was found to be highly sensitive to its surface structure [21.133]. An unparalleled increase by nearly two orders of magnitude in catalytic activity was achieved on **NPG** electrodes decorated with submonolayer Pt atoms, as compared with commer-

cial Pt/C catalyst under the same testing conditions. Figure 21.20 shows the catalytic activity of Pt-**NPG** membrane catalysts towards electrooxidation of small organic molecules. Through a simple immersion-electrodeposition (**IE**) method, a tiny amount of Pt can be deposited in quasi-two-dimensional form onto the **NPG** substrate, forming nanostructured bimetallic Pt-Au catalysts [21.134]. Such Pt-Au nanostructures have much higher structural stability than the bare **NPG**. Moreover, they exhibit better catalytic activity and stronger poison resistance than commercial Pt-Ru catalysts because of the synergistic effect of the bimetallic composition.

Ultrathin Pt films from one to several atomic layers can be decorated onto **NPG** membranes by utilizing **UPD** of Cu onto Au or Pt surfaces, followed by in situ redox replacement reaction (**RRR**) of **UPD** Cu by Pt [21.135]. The thickness of Pt layers can be controlled precisely by repeating the Cu-**UPD**-**RRR** cycles. **TEM** observations coupled with electrochemical testing suggest that the morphology of the Pt overlayers changes from an ultrathin epitaxial film in the case of one or two atomic layers to well-dispersed nanoislands in the case of four and more atomic layers. Moreover, the as-prepared **NPG**-Pt membranes maintain a single-crystalline structure, even though the thickness of the Pt films reaches six atomic layers, indicating that the decorated Pt films retain the same crystallographic relationship to the **NPG** substrate during the entire fabrication process. Due to the regular modulation of Pt utilization, the electrocatalytic activity of **NPG**-Pt exhibits interesting surface structure dependence in methanol, ethanol, and **CO** electrooxidation reactions (Fig. 21.21). These novel bimetallic nanocatalysts show excellent electrocatalytic activity and greatly enhanced poison tolerance as compared with commercial Pt/C catalysts.

Recently, Wang et al. successfully fabricated a new type of sandwich-type nanostructured electrocatalyst, **NPG**-Pt-Au, that simultaneously fulfills three key requirements as a good practical formic acid electrooxidation catalyst: ultralow Pt loading, great tolerance to poisoning, and high stability (Fig. 21.22) [21.136]. Time-resolved surface-enhanced infrared absorption (**SEIRA**) spectroscopy demonstrated that the greatly enhanced catalytic activity was achieved by changing the reaction pathways by using Au surface clusters, which also contribute to the stabilization of the catalyst. Considering that it is possible to tailor the respective structures and compositions within each structure unit, this work represents a general design strategy to

Fig. 21.20a–c Cyclic voltammetry (CV) curves for Pt-NPG samples in (a) 0.1 M HClO₄ + 0.1 M HCOOH, (b) 0.1 M HClO₄ + 0.1 M HCHO, and (c) 0.1 M HClO₄ + 0.1 M CH₃CH₂OH (MSE = mercury/mercurous sulfate electrode) (after [21.133]) ◀

functional nanocatalysts that shows great potential for various energy and environmental applications.

It is known that monometallic Pt is susceptible to deactivation or poisoning during catalytic and electrocatalytic processes; for example, Pt catalysts can be deactivated due to carbon deposition or coking in many heterogeneous catalytic reactions, and can also be poisoned by CO adsorption due to the strong bonding of CO on the Pt surface. Adding a second metallic component can enhance the activity, selectivity, and stability of pure metal catalysts. It has been reported that formation of bimetallic alloy nanostructures with other metals, such as Ru, Ag, and Au, can reduce CO poisoning. Nanoporous Au-Pt and Pt-Ru alloys with predetermined compositions can be fabricated through selective etching of Cu and Al from CuAuPt and PtRuAl precursors [21.98, 137]. Moreover, these high-surface-area alloy nanostructures show greatly enhanced specific activity and distinct surface reactivity toward electrooxidation of some small organic molecules, such as methanol and formic acid. The interaction between constituent metal elements may lead to special surface ensembles with unique structural properties, which can exhibit strong synergistic effects with greatly enhanced catalytic activities under appropriate conditions.

In addition, dealloying has been found to be an effective route to enhance the electrocatalytic properties of some other nanostructures, such as core-shell nanoparticles, nanowires, etc. Shao et al. [21.138] reported synthesis of a core-shell catalyst consisting of a Pt monolayer as the shell and porous/hollow Pd-Cu alloy nanoparticles as the core. The porous/hollow Pd-Cu nanoparticles were fabricated by selectively dissolving a less noble metal, Cu, using an electrochemical dealloying process. The Pt mass activity for the oxygen reduction reaction (ORR) of a Pt monolayer deposited on such a porous core is 3.5 times higher than that of a Pt monolayer deposited on bulk Pd nanoparticles and 14 times higher than that of state-of-the-art Pt/C electrocatalysts. Strasser's group found that voltammetric dealloying of bimetallic platinum-copper (Pt-Cu) alloys is an effective strategy to modify the surface electrocatalytic reactivity of Pt bimetallic nanoparticles [21.139–

141]. The dealloyed active catalyst phase consists of a core-shell structure in which a multilayer Pt-rich shell surrounds a Pt-poor alloy particle core. The electrocatalytic Pt mass activity of the dealloyed core-shell particles for the ORR exceeds that of state-of-the-art Pt electrocatalyst by more than a factor of 4 and thus meets performance targets for fuel cell cathodes [21.142]. Liu et al. [21.143–145] fabricated nanoporous Pt-Co, Pt-Ni, and Pt-based multimetallic alloy nanowires through the combination of electrodeposition into AAO templates with dealloying. These nanoporous alloy nanowires exhibit distinctly enhanced electrocatalytic activities toward methanol oxidation as compared with current state-of-the-art Pt/C and PtCo/C catalysts.

The improvement of catalysts for the four-electron ORR ($\text{O}_2 + 4\text{H}^+ + 4\text{e}^- \rightarrow 2\text{H}_2\text{O}$) remains a critical challenge for fuel cells and other electrochemical energy technologies. Recently, Snyder et al. [21.146] showed that a tailored geometric and chemical materials architecture can further improve ORR catalysis by demonstrating that a composite nanoporous Ni-Pt alloy impregnated with a hydrophobic, high-oxygen-solubility, protic ionic liquid has extremely high mass activity (Fig. 21.23). They stated that the results are consistent with an engineered chemical bias within a catalytically active nanoporous framework that pushes the ORR towards completion.

21.2.4 Mechanical Properties

Mechanical breakdown or fracture in random porous media has been the subject of considerable computational and theoretical research [21.147]. Nanoporous metals should serve as a new model system for studying various physical properties and mechanical properties associated with three-dimensional random porous structures.

It should be noted that in network systems the terms “ductile” and “brittle” refer to the nature of the damage introduced into the sample during the fracture process. If many separated or distributed microcracks develop in the sample during fracture, the behavior of the system is termed *ductile*, and if only a few cracks form in the sample prior to failure, it is characterized as *brittle*. Li and Sieradzki [21.148] first observed a microstructural length scale-controlled ductile–brittle transition in NPG, similar to previous results for a network system described by Kahng et al. [21.149]. The sample-size-driven ductile–brittle transition may be quite universal with respect to the exact nature of the constitutive behavior of the individual ligaments in the random

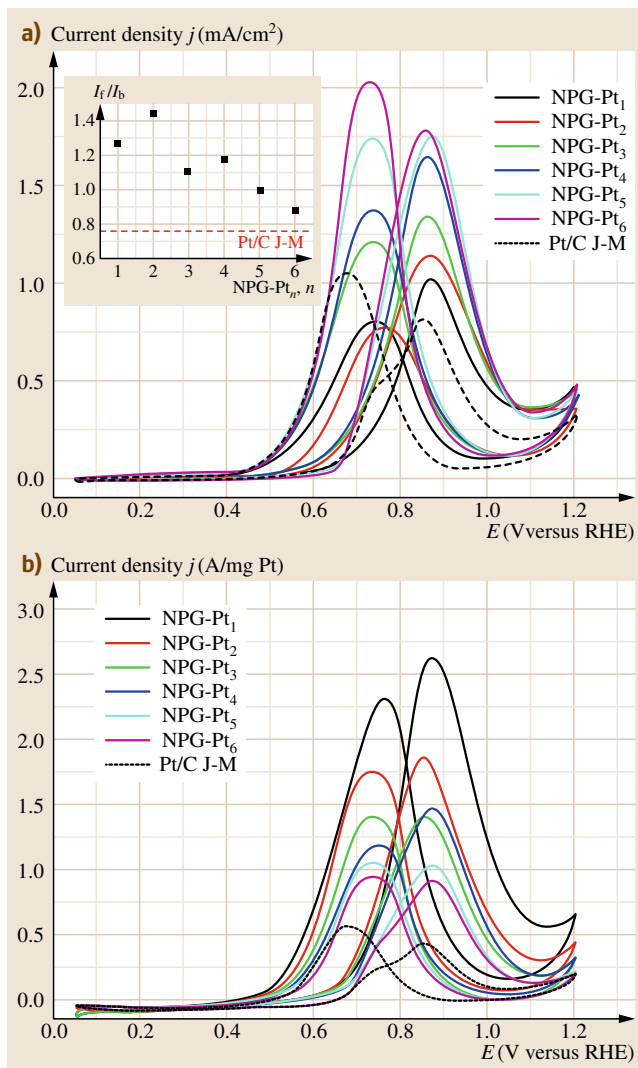

Fig. 21.21a,b ECSA (a) and mass (b) normalized CVs of NPG-Pt_n for methanol electrooxidation in 0.5 M H₂SO₄ + 1.0 M CH₃OH. CV curve (dotted black line) for a commercial Pt/C catalyst (Johnson Matthey, 20 wt %) is also included for comparison. The inset in part (a) shows the I_f/I_b values of NPG-Pt_n along with that for the commercial Pt/C catalyst (red line). Scan rate: 20 mV/s (RHE = reversible hydrogen electrode) (after [21.135])

structure. Thus, the strong length scale dependence of the mechanical behavior of NPG makes it a particularly useful material to study nanoscale mechanics.

The question still remains whether the brittle nature of nanoporous Au is caused by intrinsic brittleness of Au ligaments on the nanometer length scale or is

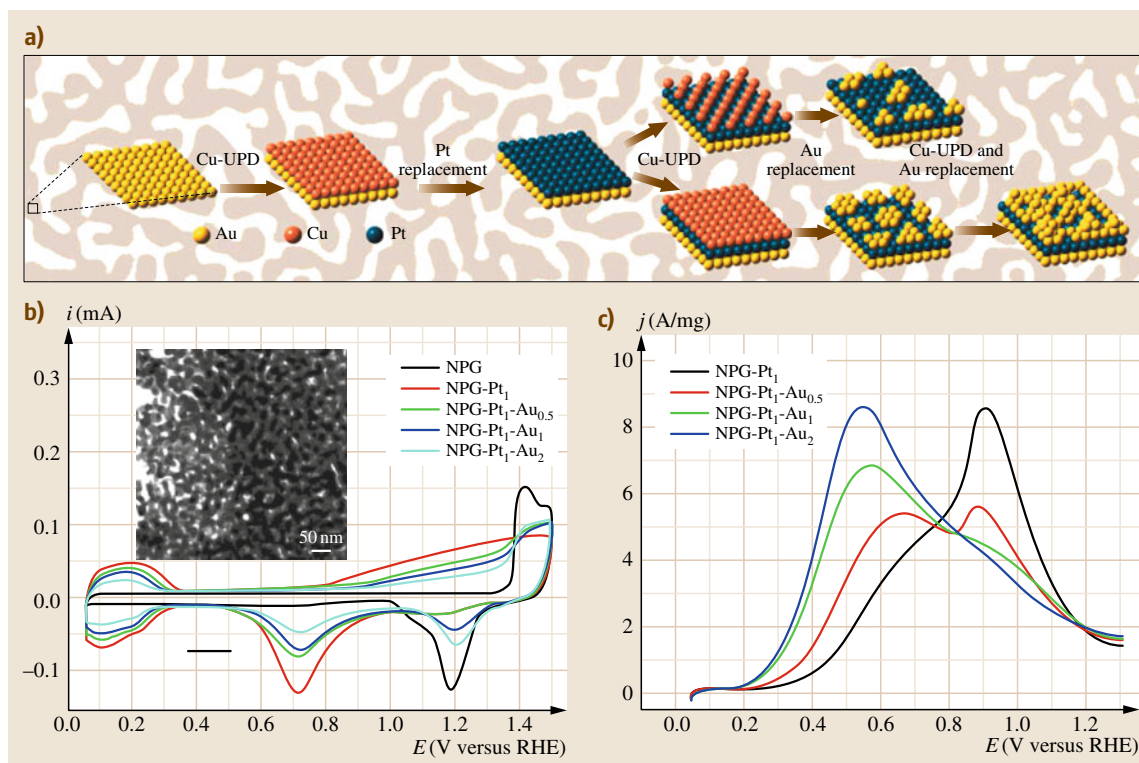

Fig. 21.22 (a) Schematic illustration of the fabrication procedure of NPG-Pt₁-Au_x catalysts. (b) Electrochemical CV for NPG-Pt₁-Au_x catalysts in 0.5 M H₂SO₄ (RHE, reversible hydrogen electrode). Inset: TEM image of NPG. (c) Mass-specific forward CV segments of NPG-Pt₁-Au_x catalysts in 0.1 M HClO₄ and 0.05 M HCOOH (after [21.136])

a consequence of the macroscopic structure. Biener et al. [21.150] reported on the fracture behavior of NPG with an open sponge-like morphology of interconnecting ligaments on the nanometer length scale. Despite its macroscopic brittleness, NPG is microscopically a very ductile material, as ligaments strained by as much as

Fig. 21.23 Potentiostatic ORR curves and half-wave as a function of roughness factor. np-NiPt (red) and np-NiPt + [MTBD][beti] (blue) electrodes in O₂-saturated 0.1 M HClO₄ at 25 °C ($R_f = 143$ for all electrodes) with disc electrode rotation rate of 1600 rpm. Potentiostatic current measures were made at the indicated potential values (circles). Inset: Half-wave potential for both np-NiPt and composite np-NiPt + [MTBD][beti] as a function of H_{UPD} surface area, dealloyed depth, and roughness factor (R_f) (RHE = reversible hydrogen electrode; [MTBD][beti] = [7-methyl-1,5,7-triazabicyclo[4.4.0]dec-5-ene][bis(perfluoroethylsulfonyl)imide]) (after [21.146])

200% can be observed in the vicinity of crack tips. Cell-size effects on the microscopic failure mechanism were studied by annealing treatments that increased the typical pore size/ligament diameter from 100 nm to 1 μm . Ligaments with diameter of 100 nm fail by plastic flow and necking, whereas failure by slip was observed for larger ligaments with diameter of 1 μm . The absence of slip marks in 100 nm-sized ligaments suggests strongly suppressed dislocation activity, consistent with the high yield strength of NPG. They also investigated the plastic deformation of NPG under compressive stress by depth-sensing *nanoindentation* [21.151]. Mean hardness of 145 ± 11 MPa was reported for the investigated NPG with a length scale of 100 nm, which is 10 times higher than the hardness predicted by scaling laws of open-cell foams. *Volkert et al.* [21.152] investigated the mechanical properties of NPG by uniaxial compression. Micrometer-sized columns were machined in the surface of NPG using a focused Ga^+ beam and compressed with a flat punch in a nanoindenter. Using scaling laws for foams, the yield strength of the 15 nm-diameter ligaments was estimated to be 1.5 GPa, close to the theoretical strength of Au. This value agrees well with extrapolations of the yield strength of submicron, fully dense gold columns and shows that, in addition to foam density and structure, the absolute size of ligaments and cell walls can be used to tailor foam properties. *Hodge et al.* [21.153] systematically investigated the mechanical properties of NPG with a wide range of ligament sizes and densities, and concluded that (a) NPG has a fracture behavior dictated by the ligament size, and (b) NPG is a high-yield-strength material.

Biener et al. [21.155] further demonstrated that nanoporous metals can be envisioned as a three-dimensional network of ultrahigh-strength nanowires, thus bringing together two seemingly conflicting properties: high strength and high porosity. They characterized the size-dependent mechanical properties of NPG using a combination of nanoindentation, column microcompression, and molecular dynamics simulations. They found that NPG can be as strong as bulk Au, despite being a highly porous material, and that the ligaments in NPG approach the theoretical yield strength of Au. *Mathur and Erlebacher* [21.156] determined the Young's modulus of NPG with controlled porosity variation between 3 and 40 nm by mechanical testing of ≈ 100 nm-thick, free-standing, large-grained, stress-free films of NPG using a buckling-based method. Their results show a dramatic rise in the effective Young's modulus of NPG with decreasing ligament size, especially below 10 nm. *Hodge et al.* [21.154]

Fig. 21.24 Relationship of ligament size to ligament yield stress for nanoporous gold obtained by nanoindentation and by column microcompression testing (after [21.154])

performed depth-sensing nanoindentation tests on NPG ranging from 20% to 42% relative density with ligament sizes ranging from 10 to 900 nm. The Gibson and Ashby yield strength equation for open-cell macrocellular foams was modified to incorporate ligament size effects. Their study demonstrated that, at the nanoscale, foam strength is governed by ligament size, in addition to relative density (Fig. 21.24). Furthermore, the ligament length scale was presented as a new parameter to tailor foam properties and achieve high strength at low densities. Later, *Hodge et al.* [21.157] studied the effect of Ag and the relative density on the elastic properties of NPG by depth-sensing nanoindentation. It was observed that the effect of the relative density on the elastic properties of NPG seems to be much stronger than predicted by the Gibson and Ashby relationship. Even Ag contents as low as 1 at. % can significantly change the modulus values. On the other hand, the elastic modulus of NPG seems to be independent of the ligament size.

Lee et al. [21.158] fabricated a free-standing dog-bone-shaped specimen with a gage section 7 μm long, 300 nm wide, and 100 nm thick, from NPG by dealloying *white gold* leaf ($\text{Au}_{37.4}\text{Ag}_{62.6}$ in [at. %]). The elastic modulus, residual stress, and yield stress were measured by deflective tensile testing and nanoindentation to be about 9 GPa, 65 MPa, and 110 MPa, respectively.

According to scaling laws, they further determined the yield stress within an individual ligament to be as high as 1.45 GPa, which approaches the theoretical shear strength of the material at which adjacent atomic planes slide past one another without the mediating influence of dislocations [21.159].

Seker et al. [21.160] investigated the effects of postfabrication annealing on the mechanical properties of free-standing nanoporous gold structures. Mechanical properties were measured using combinations of free-standing beam deflection, wafer curvature, and nanoindentation. The relative density of all sample geometries increased as the annealing temperature was increased. However, the evolution of the average pore size (with annealing) depended on the geometry, and hence on the boundary conditions, of the specimen. Differences in porosity evolution were reflected in the mechanical property measurements: while the elastic modulus and residual stress generally increased with increasing annealing temperature (due to densification), pore coalescence in films on substrates led to the most dramatic changes. Later, *Seker et al.* [21.161] studied the effects of annealing prior to dealloying on the mechanical properties of nanoporous gold microbeams. Normally, free-standing nanoporous gold beams fracture during dealloying owing to volume shrinkage. They found that annealing after release, yet prior to dealloying, prevents failure during the selective dissolution step. Experiments in which annealing was performed at temperatures $< 400^\circ\text{C}$ illustrate that permanent buckling of the free-standing solid alloy beams is required to prevent failure of the nanoporous beams during dealloying. In contrast, annealing of beams prior to release, or annealing temperatures $< 200^\circ\text{C}$ (which do not cause permanent buckling deformation), do not mitigate dealloying failures.

Jin et al. [21.162] recently reported on the fabrication and mechanical behavior of macroscopic, crack-free nanoporous gold samples which exhibit excellent ductility in compression tests. Their yield stress is significantly lower than that expected based on scaling laws or on previous nanoindentation experiments. Electron backscatter diffraction imaging reveals a polycrystalline microstructure with grains larger than $10\mu\text{m}$, which acquire a subdomain structure during plastic flow but remain otherwise intact. They highlighted the action of lattice dislocations which can travel over distances much larger than the ligament size. This results in collective deformation of the many ligaments in each grain. Remarkably, the dislocation cores are partly located in the pore channels. Their results suggest

a critical view of the conversion between indentation hardness and yield stress in previous work.

The selection of a structural material requires a compromise between strength and ductility. Materials design strategies that allow for recoverable tuning of the mechanical properties would thus be desirable, either in response to external control signals or in the form of spontaneous adaptation, for instance, in self-healing. Most recently, *Jin and Weissmüller* [21.163] designed a material that has a hybrid nanostructure consisting of a strong metal backbone that is interpenetrated by an electrolyte as the second component. By polarizing the internal interface via an applied electric potential, they accomplished fast and repeatable tuning of yield strength, flow stress, and ductility (Fig. 21.25). Their results thus allow the user to select, for instance, a soft and ductile state for processing and a high-strength state for service as a structural material.

21.2.5 Optical Properties

Maaroof et al. [21.164] used ellipsometry and spectrophotometry to study the optical properties of mesoporous gold films obtained by dealloying of Al_2Au precursor. The complex refractive indices of the optically equivalent uniform smooth layer satisfy Kramers–Kronig (KK) self-consistency but have unusual dispersion relations and magnitudes for a film containing the amount of noble metal present. Mesoporous gold films exhibit unique dispersion in their optical response across all near-infrared (NIR) wavelengths. The effective optical constants as a function of wavelength, which are physically acceptable from a dispersion viewpoint, are neither metal nor insulator like. This is in effect a quite new class of optical material.

Later, *Maaroof et al.* [21.165] investigated and modeled the far-field plasmonic behavior of nanoporous gold films with void densities ranging from 60% to 90%. These layers have good direct-current (DC) conductivity and quite different nanostructure from traditional porous layers in which the metal percolates. Gold films with void density f above 70% have high thermal emittance for a conductor of their thicknesses, and their flat spectral response at visible and near-infrared wavelengths is not metal like. They derived effective optical constants which become plasmonic at wavelengths between 1.8 and $4\mu\text{m}$ for f from 72% to 87%. This onset is much longer than that in bulk gold. For void densities below 70%, the onset of plasmonic behavior is much closer to the dense material. A test was implemented for surface plasmon polaritons (SPPs)

Fig. 21.25a,b Potential dependence of strength and flow stress of NPG. **(a)** Compressive stress–strain curves of engineering stress σ , versus engineering strain ϵ , measured in situ at constant potentials. Ligament surface is covered with submonolayer-thick oxygen when $E = 1.48$ V and is clean when potential is held at 1.03 V. The inset is a photograph of NPG samples with clean surface before and after compression. **(b)** Responses of plastic flow (red) to potential jumps. Data obtained at constant potential of 1.03 V (gray) were plotted for comparison (SHE = standard hydrogen electrode) (after [21.163])

under illumination. The more porous films show no evidence of SPP, while the less porous films display weak evidence. Thus, by tailoring the void content in these nanostructures, one can tailor the onset of effective plasmonic response across a wide range from 0.8 to 4 μm and emittance from around 0.9 down to low values. An effective uniform metal response was thus found in the presence of surface nanostructure without the interface absorption found in dense gold layers with structured surfaces.

Materials multifunctionality for optical sensing of adsorbates has obvious advantages: in addition to the potential for greater sensitivity, the different length scales associated with a variety of optical phenomena allow a greater variety of adsorption characteristics to be examined. Yu et al. [21.166] demonstrated that ultrathin (100 nm) nanoporous gold membranes possess features of both planar metal films that exhibit propagating surface plasmon resonance (SPR) excitations and nanofeatured metals that exhibit localized SPR excitations. They gave illustrative examples of using this material to probe biorecognition reactions and to probe the structure evolution of layer-by-layer deposition of charged dendrimers. Their results are consistent with the very different lengths of the tail of the

evanescent field decays associated with each of these plasmon excitation modes. Later, they quantified the plasmonic properties of NPG through direct comparison with thermally evaporated gold (EG) films [21.167]. Cyclic voltammetry and electrochemical impedance spectroscopy experiments reveal that the NPG films have 4–8.5 times more accessible surface area than EG films. Assemblies of streptavidin–latex beads generate p-SPR responses on both NPG and EG films that correlate well with the bead density obtained from SEM images. A layer-by-layer assembly experiment on NPG involving biotinylated anti-avidin IgG and avidin, studied by l-SPR and SEM, showed that the l-SPR signal is directly linked to the accessibility of the interior of the NPG porosity.

Tuning of the localized surface plasmon resonance (l-SPR) of nanoporous metals lies at the heart of manipulating light within extremely small volumes for the implementation of optical devices at the nanoscale. Qian et al. [21.168] deposited amorphous alumina on chemically etched nanoporous gold films using atomic layer deposition at room temperature. Nanoporous gold with ultrafine pores of 7 nm diameter was uniformly coated with alumina film as thin as 1.4 nm. l-SPR of the gold skeleton exhibits a detectable red-shift

Fig. 21.26 (a) Transmittance spectra of nanoporous gold and nanoporous gold–alumina film with different shell thicknesses. The transmittance spectrum of 100 nm-thick gold film without pores is plotted for comparison. (b) Fitted spectrum of nanoporous gold indicates two isolated bands at 492 and 537 nm (after [21.169])

in the optical transmittance spectra, the magnitude of which depends on the thickness of the alumina layer. They further investigated the optical properties of nanoporous gold–alumina core–shell films with fixed gold skeletons and different thicknesses of alumina shells [21.169]. Optical transmission of the nanoporous composite films can be tailored through I-SPR excitations of the three-dimensional gold skeleton and the alterable alumina shells as the covering dielectric. A 92 nm red-shift of the I-SPR band is attained via its dielectric medium dependence and the comparable decay length with pore size (Fig. 21.26). The widely tunable optical transmission and significantly improved stability thus suggest incorporating nanoporous gold–alumina into promising nanodevices with reliable performance. Low-temperature surface decoration ($< 100^\circ\text{C}$) provides a universal route to tune the optical properties while retaining the spatial geometry of the metallic nanostructures.

Surface-enhanced Raman scattering (SERS) originates from the improved inelastic scattering of molecules adsorbed on nanostructured metals and alloys. The SERS enhancements generally depend on the nanoscale characteristics of the metallic substrates, such as surface morphology, size, and aggregation state of nanoparticles. Nanoporous gold with excellent thermal stability and chemical inactivity has recently been exploited as an attractive substrate for SERS

applications because of its large surface area and bicontinuous porous structure in three dimensions. Kucheyev et al. [21.170] reported that NPG with average pore widths of 250 nm exhibits the largest SERS signal for 632.8 nm excitation. They attributed this to the electromagnetic SERS enhancement mechanism with additional field localization within pores. Dixon et al. [21.171] prepared thin nanoporous gold films, ranging in thickness from 40 to 1600 nm, by selective chemical etching of Ag from Ag/Au alloy films supported on planar substrates. Raman scattering measurements for films functionalized with a self-assembled monolayer formed from 4-fluorobenzenethiol show significant enhancements which vary sharply with film thickness and etching times. The maximum enhancement factors reach $\approx 10^4$ for 632.8 nm excitation, peak sharply in the 200 nm thickness range for films prepared at optimum etching times, and show high spot-to-spot reproducibility with $\approx 1\ \mu\text{m}$ laser spot sizes.

Chen's group at the Tohoku University carried out very systematic studies of the SERS behaviors of nanoporous metals. They found that the high SERS of nanoporous gold actually results from smaller microstructure features, either smaller pore sizes or the rough gold ligament surfaces, which are believed to promote electromagnetic field enhancements and provide more active sites for molecule adsorption. Moreover, the strongest SERS enhancement of nanoporous gold

Fig. 21.27a,b SERS spectra of nanoporous gold with different pore sizes for (a) 10^{-7} mol/l R6G aqueous solution and (b) 10^{-5} mol/l CV methanol solution. Laser excitation: 514.5 nm for R6G and 632.8 nm for CV (CV = crystal violet 10B, R6G = rhodamine 6G) (after [21.172])

takes place for samples with ultrafine nanopore size of 5–10 nm (Fig. 21.27) [21.172]. The SERS intensities from the fracture surfaces of nanoporous gold are about one order of magnitude higher than those from the as-prepared samples [21.173]. Microstructural characterization reveals that the fracture surfaces contain numerous sharp protrusions with 5–10 nm apexes, produced by localized plastic deformation of gold ligaments during failure. They also reported a geometric effect on surface-enhanced Raman scattering of nanoporous gold and found that Raman scattering can be improved by tailoring ligament and nanopore ratios [21.174]. They studied SERS of NPG with var-

ious nanopore sizes at temperatures ranging from 80 to 300 K using rhodamine 6G (R6G) as probe molecule. It was found that the SERS intensity dramatically increases as temperature and nanopore size decrease. The improved SERS enhancements result from the combined effects of electron–phonon scattering, the finite ligament size effect, and the electromagnetic coupling between neighboring gold ligaments [21.175]. Moreover, the tunable nanoporosity leads to significant improvements in SERS of nanoporous copper, and peak values of SERS enhancements for both rhodamine 6G and crystal violet 10B (CV) molecules are observed at pore size of 30–50 nm [21.176]. In addition, silver on nanoporous copper core–shell composites also exhibit a dramatically improved SERS effect compared with that of the as-prepared nanoporous copper, and the enhancement factor strongly depends on the reaction time and Ag shell thickness [21.177]. Recently, Qian et al. [21.178] reported giant Raman enhancement on nanoporous gold film by conjugating with nanoparticles for single-molecule detection.

Lang et al. [21.179] reported molecular fluorescence enhancement of free-standing nanoporous gold with tunable nanopore size. They found that the fluorescence intensity of indocyanine green adsorbed on human-serum-albumin-coated nanoporous gold films significantly increases with decreasing nanopore size. The large fluorescence enhancement results from the near-field enhanced excitation and radioactive decay rate of fluorophore due to the strong electromagnetic fields produced by nanosized curvatures as well as the coupling between neighboring gold ligaments. By the combination of dealloying and electroless gold plating, they further tailored molecular fluorescence enhancement of free-standing nanoporous gold [21.180]. The nanoporous gold fabricated by this facile method possesses unique porous structures with large gold ligaments and very small pores, and exhibits significant improvements in surface-enhanced fluorescence as well as structure rigidity.

21.2.6 Sensing and Actuation Properties

Chou et al. [21.181] reported a nonenzymatic sensor using a nanoporous platinum electrode to detect glucose directly. The electrode was fabricated by electrochemical deposition and dissolution of Pt-Zn alloy in zinc chloride-1-ethyl-3-methylimidazolium chloride (ZnCl_2 -EMIC) ionic liquid. Amperometric measurements allowed observation of the electrochemical oxidation of glucose at 0.4 V (versus Ag/AgCl) in pH 7.4

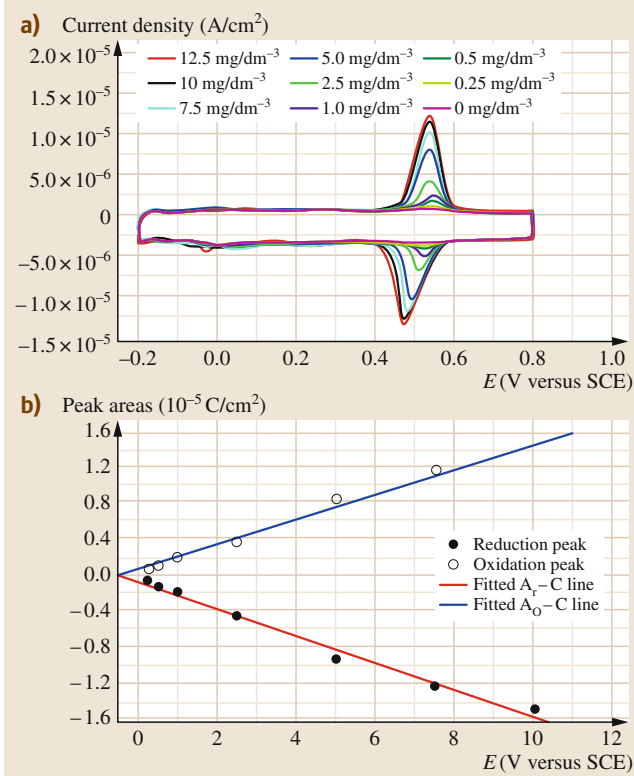

Fig. 21.28 (a) CVs for NPG electrode in 0.1 mol/dm³ H₂SO₄ containing various concentrations of *p*-NP at 50 mV/s. (b) The linear dependence of redox peak areas on *p*-NP concentrations (after [21.182])

phosphate buffer solution. The sensor also demonstrates significant reproducibility in glucose detection; the higher the roughness factor of the Pt electrode, the lower the detection limit of glucose. Interfering species such as ascorbic acid and *p*-acetamidophenol can be avoided by using a Pt electrode with a high roughness factor of 151. Overall, the nanoporous Pt electrode is promising for enzymeless detection of glucose at physiological condition.

Qiu et al. [21.183, 184] have shown that nanoporous metals would be very good supports for immobilization of enzymes such as laccase, horseradish peroxidase (HRP), etc. Laccase was immobilized on the surface of NPG by physical adsorption. Laccase immobilized on NPG (100 nm in thickness) was used for enzyme electrode construction. Direct electrochemistry of laccase on NPG supported by glassy carbon electrode (NPG/GC) was achieved with high efficiency due to the outstanding physicochemical characteristics of the

NPG. HRP can be immobilized on nanoporous copper by adsorption. Compared with free enzyme, the thermal stability of the immobilized enzyme was greatly improved due to the multiple attachments between the enzyme molecule and the nanoporous copper surface. Moreover, the HRP immobilized nanoporous electrode shows excellent sensing properties for electrochemical detection of *O*-phenylenediamine (OPD).

Liu et al. [21.182] used NPG samples as the working electrode to investigate the redox behavior of *p*-nitrophenol (*p*-NP) by cyclic voltammetry (CV). Quite different from the voltammetric behavior of polycrystalline gold electrode, the CV profiles of NPG display a pair of nearly symmetric redox waves which are ascribed to the reaction of the 4-(hydroxy-amino)phenol/4-nitrosophenol couple. They also found that this pair of redox waves are hardly affected by the isomers of *p*-NP; and moreover, their peak areas are linear with the concentration of *p*-NP in the range from 0.25 to 10 mg/dm³ (Fig. 21.28). Because of high sensitivity and good selectivity, NPG is expected to act as a promising electrochemical sensor material for detecting trace *p*-NP in wastewaters.

Most recently, Ge et al. reported that ultrathin free-standing nanoporous gold leaf made by dealloying exhibits excellent electrocatalytic activities toward nitrite oxidation [21.185]. The electrochemical response of nitrite ions on this novel nanoelectrode is found to be independent of pH over a wide range from 4.5 to 8.0, which is markedly different from that of gold oxidation, a process known to be highly pH sensitive. Amperometric study shows a linear relationship for nitrite determination in a concentration range from 1 μM to 1 mM. This nanostructured gold electrode displays good stability, repeatability, and selectivity, suggesting its potential for the development of new electrochemical sensors.

Although actuation in biological systems is exclusively powered by chemical energy, this concept has not been realized in manmade actuator technologies, as these rely on generating heat or electricity first. Biener et al. [21.186] have recently demonstrated that surface-chemistry-driven actuation can be realized in high-surface-area materials such as nanoporous gold. They achieved reversible strain amplitudes of the order of a few tenths of a percent by alternating exposure of nanoporous Au to ozone and carbon monoxide. The effect has been explained by adsorbate-induced changes of the surface stress, and can be used to convert chemical energy directly into a mechanical response, thus opening the door to surface-chemistry-driven actuator and sensor technologies. Jin et al. [21.187] fabricated

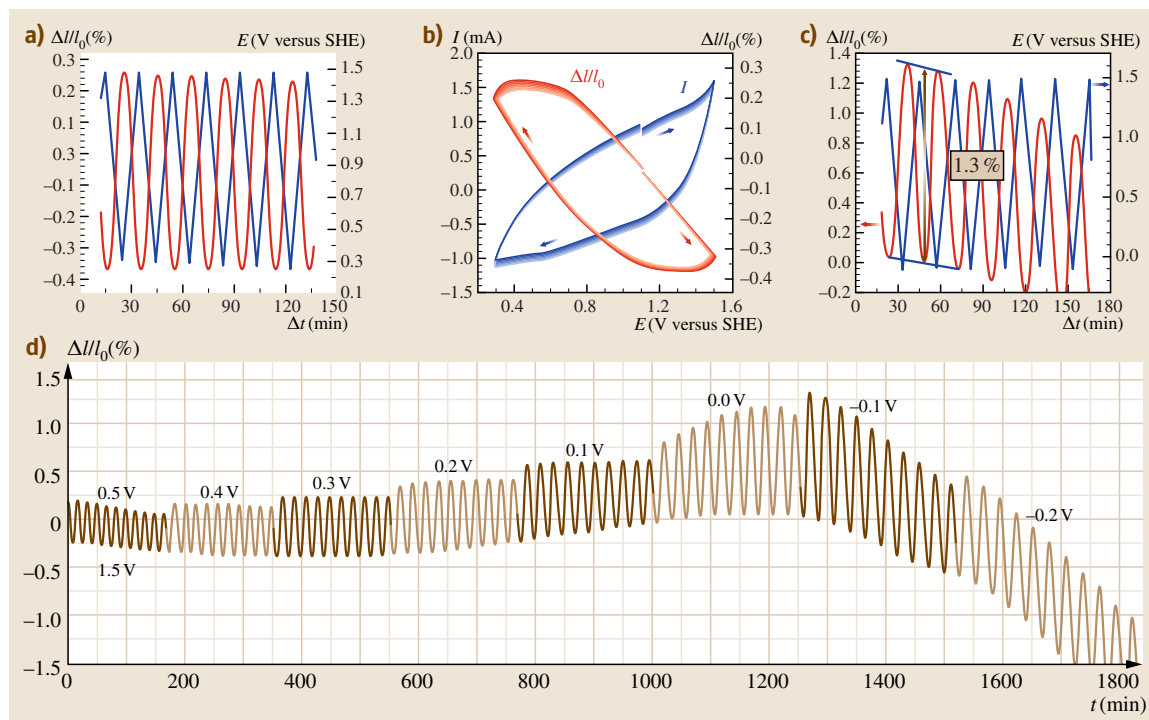

Fig. 21.29a–d Dilatometry experiments on an as-dealloyed nanoporous $\text{Au}_{0.8}\text{Pt}_{0.2}$ sample (with oxygen covered surface), in 0.7 M NaF solution. **(a)** Cyclic length change along with the potential sweep (10 successive scans) between 0.3 and 1.5 V. **(b)** The voltammogram and the reversible strain. **(c)** Cyclic length change along with the potential sweep between -0.1 and 1.5 V, showing largest strain up to 1.3% . **(d)** Cyclic length change during potential sweep. nanoporous Au-Pt alloys with pore and ligament size down to a few nanometers by dealloying Ag-Au-Pt. Owing to the small structure size and large specific surface area, the surface stress and its variation give rise to significant stress and strain in the bulk of these materials. Dilatometry experiments find electrochemical actuation with large reversible strain amplitude (Fig. 21.29). The linear strain reaches $\approx 1.3\%$, and the strain energy density is up to 6.0 MJ/m³. The associated stresses may approach the elastic limit of the alloy. Their results show that nanoporous Au-Pt alloys are potential materials for use in large-strain electrochemical actuators.

21.2.7 Electrical, Thermal, and Magnetic Properties

Mishra et al. [21.188] measured the electrical conductivity of nanoporous gold in situ during charging and

decharging of the surface of the metal. Charge was induced on the surface by making the sample a working electrode in an electrochemical cell. The conductivity was observed to vary reversibly with the induced surface charge. We have shown that the electrical resistivity of the nanoporous metals (Au, Ag, Cu) is one to two orders of magnitude higher than that of their bulk counterparts [21.60]. Fujita et al. [21.189] reported the electric conductivity of three-dimensional (3-D) nanoporous gold at low temperatures and in strong magnetic fields. It was found that topologically disordered 3-D nanoporosity leads to extremely low magnetoresistance and anomalous temperature dependence as the characteristic length of nanoporous gold is tuned to be 14 nm. Their study underscores the importance of the 3-D topology of a nanostructure on the electronic transport properties and has implications for manipulating electron transport by tailoring 3-D nanostructures.

Xia et al. [21.190] measured the thermal and electrical conductivities of nanoporous Au thin foils in the temperature range 93–300 K. Resulting from the nanoscale microstructure, the two types of conductivities are both temperature dependent and significantly lower than those of bulk Au. However, the corresponding Lorenz number is strikingly similar to that of bulk Au, indicating that the Wiedemann–Franz law holds perfectly well for nanoporous metals in this temperature range. Compared with the bulk value, the Debye temperature of nanoporous Au is decreased. The theoretical Debye temperature of nanoporous Au can be predicted by its relation to the elastic constants. The results indicate that the nanoporous Au foils should be comprised of macroscopic, single-crystalline porous grains rather than nanocrystals.

Wahl et al. [21.191] reported that the electrical resistance of nanoporous gold prepared by dealloying can be tuned by charging the surfaces of the porous structure in an electrolyte. Reversible variations in the resistance up to approximately 4% and 43% occur due to charging in the regimes of double-layer charging and specific adsorption, respectively. Charging-induced variations in the electron density or of the volume cannot account for the resistance variation, indicating that this variation is primarily caused by charge-induced modifications of the charge carrier scattering at the solid–electrolyte interface. The relative resistance variation in nanoporous Au with surface charging is found to be much higher than reported for porous nanocrystalline Pt. This is due to the lesser resistance contribution from internal grain boundaries. The resistance variation in nanoporous Au is also higher than that found in thin films owing to

the stronger surface scattering in the ligament structure compared with plane surfaces. They argued that the strong resistance variation of up to 43% in the regime of specific adsorption is due to reversible formation of a chemisorbed surface layer acting as scattering centers for the charge carriers.

Sun et al. [21.59] reported that nanoporous nickel obtained by dealloying electrodeposited $\text{Ni}_x\text{Cu}_{1-x}$ alloys exhibits enhanced coercivity and reduced magnetic anisotropy. Hakamada et al. [21.192] reported that the coercivity of nanoporous Ni decreased with decreasing ligament length in a range below the critical size of about 50 nm. This trend for the nanoporous Ni is the same as those for nanoparticles and nanocrystals. However, the size dependence of coercivity for the nanoporous Ni is lower than those for the other materials. It is suggested that the dimension of the exchange length in the ligament is 1–2 for the nanoporous Ni, resulting in the low size dependence of coercivity. They also fabricated nanoporous Ni specimens with ligament lengths of 10–210 nm and specific surface areas of $0.03\text{--}0.58\text{ nm}^{-2}$ by dealloying of $\text{Ni}_{0.25}\text{Mn}_{0.75}$ alloy and annealing at 473–873 K, and investigated the saturation magnetization in terms of their size dependence [21.193]. Saturation magnetization decreased with decreasing ligament length or increasing specific surface area. This trend is the same as that for Ni nanoparticles. However, the saturation magnetization of nanoporous Ni tends to be lower than that of the Ni nanoparticles when their specific surface areas are the same. It is suggested, therefore, that the surface effect due to a noncollinear arrangement is enhanced by the surface defects in the nanoporous Ni.

21.3 Applications

Due to their unique mechanical, physical, and chemical properties associated with the 3-D bicontinuous interpenetrating ligament–channel structure, nanoporous metals show potential applications in the fields of fuel cells, sensors, actuators, supercapacitors, etc. Here, some examples are briefly summarized.

Increasingly stringent regulations on energy use and environmental protection lead to greater demands to commercialize clean energy-conversion technologies such as polymer electrolyte membrane fuel cells (PEMFCs). Considering that major obstacles remain for hydrogen mass production, storage, and transportation, direct methanol or formic acid fuel cells

(DMFCs, DFAFCs) are gaining increasing attention. Therefore, there is growing interest in fabrication of effective electrocatalysts for formic acid and methanol electrooxidation, which is of great significance for commercialization of PEMFCs. One of the main obstacles to the commercialization of PEMFCs is the high cost of catalyst, which involves excess use of precious Pt. In comparison with nanoparticle catalysts supported on carbon black, platinum-coated NPG membranes simultaneously provide superior catalyst/substrate binding as well as high volume dispersion of catalyst, uniformly distributed through a very thin porous electrode with high in-plane conductivity [21.50]. Because the Pt load-

ing in platinum-plated nanoporous gold leaf (Pt-NPGL) can be controlled down to 0.01 mg/cm^2 using only simple benchtop chemistry, the material holds promise as a low-Pt-loading, carbon-free electrocatalyst [21.194]. Stable and high-performance Pt-NPGL/Nafion membrane electrode assemblies (MEAs) were made using a stamping technique by Zeis and coworkers. The performance of Pt-NPGL MEAs is comparable to conventional carbon-supported nanoparticle-based MEAs with much higher loading, generating output power density of up to 4.5 kW/g Pt in a nonoptimized test configuration. Through the construction of a novel NPG-Pt-Au nanostructure, superior performance of high activity and durability in electrocatalytic oxidation of formic acid was achieved at ultralow Pt loading down to microgram per unit-area scale [21.136]. Ob-

viously, creating precious metal skins over nanoporous metal supports is a viable strategy for designing new catalysts for PEM fuel cells.

Chemisorption from the gas or liquid phase can result in a measurable resistance change in a metallic material when at least one dimension is smaller than the mean free path for electrons. Liu and Searson [21.196] reported on the fabrication of single nanoporous gold nanowires and demonstrated that adsorption of an alkanethiol can be monitored in real time. Single nanowire devices were fabricated by in situ etching of $\text{Au}_{0.18}\text{Ag}_{0.82}$ alloy nanowires in dilute nitric acid. The evolution of the porous structure was characterized by monitoring the resistance change and comparing with cross-sectional images. The feature size of about 10 nm is less than the mean free path for

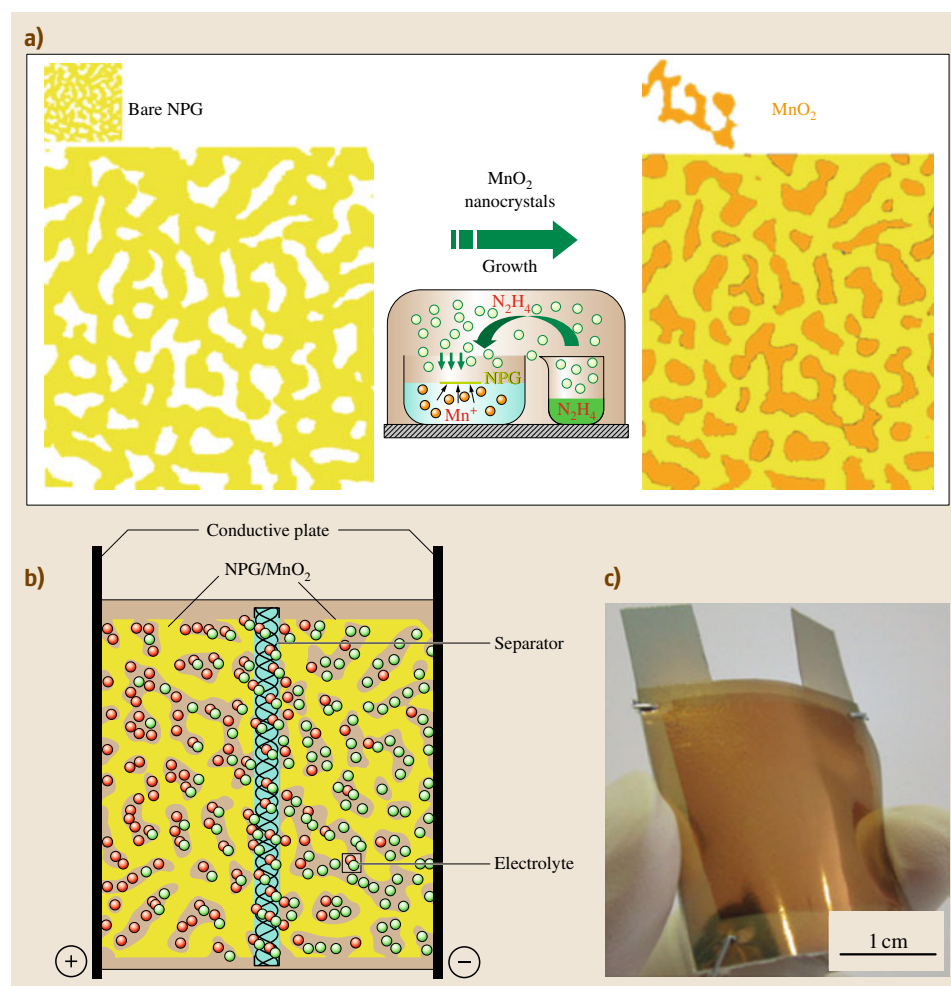

Fig. 21.30a–c Nanoporous gold/ MnO_2 -based supercapacitors. **(a)** Schematic showing the fabrication process for nanoporous gold/ MnO_2 hybrid materials by directly growing MnO_2 (orange) onto nanoporous gold. **(b)** Supercapacitor device constructed with nanoporous gold/ MnO_2 films as electrodes, aqueous Li_2SO_4 as electrolyte, and tissue paper as separator. **(c)** Photograph of a nanoporous gold/ MnO_2 -based supercapacitor (after [21.195])

electrons in bulk gold, and hence the resistance is dominated by surface scattering. Adsorption of a monolayer of octadecanethiol onto the nanoporous gold nanowire results in a resistance change of about 3%. The sensitivity factor of $1.0 \times 10^{-16} \text{ cm}^2$ is comparable to values reported for adsorption on ultrathin films.

Electrochemical supercapacitors can deliver high levels of electrical power and offer long operating lifetimes, but their energy storage density is too low for many important applications. Pseudocapacitive transition-metal oxides such as MnO_2 or SnO_2 could be used to make composite electrodes for such purposes, because they are predicted to have high capacitance for storing electrical charges while also being inexpensive and not harmful to the environment. However,

the poor conductivity of MnO_2 (10^{-5} – 10^{-6} S/cm) limits the charge/discharge rate for high-power applications. Most recently, *Lang et al.* [21.195] showed that hybrid structures made of nanoporous gold and nanocrystalline MnO_2 have enhanced conductivity, resulting in a specific capacitance of the constituent MnO_2 ($\approx 1.145 \text{ F/g}$) that is close to the theoretical value. The nanoporous gold allows electron transport through the MnO_2 , and facilitates fast ion diffusion between the MnO_2 and the electrolytes while also acting as a double-layer capacitor (Fig. 21.30). The high specific capacitances and charge/discharge rates offered by such hybrid structures make them promising candidates as electrodes in supercapacitors, combining high energy storage densities with high levels of power delivery.

21.4 Concluding Remarks and Prospects

Nanoporous metals with three-dimensional bicontinuous ligament–channel structure can be fabricated by chemical or electrochemical dealloying, which involves selective dissolution of the less noble element and surface diffusion/agglomeration of the more noble element. The length scale of the ligaments and channels in nanoporous metals ranges from a few nanometers to several microns, and can be tuned by changing parameters such as the composition and microstructure of precursors, the applied potential, the kind and strength of the electrolyte, and the dealloying temperature and time, or by adopting post-dealloying treatments such as thermal annealing. By alloy design of precursors (addition of elements with lower surface diffusivity) and control over the applied dealloying potential or temperature, ultrafine pores of well below 10 nm can be achieved in nanoporous metals, which show enhanced SERS effects, superior catalytic activity towards CO oxidation, improved effective Young's modulus, etc. Both monoliths (films, ribbons, bulk) and nanostructures (nanoparticles, nanowires, nanotubes) can be obtained for nanoporous metals. Besides pure metals (containing a minor residue of the less noble element), nanoporous alloys can be produced by dealloying ternary or multi-component precursors. Moreover, one can continuously modulate the compositions of these nanoporous alloys. Through combination with other routes such as

the template method, UPD deposition, etc., dealloying provides more space to tailor the microstructure of nanoporous metal materials. Due to the bicontinuous porous structure and ultrahigh specific surface area, nanoporous metals show unique mechanical, catalytic, electrocatalytic, optical, electrical, sensing, and actuation properties, compared with their dense bulk counterparts or nonporous nanostructures; for example, the tunable length scale of ligaments and channels allows for investigation of the size-dependent mechanical behavior of nanoporous metals. The ultrahigh specific surface area is desirable for high sensitivity, and the 3-D channels contribute to fast transfer of adsorption species and shorter response time for applications of sensors. This point is also desirable for electrocatalysis in fuel cell applications. On the one hand, nanoporous metals can serve as model materials for investigations of mechanical, physical, and chemical properties of random porous solids, from the viewpoint of fundamental science; On the other hand, from the technological viewpoint, nanoporous metals show potential applications in many fields such as catalysis, electrocatalysis, sensors, actuators, fuel cells, supercapacitors, etc. It is expected that more and more fascinating properties of dealloyed nanoporous metals will soon be uncovered, as well as their tremendous potential for actual applications.

Zeolites

22. Zeolites

István Pálinkó, Zoltán Kónya, Ákos Kukovecz, Imre Kiricsi

Zeolites are natural materials that have surrounded us since the beginnings of the history of mankind. They may have been used by ancient man instinctively; however, their use is only documented from about the middle of the 18th century. They became the wonder materials of the 20th century, and remain so in our time as well. Their secret lies in their porous structure, the wide variety of their three-dimensional channel system, and the diversity of their pore size, reaching nanometer dimensions. Their synthesized varieties have many applications, as described in this chapter, but perhaps the most important is their use as catalysts. Indeed, their use in acid-catalyzed isomerization of straight-chain hydrocarbons to produce high-octane gasoline has shaped our world and generated much wealth. However, this is not their only catalytic application; their tunable structural features and the constrained environment they provide allow their use in catalysis of many types of reactions, tremendously influencing the selectivities of transformations.

22.1 Common Zeolite Frameworks	822
22.1.1 Zeolites A, X, Y	822
22.1.2 Mordenite	822
22.1.3 Zeolites of Intermediate Pore Size	822
22.1.4 Other Zeolites of Commercial Interest	823
22.2 Zeolite and Zeolite-Related Molecular Sieves	823
22.2.1 Isomorphous Substitution of Si and/or Al Atoms in Zeolite Frameworks	823
22.2.2 New Large-Pore Zeolites	824
22.3 Natural Zeolites: Occurrence and Formation	825
22.3.1 Formation and Occurrence of Natural Zeolites	826
22.4 Methods of Identification and Characterization	828
22.4.1 Determining the Chemical Composition	828
22.4.2 Thermal Analysis Methods	828
22.4.3 Diffraction and Microscopic Techniques	828
22.4.4 Nuclear Magnetic Resonance (NMR) Spectroscopy	828
22.4.5 EPR Spectroscopy	829
22.4.6 Vibrational Spectroscopies	829
22.4.7 UV-Vis Spectroscopy	830
22.4.8 Mössbauer Spectroscopy	830
22.4.9 X-Ray Photoelectron Spectroscopy	830
22.5 Synthesis of Zeolitic Materials	830
22.5.1 Effects of Major Chemical Components and Further Additives	831
22.5.2 Influence of Various Physical Parameters on Zeolite Synthesis	834
22.5.3 Mechanisms of Zeolite Crystallization	835
22.5.4 Alternative Synthesis Procedures	835
22.6 Ion Exchange, Sorption, and Diffusion in Microporous Materials	836
22.6.1 Ion-Exchange Properties	836
22.6.2 Molecular Sieving Properties	837
22.6.3 Diffusion Properties	838
22.7 Acid-Base Properties of Zeolites	841
22.7.1 Acidity of Zeolites	841
22.7.2 Basicity of Zeolites	842
22.8 Stability and Modification of Zeolite Structures	843
22.8.1 Thermal Stability	843
22.8.2 Dealumination of Zeolites	843
22.8.3 Formation of Secondary Pore Structure	843
22.8.4 Isomorphous Substitution	844
22.8.5 Transition-Metal Ions and Metal Particles in Zeolites	845
22.8.6 Coke Formation in Zeolites	845

22.9 Zeolites as Catalysts	846	22.10 Some Special Applications of Zeolites	848
22.9.1 Zeolites in the Refining and Petrochemical Industry.....	847	22.11 Conclusions.....	850
22.9.2 Zeolites in the Fine Chemical Industry	847	References	850

Zeolites are crystalline aluminosilicates of group IA and group IIA elements such as sodium, potassium, magnesium, and calcium. Chemically, they are represented by

the empirical formula

$$M_{2/n}O \cdot Al_2O_3 \cdot ySiO_2 \cdot wH_2O, \quad (22.1)$$

Fig. 22.1 Construction of zeolite frameworks

Table 22.1 Pore size dimensions of various zeolites and molecular sieves. (After [22.1])

Pore size (Å)	Definition	Typical material	Ring size	Pore diameter (Å)
> 500	Macroporous			
20–500	Mesoporous	MCM-41		15–100
< 20	Microporous			
	<i>Ultralarge pore</i>	Cloverite	20	6.0×3.2
		VPI-5	18	12.1
		AIPO ₄ -8	14	7.9×8.7
	<i>Large pore</i>	Faujasite	12	7.4
		AIPO ₄ -5	12	7.3
		ZSM-12	12	5.5×5.9
	<i>Medium pore</i>	ZSM-48	10	5.3×5.6
		ZSM-5	10	5.3×5.6
				5.1×5.5
	<i>Small pore</i>	CaA	8	4.2
		SAPO-34	8	4.3

where n is the charge of the cation, y varies from 2 to infinity, and w represents the water contained in the voids of the zeolite.

All zeolite framework structures are a three-dimensional arrangement of TO_4 tetrahedra ($T =$ tetrahedrally coordinated atom, usually Si^{4+} , Al^{3+}), assembled together through sharing of oxygen atoms to form subunits, and finally infinite lattices by the repeat of identical building blocks (unit cells) (Fig. 22.1) [22.2–4].

The presence of trivalent T -atoms (Al^{3+}) generates negative charges in the framework. These charges can be compensated either by pentavalent T -atoms in the neighborhood (e.g., P^{5+} in aluminophosphates, AIPOs) or by the presence of cationic species in the voids of the framework, generating cation-exchange properties. In addition, the voids of the crystal structure (cages or channels) usually contain water or organic molecules (or salts) in addition to the cation. Removal of water or organics, by heating for instance, gives rise to a regular porous structure of molecular dimensions, which is responsible for the unique adsorption properties of zeotype materials [22.4–6].

Zeolite structures are not static systems. Indeed, various parameters will lead to modification of the zeolite symmetry, usually by bond angle and bond length modification. Such parameters include temperature, pressure, adsorbed molecules, or the cation species occluded in the crystal structure. The zeolite structure will always relax to the most favorable configuration upon variation of the circumstances [22.7–9].

In addition to their chemical composition, which can vary considerably, zeolites and zeolite-related materials are often classified according to their framework structure. Most of the known zeolitic framework topologies have been designated by an identification code of three letters by the International Zeolite Association (IZA) [22.3, 10]. Each framework type can be described by its secondary building units, framework density [number of tetrahedral atoms (T -sites) of the lattice/1000 Å], channel system, crystal symmetry, and unit cell content (number and configuration of T -sites).

The arrangement of the structural unit in zeolite frameworks results in the generation of pores and cavities of various dimensions (Table 22.1), responsible for the molecular sieving and confinement effects during adsorption of molecules. Generally, zeolites are classified as small-pore materials, with pore apertures consisting of six, eight, or nine tetrahedra (6-, 8-, and 9-membered rings), as medium-pore materials (10-membered rings), or as large-pore materials (12-membered rings). A new large-pore material, VPI-5, has been prepared by the team of the Virginia Polytechnic Institute. This material has 18-membered ring pores and thus is able to adsorb large molecules [22.11]. Other large-pore materials are AIPO-8 [22.10, 12] with 14-membered rings and cloverite [22.13] with 20-membered ring pores. Not too long ago a new family of mesoporous molecular sieves, MCM-41, was discovered [22.14].

22.1 Common Zeolite Frameworks

Many different structure types are known, and new structural varieties are constantly synthesized; thus, this area is diverse. Nevertheless, certain zeolites or zeolite-like materials occur more frequently in applications, as described below.

22.1.1 Zeolites A, X, Y

Linde type A (LTA) zeolite (Fig. 22.1) is one of the most frequently used zeolites. It can be considered as either a combination of double 4-ring (4–4) units, or truncated octahedra linked together through double 4-rings. Its pore structure consists of truncated octahedra linked to other cavities through 6-membered rings and of truncated cuboctahedra linked together through 8-membered rings. The most important uses of zeolite A include in ion exchange (water softening) and as adsorbents.

Synthetic faujasite materials are mainly zeolite X (high Al content, Si/Al ratio close to 1) and zeolite Y (higher Si/Al ratio). The structure of faujasite is presented in Fig. 22.1. It can be constructed from sodalite (truncated octahedra) cages in a diamond-like array, the sodalite cages being interconnected through 6–6 secondary building units (SBUs). In addition to the sodalite cages, the main cavities of faujasite material are about 11 Å in diameter, and they are interconnected through 12-membered rings with apertures about 7.4 Å in diam-

eter, allowing large molecules such as trimethylbenzene to enter the supercage.

22.1.2 Mordenite

Mordenite, originally known as a natural mineral, was first synthesized by *Barrer* [22.16]. Its structure is composed of 4- and 5-membered rings, generating a porous system delimited by 8- and 12-membered rings. The porous system consists of linear channels, oriented along the crystallographic *c*-axis, with apertures consisting of 8- and 12-membered rings (6.7 Å × 7.0 Å). These channels are linked together through a secondary pore system consisting of 8-membered rings. Although first reported as a small-pore zeolite (8-membered rings), a fault-free structure exhibiting adsorption properties consistent with a 12-membered ring pore system was later synthesized [22.17].

Compared with zeolite A, X or Y, mordenite is characterized by higher silica content, resulting in higher thermal stability. In addition to a higher Si/Al ratio, the mordenite structure contains 5-membered rings, which is thought to enhance the acid site strength of the material.

22.1.3 Zeolites of Intermediate Pore Size

These materials are characterized by 10-membered or distorted 12-membered ring pore openings, being related to the mordenite/ferrierite family of materials [22.18].

The unusual properties of these materials are due to their intermediate pore size (lying between previously known small-pore and large-pore materials), their high Si/Al ratio, and the presence of 5-membered rings in the lattice. Consequently, these materials exhibit high intrinsic acidic strength, high thermal stability, and shape-selective properties.

Of these medium pore size materials, the pentasil materials (ZSM-5, ZSM-11, ZSM-8, etc.) are the most interesting, due to their three-dimensional pore system. This leads to better resistance of pentasil-based catalysts to pore blocking, e.g., through coke deposition, compared with materials with a monodimensional channel system. During the last 20 years, numerous processes have been developed using ZSM-5 or related materials [22.18] (zeolite sieve of molecular porosity, ZSM). The straight and sinusoidal channel system of ZSM-5 is displayed in Fig. 22.2 [22.15].

Fig. 22.2a–d Schematic representation of the ZSM-5 structure: (a) front [001], (b) left [100], (c) top [010], and (d) isometric projection [111]. (After [22.15], courtesy of Elsevier)

22.1.4 Other Zeolites of Commercial Interest

Zeolite L is characterized by a monodimensional pore system composed of parallel 12-membered ring linear channels and quite a low Si/Al atomic ratio. When doped with Pt metal, it is the basis of the new AROMAX process for production of aromatics by dehydrocyclization of linear paraffins [22.19].

Zeolite mazzite (omega) and offretite are also molecular sieves of 12-membered rings. Zeolite omega is only characterized by one parallel 12-membered ring linear channel system, while in offretite, the

main 12-membered ring channels are interconnected through another set of channels with 8-membered rings [22.3].

Erionite has a structure very similar to offretite. As for offretite, the erionite structure consists of an arrangement of 6-membered rings connected to each other through 4-membered rings, but with a different stacking system, i.e., with cavities interconnected through 8-membered rings instead of 12-membered ring channels. While offretite or mazzite can accommodate large molecules, erionite can only adsorb linear paraffinic molecules [22.20].

22.2 Zeolite and Zeolite-Related Molecular Sieves

Perhaps the most important property of zeolite and related materials is their structural tunability. There are many ways of influencing the framework, and new frameworks are continuously being constructed.

22.2.1 Isomorphous Substitution of Si and/or Al Atoms in Zeolite Frameworks

Isomorphous substitution of Al by Si by either direct synthesis or modification of the framework to influence secondary pore structure, concentration and strength of acid sites, or enhance thermal stability is well known.

The first breakthrough in the synthesis of very high-silica zeolite was made by *Barrer* through the use of tetraalkylammonium cations for zeolite synthesis [22.22]. This led to the discovery of numerous new structures and, e.g., to the development of the ZSM family [22.18, 23].

Another breakthrough was the use of elements other than Si or Al. This first led to the preparation of metallosilicates containing boron, beryllium, titanium, and vanadium [22.24–26] and later to the discovery of aluminophosphates (AIPOs), silicoaluminophosphates (SAPOs), metalaluminophosphates (MAPOs), metalaluminophosphosilicates (MAPSOs), and finally element aluminophosphosilicates (EIAP(S)Os) [22.27–29]. Table 22.2 lists the sizes of the atoms that can be incorporated in the tetrahedral sites of zeolite materials [22.21].

The incorporation of various elements allowed synthesis of materials with already known framework for silicoaluminate materials, but also the preparation of

new structures [22.27–29] such as the AIPO₄-5 framework, lovdarite (in which the three-membered ring units have been thought to be linked to the presence of beryllium), etc.

Finally, sodalite or sodalite-related materials have been prepared in the complete compositional range, in-

cluding the classical silicoaluminate, an all-aluminate form [22.24, 30], an all-silica form [22.24], and the AIPO [22.28] material.

22.2.2 New Large-Pore Zeolites

Different new zeolitic phases with large pore diameters have been recently synthesized or identified; they include faujasite-related materials, new high-silica large-pore zeolites, and new AIPO or AIPO-related materials including the very large-pore molecular sieves. These new materials include the hexagonal varieties of faujasite, with higher Si/Al atomic ratio: zeolite ZSM-20 [22.33, 34] a *faujasite polytype* [22.35], and possibly CSZ-1, which could be an intergrowth of hexagonal and cubic phases [22.36]. SAPO-37 is the silicoaluminophosphate counterpart of faujasite [22.27–29, 37]. Finally, CSZ-3 is a rhombohedral analog of zeolite Y, synthesized in the presence of Cs^+ , Na^+ (and Rb^+) [22.38].

Zeolite β is a high-silica material first reported in a US patent issued to Mobil Oil Corporation in 1967 [22.39]. This zeolite exhibits an open pore structure with large 12-membered ring openings and has been extensively used as a catalyst [22.40]. Due to the high degree of faulting, its structure could only be determined using the combination of various techniques [22.40–43]. The structure was found to be an intergrowth of two polymorphs: polymorph A forming an enantiomeric pair, and a chiral polymorph B. The poly-

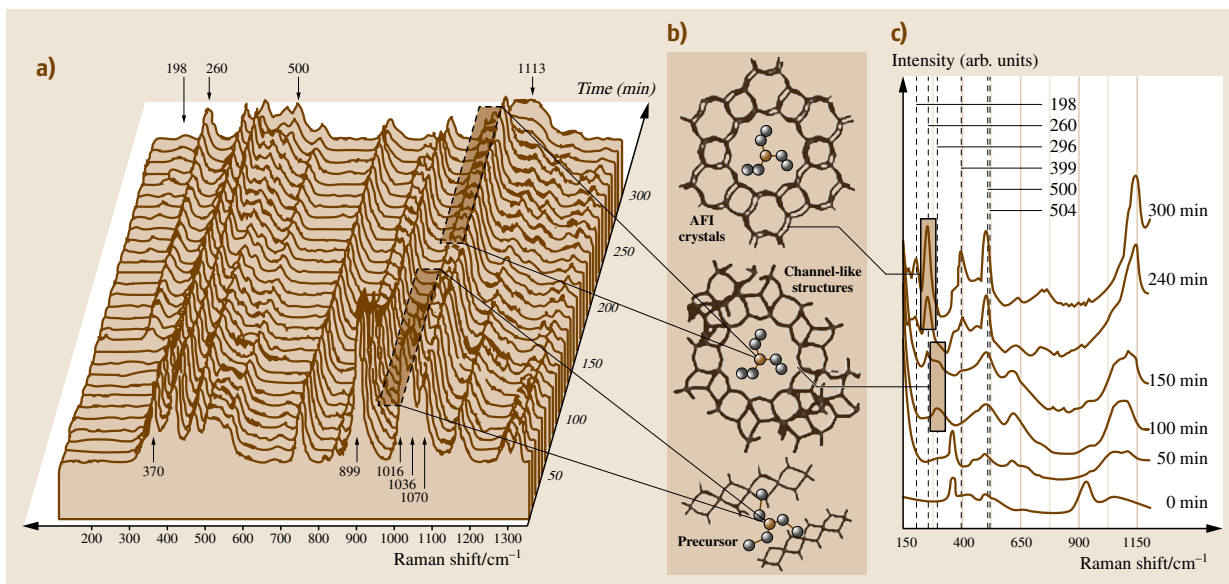

Fig. 22.4 (a) UV-Raman spectra recorded in situ during crystallization of AIPO-5. The synthesis temperature was 453 K. (b) A proposed scheme for the formation mechanism of AIPO-5 (AFI). (c) UV Raman spectra excited with 266 nm of AIPO-5 for different crystallization stages at various times of synthesis. (After [22.32], courtesy of Royal Society of Chemistry)

morphs are randomly distributed in the zeolite crystal, thus giving rise to large amounts of interplanar stacking faults. This generates a three-dimensional porous system with 12-membered ring apertures, the framework itself containing a large number of 5-membered rings. Zeolite β is the first high-silica zeolite containing 5-membered rings and having three-dimensional 12-membered rings channels. A schematic representation of the morphology and pore structure of zeolite β is shown in Fig. 22.3 [22.31]. Previously prepared or identified high-silica large-pore zeolites (ZSM-12, mordenite, mazzite) had only a one-dimensional large channel system that was not interconnected, or interconnected only through small apertures.

Another zeolite with high silica ratio and large pore system has also been identified; ECR-1 [22.44–46] is composed of an intimate twin of the mordenite and mazzite structures, constructed by interposing layers of mordenite-like sheets between layers of mazzite-like cages.

The development of the AIPO family and of related SAPO, MAPO, and MAPSO materials has produced numerous new materials with small, intermediate (AIPO₄-11), or large pore structure (AIPO-

5) [22.27–29]. The formation of the ALPO-5 structure could be followed by in situ spectroscopic methods such as ultraviolet (UV) Raman spectroscopy [22.32] (Fig. 22.4).

In addition to large-pore materials with 12-membered ring openings, the AIPO family has also produced very large-pore molecular sieves. VPI-5, the first zeotype with pore openings larger than 12-membered rings, has very open structure containing linear parallel channels with 18-membered ring apertures [22.11, 47, 48]. This material is similar to MCM-9 [22.49, 50], but different from AIPO-8 [22.50]. Indeed, AIPO-8 porous structure has apertures consisting of 14-membered rings, instead of the 18-membered rings of VPI-5 [22.10, 12, 51].

Another kind of large-pore molecular sieve has also been identified: cacozenite, with a one-dimensional pore system of 14.2 Å diameter, consisting of an arrangement of octahedrally coordinated Al atoms with tetrahedrally coordinated phosphorus [22.52, 53].

Finally, synthesis of a novel microporous aluminoborate with pore size of about 5–6 Å has also been reported. The structure was found to contain triangular BO₃ and tetrahedral BO₄ units [22.54].

22.3 Natural Zeolites: Occurrence and Formation

Zeolites were first recognized as a new group of minerals consisting of hydrated silicoaluminates of the alkali and alkaline earths by *Cronsted*, a Swedish mineralogist, as early as 1756 [22.55], with the discovery of stilbite. Because of the intumescence of these minerals when heated in a flame, they were named *zeolites*, from the Greek words *zeos* and *lithos*, meaning *boiling stones* [22.56].

Early zeolite discoveries were found in small cavities of rocks of volcanic origin, being indeed a classical zeolite occurrence, where zeolites form large crystals (Fig. 22.5).

Actually, zeolites occur in many types of rocks, but they are most common in volcanic sediments, and the largest (and also purest) zeolitic deposits are altered vitric tuffs.

Indeed, the major geologic settings of zeolites are saline, alkaline lakes; saline, alkaline soils; deep-sea sediments; low-temperature open hydrologic systems; burial diagenesis; and geothermal–hydrothermal systems [22.57].

The ion-exchange properties were already demonstrated by *Eichhorn* in 1858 (by studying the re-

versible ion-exchange properties of chabazite and natrolite) [22.58]. Hydration and dehydration were studied by *Damor* as early as 1840 [22.59]. *Friedel*, while studying the adsorption of various liquid organic compounds, suggested in 1896 that zeolites should consist of open spongy frameworks [22.60], and *Grandjean* studied adsorption of various gases after 1909 [22.61]. However, the main use of zeolites remained in jewelry for nearly 200 years.

The study of gas adsorption by *McBain*, with the development of the molecular sieve concept [22.62] in 1932 and the introduction of the physicochemical bases of zeolite science by *Barrer* [22.63] in 1938, marked the real start of zeolite technology development. This resulted in the development of synthesis procedures, first under high temperatures and autogenous pressure to simulate the formation of zeolites of volcanic origin, and later under milder conditions, producing synthetic materials either with a known naturally occurring counterpart or with a new structure [22.56, 64, 65].

Geological studies have shown that, although previously considered rare minerals, zeolites should be recognized as some of the most abundant mineral

Fig. 22.5 Photos of some natural zeolites

species on Earth. Indeed, zeolite deposits are dispersed worldwide and often occur in megaton quantities and high purity (up to more than 90%), for instance in the USA, former USSR (Russia, Ukraine, Georgia), Japan, Cuba, South Africa, Mexico, south and central Europe (Hungary), and Korea. This has recently led to the development of uses for natural zeolites, e.g., as sorbents or in ion exchange, in sewage treatment plants.

22.3.1 Formation and Occurrence of Natural Zeolites

The geological occurrence of zeolite minerals has been extensively studied over the past 50 years, and the distribution and origins of zeolites are generally well established.

Although the most beautiful zeolite crystals have usually been found in altered basalt matrices, zeolites are not restricted to this origin. Indeed, since 1950, more than 1000 occurrences of zeolite minerals of various sedimentary origins have been reported in more than

40 countries [22.66], sometimes in near-monomineral deposits.

As a result of the many geological studies, the different origins of the zeolite minerals can be included in one of the following genetic types [22.24, 56, 57, 67]:

1. Geothermal, hydrothermal systems, where zeolite crystals result from hydrothermal or hot-spring activity involving reaction between solutions and basaltic lava flow
2. Closed alkaline, saline lakes, where deposits result from alteration of volcanic sediments
3. Similar formations resulting from the action of open freshwater lakes or groundwater on volcanic sediments
4. Transformation of volcanic rock in saline, alkaline soils
5. Deep-sea deposits resulting from low-temperature or hydrothermal alteration of marine sediments
6. Burial diagenesis (low-grade metamorphism).

Features common to the different geological occurrences are [22.24, 56, 57, 67]:

1. Available SiO_2 and Al_2O_3
2. $\text{Ca} + \text{Na} + \text{K/H}$ activity ratio higher than in systems favoring phyllosilicates

The nature of the zeolites in a deposit depends on: (i) the SiO_2 and Al_2O_3 sources, (ii) the physicochemical characteristics of the pore fluids, (iii) the temperature of the deposit, and (iv) the age of the deposit.

Minerals associated with zeolites are clays, alkali feldspars, silica minerals, and other phyllosilicates. Zeolite deposits are usually zoned due to differences in water chemistry, temperature, or deposit age.

Hydrothermal–Geothermal Deposits [22.24, 56, 57, 67, 68]

Zeolites formed by hydrothermal–geothermal (e.g., geyser) alteration of basaltic lava or of hyaloclastic rock sequences in geothermal regions are found in many parts of the world. Classical occurrences are in areas such as Wairakei (New Zealand), Yellowstone National Park (USA), or Iceland.

These deposits are commonly zoned, depending on the temperature [22.69]. At low temperature, the nonzeolitic materials opal, kaolin, cristobalite, tridymite, and montmorillonite are already formed. Zeolites are formed in the 50–300 °C temperature range, while at higher temperatures, nonzeolitic materials such as albite appeared.

Saline, Alkaline Lake-Type Deposits [22.24, 56, 57]

In contrast to hydrothermal deposits, zeolite minerals formed from sediments usually consist of cemented agglomerates of very small crystallites with poorly developed crystal faces. However, these zeolites form the largest deposits, being those of economical interest.

The formation of zeolites in a saline alkaline lacustrine environment takes place in closed basins, in arid or semiarid regions, in which lake waters have gathered to produce high-pH (8–10) saline solutions containing high concentration of alkali or alkaline-earth carbonates/bicarbonates. In this environment, zeolites are readily formed by alteration of reactive materials deposited in the lake, e.g., vitric tuffs, biogenic silica, clays, etc. Zeolites found in these deposits usually include phillipsite, clinoptilolite, and erionite, and sometimes chabazite and mordenite. The deposits usu-

ally consist of different ring zones in a horizontal layer [22.24].

Deposits from Open Hydrologic Systems

Zeolites can be formed when water of high pH and salt content flows through vitric volcanic ash, causing rapid crystal growth. The high pH and salt contents of these systems are due to hydrolysis of volcanic ash.

Saline, Alkaline Soil Deposits

Zeolites can be formed at land surface, in saline alkaline soils ($\text{pH} \geq 9.5$) with high sodium carbonate content, resulting from vapotranspiration in arid or semiarid regions [22.57]. In such deposits, the unconverted parent material is at the bottom, separated at the water table from the zeolitized layer on top [22.69]. The parent materials in these soils are either volcanic tuffs or montmorillonite, claystones, etc. Zeolites frequently formed in these areas are analcime, phillipsite, chabazite, and natrolite [22.57, 69–71].

Zeolites in Marine Deposits

The largest volumes of natural zeolites are found in seabed sediments [22.72]. They result from alteration of volcanic or nonvolcanic material: basaltic rocks, nontuffaceous material such as carbonates, vitroclastic sediments or glass, glass being very slowly altered to analcime and feldspars [22.57]. The most abundant species are clinoptilolite, phillipsite, and analcime, with the amount of analcime increasing with age.

Burial Diagenesis [22.24, 57, 73]

In deposits with active diagenesis process, temperatures may range from 50–60 °C at the top to 125–130 °C at the bottom of the zeolitization zones. Reaction occurs following either the so-called alkali zeolite reaction series: silicic volcanic glass + $\text{H}_2\text{O} \rightarrow$ clinoptilolite + mordenite + low cristobalite \rightarrow analcime + quartz + $\text{H}_2\text{O} \rightarrow$ albite + H_2O , or the so-called calcic zeolite reaction series: clinoptilolite + $\text{Ca}^{2+} \rightarrow$ heulandite \rightarrow laumontite + quartz + H_2O . The reaction pathways may of course be influenced by the circulation of groundwater through transportation of reactants. However, a temperature gradient resulting in very slow alteration is the main factor governing formation of zeolites in burial diagenesis.

22.4 Methods of Identification and Characterization

For efficient use of zeolites, their chemical compositions have to be known, whether they are of natural origin or synthetic and/or modified varieties. Their structures and properties also have to be characterized accurately and by as many means as possible.

22.4.1 Determining the Chemical Composition

To characterize these materials well, the chemical composition has to be accurately determined. In as-synthesized microporous materials, the concentration distribution of different framework constituents is generally not uniform; rather, a concentration gradient is frequently found. Hence, both bulk and surface analysis techniques are necessary to characterize samples.

Atomic absorption spectroscopy (AAS) and inductively coupled plasma (ICP) are considered among the best techniques for analysis of zeolites with high Si/Al ratios. However, proton-induced γ -ray emission offers the supplementary advantage of simultaneous multielement analysis. For low-Si/Al samples, a variety of other techniques are available [22.74–77].

For determining concentration gradients, microprobe techniques are recommended, combining both bulk and surface concentration measurements. Secondary-ion mass spectrometry (SIMS) or fast atom bombardment mass spectroscopy (FABMS) is the recommended technique [22.77].

22.4.2 Thermal Analysis Methods

Thermal analysis gives information on the water content and the organic molecules occluded in the cavities and/or channels during synthesis. Combined thermal analysis methods (thermal gravimetry–differential thermal analysis and differential thermal gravimetry) have been extensively used to characterize natural and synthetic microporous materials [22.78].

22.4.3 Diffraction and Microscopic Techniques

Since the development of zeolite science, determination of zeolite structure has involved an increasing number of techniques.

The crystal structure of zeolites (i.e., the TO_2 skeleton and the occluded species: cations, salts, water or organic molecules) can be resolved using modern

x-ray single-crystal techniques [22.79, 80]. Some special synthesis techniques have been developed to obtain large crystals; however, synthetic zeolites are often obtained as powder, not suited for single-crystal refinement [22.2]. Nevertheless, recent use of synchrotron radiation sources has allowed use of smaller crystals for structure determination [22.81].

X-ray powder diffraction can be performed on a powder sample, producing a diffraction pattern from the regular arrays of atoms or ions within the crystal structure. This pattern reflects the symmetry of the constituents of the zeolite framework, and the diffraction angles represent a fingerprint characteristic of the structure. The pattern can thus be used for identification of known structures, by comparison with *standard patterns* obtained from known phases or published in the literature.

Other diffraction techniques can be used in conjunction with or to complement x-ray diffraction. Neutron diffraction, for instance, enables one to distinguish between Si and Al ordering in the zeolite framework, since Si and Al have different neutron scattering properties (but similar x-ray scattering properties) [22.82, 83]. Electron diffraction, coupled with scanning electron microscopy (SEM), allows identification of structural defects and intergrowths of superlattices [22.84, 85].

High-resolution electron microscopy (HREM) gives direct insight into zeolite symmetries, and, at very high resolution, one can even see zeolite pore structures. HREM is the most suitable technique to study defect or mixed zeolite phases [22.86, 87].

22.4.4 Nuclear Magnetic Resonance (NMR) Spectroscopy

NMR spectroscopy is particularly well suited for study of the surroundings of T-atoms or extraframework species. ^{29}Si magic-angle spinning (MAS) NMR in the solid state enables us to distinguish between Si surrounded by 0–4 Al atoms [22.88, 89]. In addition, chemical shifts of ^{29}Si NMR spectra (for silica-rich materials) are related to structural parameters such as T–O bond length or T–O–T angle, thus distinguishing between different T-sites [22.90–92]. Developments in two-dimensional (2-D) NMR techniques have enabled direct determination of connectivities [22.93]; as an example, the 2-D correlation spectroscopy (COSY) spectrum of ZSM-39 zeolite is displayed in Fig. 22.6. This zeolite has three different crystallographic sites:

T_1 , T_2 , and T_3 . The connectivities between T_1 and T_2 , and T_2 and T_3 are clearly observed, while, as expected, that between T_1 and T_3 is not seen [22.94].

^{27}Al MAS NMR measurements allow determination of the Al coordination in the material (tetrahedral Al in the lattice, extraframework octahedral, or pentavalent Al) [22.95, 96]. The combination of ^{29}Si and ^{27}Al measurements permits, to some extent, the determination of Si, Al orderings in aluminosilicate materials [22.97–99].

Among the different constituents of zeolite or zeotype materials, oxygen is one of the most important and abundant elements. However, due to the low isotopic abundance of ^{17}O , the NMR-sensitive nucleus, and its low magnetic susceptibility, study of the insertion of oxygen into the framework by O^{17} NMR requires the use of isotopically enriched materials [22.95, 100].

Other atoms (^{11}B , ^{31}P , ^{71}Ga , etc.) that can be incorporated into the tetrahedral sites of zeolite (or zeotypes) can also be studied by solid-state NMR [22.101–103].

Finally, analysis of probe molecules by ^{129}Xe , ^{31}P or ^{13}C NMR can allow determination of the cavity dimensions in zeolitic materials.

22.4.5 EPR Spectroscopy

Electron paramagnetic resonance (EPR) spectroscopy is typically used to characterize the environment of paramagnetic ions introduced into either the zeolitic framework or cation-exchange sites of zeolites. Schoonheydt and coworkers pioneered the use of EPR methods to investigate zeolites [22.104, 105]. Experimental and simulated spectra of zeolites containing Cu^{2+} and Ni^{2+} ions and different Ag clusters were reported in their works.

The behavior of different transition-metal oxide–zeolite mixtures was systematically studied by Kucherov and Slinkin by applying EPR spectroscopy [22.106–109]. Modification of HZSM-5 zeolite with Mn^{2+} ions via solid-state ion-exchange method was monitored using EPR spectroscopy by Wichterlova et al. [22.110].

The EPR parameters of metal particles generated upon alkaline metal vapor treatment of FAU-X and -Y zeolites have been published and summarized by the groups of Kevan [22.111, 112] and Simon et al. [22.113].

22.4.6 Vibrational Spectroscopies

Raman spectroscopic measurements are particularly useful for studying zeolites with similar structures [22.114].

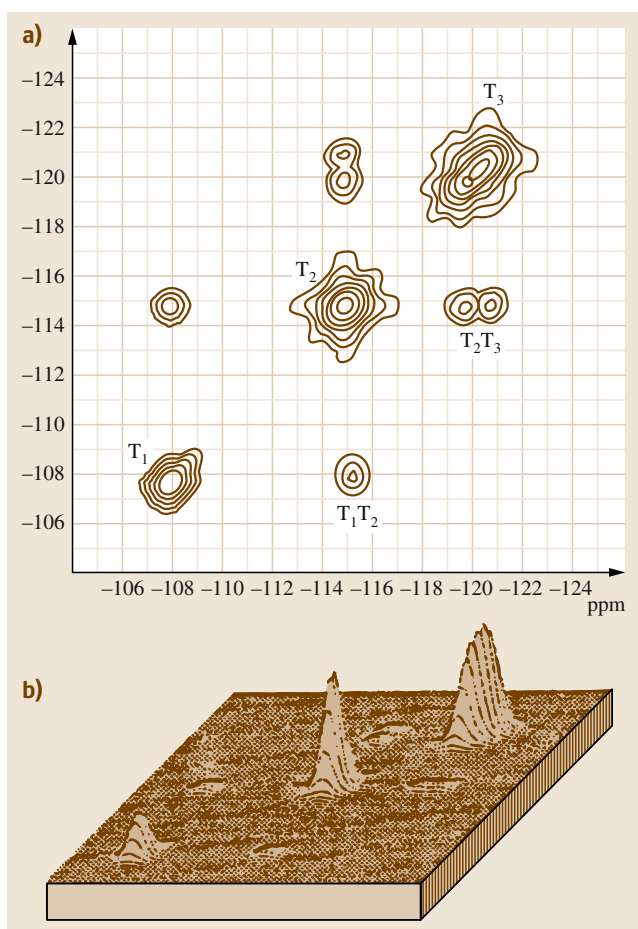

Fig. 22.6 Contour and stacked plots of a 2-D COSY experiment on ZSM-39 at 373 K. (After [22.94], courtesy of Elsevier)

Infrared (IR) spectroscopy is well suited to distinguish between different building units as well as to characterize acid sites.

Mid-IR spectra of zeolites in the 1400 to 200 cm^{-1} range are generally used for investigation of framework properties. The spectrum of FAU-Y zeolite is given as an example in Fig. 22.7 [22.115].

The observed bands were classified into two groups: (i) internal vibrations of the TO_4 tetrahedra, representing structure-insensitive modes, and (ii) external vibrations of the zeolite skeleton, being sensitive to the structure. Some of the structure-sensitive bands are shifted to lower frequencies with increasing Al content. This provides a fast and easy method to determine the fraction of Al in the zeolitic framework. Miessner and coworkers established the correlation

Fig. 22.7 Infrared assignments of the framework vibrations of Na-faujasite. (After [22.115], courtesy of ACS)

between unit cell parameters, skeletal stretching vibrations, and the molar fraction of faujasite-type zeolites for Si/Al = 1.1–1000 [22.116].

The far-IR region (400 to 10 cm^{-1}) is routinely accessible by modern spectrometers. In this range, low-frequency framework vibrations and vibrations of exchangeable cations can be observed. This field of zeolite characterization was developed and has been ex-

haustively discussed by *Ozin* and coworkers [22.117, 118].

22.4.7 UV-Vis Spectroscopy

In some special cases, UV-Vis spectroscopy has also been used to characterize transition-metal and/or complex ions and radicals present in zeolites [22.119].

22.4.8 Mössbauer Spectroscopy

Mössbauer spectroscopy can only be applied for zeolite characterization if the framework or the pores contain one of the few Mössbauer-active species. The method is very important in characterizing iron- and tin-containing materials. Mössbauer measurements reveal the coordination modes and oxidation states of these ions [22.120].

22.4.9 X-Ray Photoelectron Spectroscopy

X-ray photoelectron spectroscopy (XPS) is a powerful tool to analyze near-surface regions of zeolite crystals. Using the combination of classical elemental analysis and XPS measurements, information can be gathered on the distribution of framework constituents in the bulk phase as well as in the near-surface region [22.121].

22.5 Synthesis of Zeolitic Materials

Although the first zeolite synthesis was claimed as early as the 19th century, the first zeolite synthesis with reliable characterization by chemical analysis, optical properties, and x-ray diffraction was reported by Barrer in the early 1940s [22.2, 4, 24, 122]. This work led to production of synthetic counterparts of naturally occurring species as well as the preparation of new phases. This resulted in the synthesis of zeolite A in the Union Carbide laboratories by *Milton* and *Breck* and collaborators, under mild conditions ($< 100^\circ\text{C}$ and atmospheric pressure) [22.64, 65]. Zeolite A is regarded as the first fully characterized zeolite structure without corresponding natural minerals [22.2, 4, 24].

Since these early works, numerous systematic studies of zeolite syntheses have been carried out and have resulted in the preparation of many species with different structures, chemical compositions, or crystal habits. In addition, these works have helped increase understanding of mechanisms of zeolite crystallization as well as their formation under natural conditions.

Classically, zeolite synthesis involves preparation of an inhomogeneous gel, obtained by combining a silica source and an alumina source in water, under basic pH. Various additives can be added to the gel: alkali or alkaline-earth cations introduced as their oxides, hydroxides, or salts; ammonia in the form of ammonium salts, alkylamines, and alkylammonium compounds; etc. These compounds act in the synthesis as OH^- ion source, as electrolyte (salting-in or salting-out effects), as counterions of the formed anionic framework, or as structure-directing agents.

In addition to the composition of the reaction mixtures, two other major variables direct the formation of zeolites: temperature and time.

The effect of parameter variations can be studied, e.g., through crystallization curves (amount of zeolite produced against time). The crystallization curve is usually obtained using x-ray powder diffraction patterns of the sample taken at preselected times from the reaction mixture [22.123] (Fig. 22.8), often presented as %crys-

Fig. 22.8 (a) XRD patterns recorded during crystallization of CoAPO-5. (b) Schematic of the three-stage crystallization model. Color code: Co^{2+} – blue, Al^{3+} – pink, P^{5+} – orange, O^{2-} – red. (After [22.123], courtesy of ACS) ►

tallinity (determined using a standard sample) against crystallization time. This method can be used to monitor crystallization of different species.

22.5.1 Effects of Major Chemical Components and Further Additives

The silica/alumina ratio of the synthesis mixture used to crystallize a zeolite is of paramount importance, since it directly governs both the silica/alumina ratio of the zeolite product and also the framework structure. Some zeolites only crystallize in a very narrow range of Si/Al atomic ratio (zeolite A, FAU-X, and FAU-Y). Other materials such as the pentasil-type zeolites crystallize in a very broad composition range: Si/Al atomic ratio of about 7.5 to infinity. Sodalite is the only material known to crystallize over the full compositional range: Si/Al = 1 to infinity [22.24, 122, 124]. Attempts to change the Si/Al ratio of a zeolite by changing the Si/Al ratio of the synthesis mixture often lead either to the formation of the desired structure with crystalline impurities or amorphous phase, or to the formation of completely different products.

Changing the nature of the silica or alumina sources can also lead either to changes in the final composition of the crystalline products or even to changes of the structure formed. This is exemplified in Table 22.3 for the synthesis of zeolite Y, zeolite ZSM-20, faujasite polype, and zeolite β .

The hydroxide content of the system strongly influences the nature of the species (*monomeric* or *polymeric*) present in the reaction mixture, the concentration of dissolved silicoaluminate fragments, the charge of these species, and also the rate of hydrolysis or exchange between solid and liquid phases or between different species in solution. The hydroxide content of a reaction mixture is conventionally calculated by summing the moles of OH^- added as ROH, $\text{R} = \text{Na}^+$, K^+ , quaternary ammonium ion, etc. as sodium silicate (defined as $\text{NaOH} + \text{SiO}_2$), and as sodium aluminate (defined as $\text{NaOH} + \text{Al}_2\text{O}_3$) and subtracting any moles of acid that has been added, as either free acid (HCl , H_2SO_4) or salt [$\text{Al}_2(\text{SO}_4)_3 = \text{Al}_2\text{O}_3 + 3\text{H}_2\text{SO}_4$]. Al_2O_3 is considered as two moles of acid, as it will be converted to aluminate framework ions, and thus it must be considered in the hydrox-

ide content calculation [22.122]. Hydroxide content can alter the crystallization rate of a particular structure or alter the type of framework formed or their composition. Indeed, silica species are more soluble than alumina species; i.e., when the hydroxide content is increased, this will encourage the formation of lower-silica/alumina zeolites. In addition, to maximize the solid yield of a synthesis, it is important to minimize the hydroxide content to avoid too high a level of unreacted silicate ions in solution. Finally, when different phases can be formed successively in a synthesis mixture, by optimizing the hydroxide content of the synthesis mixture, we can favor one or other species, or we are even able to prepare a pure metastable structure.

The pH of the reaction mixture does not relate directly to the total hydroxide ion concentration, since it will be greatly influenced by the nature of the dissolved species (degree of depolymerization), and also by the presence of organic species (such as amines) that can act as buffer, maintaining the alkaline pH. In many systems, crystallization of a zeolite is accompanied by a marked pH change, which can be used to monitor the crystallization process. However, this change is usually negligible in very alkaline media (too high pH), and it also depends on the crystallization mechanism to a large extent.

One of the primary roles of inorganic cations is to balance the zeolite framework charge created by the incorporation of Al(III) in the lattice. Since the space available for cations in a zeolite can be limited, exchanging a divalent cation by a monovalent cation, or replacing a cation by another one with larger dimensions, will tend to reduce the Al content of

the framework [22.24]. On the other hand, replacing a monovalent cation by a divalent one will allow a larger charge density in the framework. One of the most spectacular examples of the latter case is sodalite. Na-sodalite has Si/Al atomic ratio of 1. However, replacing Na⁺ by Ca²⁺ allowed the formation of an all-aluminate framework of the sodalite structure [22.24]. In addition to balancing the zeolite framework charge, inorganic cations often play a dominant role in determining the structure formed. The presence of inorganic cations can also alter the morphology of zeolite crystals, either by favoring nucleation of new crystals, or by selectively enhancing the crystal growth along a given direction. This has been extensively studied for numerous systems, but more particularly for ZSM-5 [22.130–132]. In addition, inorganic cations can decrease the induction time needed before the start of crystal growth [22.130, 131]. Finally, since one structure can often be favored by different cations, addition of a cation to the synthesis mixture can result in an increase of the crystallinity of the product. Such an effect has been observed by changing the Na/K ratio in the starting gel used to synthesize offretite [22.133]. The atomic force microscopy (AFM) method allows visualization of crystallization at near-molecular level [22.134] (Figs. 22.9, 22.10).

Use of organic amines or quaternary ammonium ions in zeolite synthesis was first developed by Barrer in the early 1960s [22.24], and has resulted in the discovery of numerous new zeolitic structures. In addition, use of organics during zeolite synthesis has often resulted in wider ranges of Si/Al atomic ratio than in conventional synthesis. In a synthesis mixture, the organic compounds can behave in different ways; they can (i) act

Fig. 22.9 AFM image of the solid phase separated from the reaction mixture after its hydrothermal treatment at 170 °C for $t_{\text{cryst}} = 2$ h. Image scan size: 700 nm \times 700 nm, maximum particle height 200 nm. (After [22.134], courtesy of Elsevier)

as structure-directing or templating molecule, (ii) act as a gel modifier, which would allow the formation of structure with higher Si/Al ratio than could be obtained without organic additives, (iii) interact chemically with other component of the gel, altering the character of that gel, for instance, the alkalinity, (iv) interact physically with the gel, modifying the gelling process, the solubility of various species, the ageing process, the transport properties, and the mono- or multiphase behavior, and (v) act as a void filler, as water has been postulated to partake in the synthesis of higher aluminium-containing (hydrophilic) zeolites, being adsorbed into the structure during crystal formation.

The role of inorganic or organic species as *templating* or *structure-directing* agent has been thoroughly investigated in numerous zeolitic systems. Indeed, an ionic or neutral species is usually recognized as a structure-directing agent when its addition to the synthesis mixture results in the formation of a zeolite that would not have been formed without the agent. The way in which a species can direct the formation of a specific structure is not fully understood, yet. However, it is believed that (i) the structure-directing agent can favor a specific species in the gel, e.g., the double four ring (D4R) unit, and (ii) the zeolite structure grows around

Fig. 22.10 AFM image showing a detail of characteristic silicalite-1 growing terraces. The solid phase was separated from the reaction mixture after its hydrothermal treatment at 170 °C for $t_{\text{cryst}} = 3$ h. the template, thus tending to stabilize certain pore structures or subunits [22.135, 136].

Using tetraalkylammonium ions for zeolite synthesis has allowed synthesis of high-Si/Al materials. Indeed, due to the large size of the organic species, they can counterbalance only a limited number of negative centers of the lattice. This led, for instance, to the preparation of zeolite ZK-4, which is isostructural to zeolite A but with higher Si/Al ratio [22.137]. However, in materials with very high Si/Al ratio, the amount of organic (or inorganic) cations included does not match the amount of Al incorporated into the lattice. Indeed, the pentasil zeolite family with various Si/Al ratios has been extensively studied. Solid-state NMR measurements as well as thermal analysis data have shown the presence of structural defects, such as $\equiv\text{Si}-\text{OR}$ (R = tetrapropylammonium, or an inorganic cation) groups. Removal of excess cations by successive calcinations (in air) and ion exchanges with NH_4^+ led to the formation of $\equiv\text{Si}-\text{OH}$ group and successive condensation to $\equiv\text{Si}-\text{O}-\text{Si}\equiv$ [22.138, 139].

Organic additives used for zeolite synthesis are frequently alkylamines or polyamines. Thus, these

species can behave as pH buffer, maintaining the pH at a constant level during the crystallization process and modifying the solubility and the polymerization degree of the silicate (or silicoaluminate) species of the aqueous gel. Moreover, addition of large amounts of organics can also change the solubility of the silicate species, by modifying the surface charge of the gel particles or the viscosity or dielectric constant of the media, selectively complexing with some compounds, or producing biphasic or micellar systems. Indeed, some syntheses have been carried out without water or with very limited amounts of water [22.124]. Other procedures using biphasic (micellar) systems have been described for preparation of aluminophosphate materials and their derivatives [22.140]. It has been shown that water plays an active role as a void-filler, stabilizing the zeolite porous framework during the crystallization process. It is possible that incorporation of organics into the pores can play a similar role. This is well illustrated for the synthesis of clathrasils (silica with a structure analogous to clathrate hydrates) [22.139], or for preparation of molecular sieves in nonaqueous environment [22.124]. This has also been proposed for the synthesis of ZSM-5, where the organics act as structure-directing agent and a pore-filling moiety [22.135].

Other nonionic or anionic compounds have also been used to modify the zeolite crystallization process. Inert simple gases were applied in the synthesis of clathrasils, including CH₄, N₂, and Ar molecules [22.142]. Organic dyestuffs have also been used to control the shape of zeolite microcrystals (e.g., mordenite [22.143]); these compounds are thought to adsorb on the surface of certain crystal faces, inhibiting their growth rate [22.24]. In addition to amines, alcohols are often present in the synthesis medium. They are produced by hydrolysis of alumina or silica sources (e.g., tetraethylorthosilicate), or are added intentionally either to act as template/pore-filling agents or to partially or fully replace water in the synthesis mixture [22.140]. Not long ago, a novel synthesis procedure applying fluoride ions has been developed, which allows operation at low pH and preparation of more fault-free material (Sect. 22.5.4) [22.144].

22.5.2 Influence of Various Physical Parameters on Zeolite Synthesis

Time is a very important parameter for control of zeolite synthesis. Indeed, crystallization of a zeolite is usually

Fig. 22.11 Crystallization curves of ZSM-20 and zeolite β . Crystallinity was determined by powder XRD measurements. (After [22.141], courtesy of Elsevier)

followed using a crystallization curve (crystallinity as defined by powder x-ray diffraction), as exemplified in Fig. 22.11 [22.141]. Since a desired zeolitic species is often a metastable product that can undergo further dissolution, while a more stable *parasite* species can be formed, it is very important to know the crystallization kinetics in order to prepare pure crystalline phases.

Originally, zeolite synthesis was usually performed under high temperature and pressure to mimic the synthesis conditions in nature [22.4]. Syntheses at low temperature were first proposed by Union Carbide in the 1950s and led to preparation of zeolites A, X, and Y [22.145]. Temperature can alter several factors in zeolite synthesis such as (i) the nature of the zeolite phase (higher temperature usually produces more dense phases), and (ii) the crystallization kinetics (the induction period is usually shorter at high temperature, and the metastable species are decomposed faster) [22.4, 122]. Pressure is often a minor parameter in the synthesis of zeolites, since crystallization is usually performed under autogenous pressure. However, pressure can play an important role when the synthesis is performed in the presence of a volatile reagent (e.g., NH₃, N₂, or CH₄) and may thus affect both the pH and the concentration of dissolved species.

Stirring of the synthesis mixture during preparation of a zeolite can have different effects. It can modify the local concentration of the reagents, tending to produce a more uniform concentration of the reagents throughout the mixture, and may thus result in a lower gradient from a solid particle under dissolution to the surrounding media. It can change the transport properties of the different species and can break the *structure* of the gel, for example, by decreasing the viscosity.

22.5.3 Mechanisms of Zeolite Crystallization

Since the first successful syntheses of zeolites, numerous researchers have been attempting to understand how these microporous materials form from complex mixtures. In addition to the investigation of different parameters governing zeolite synthesis already described, two directions of experimental work have also been investigated:

- Identification of the different species present in liquid, gel, or solid phases during the crystallization process
- Studying the crystallization kinetics that characterize zeolite synthesis.

Major events taking place in the crystallizing mixture are (i) precipitation of an initial gel phase, (ii) dissolution of the gel, (iii) nucleation from the gel or the solution phase, (iv) crystallization and crystal growth of these structures, (v) dissolution/recrystallization of metastable phase, (vi) successive nucleation, crystallization, and dissolution of further nucleation phases, and (vii) formation of the equilibrium phase [22.146]. Corresponding processes occurring at the atomic level are the formation of simple or polynuclear species, formation of larger units (zeolite-like substructure) and nucleation of the zeolite by aggregation of various species, crystal growth through transportation, and rearrangement of species present in the gel or in the solution [22.122].

For identifying the species present in the synthesis mixture, numerous techniques are used [22.122, 139], such as chemical analysis of the phases, powder x-ray diffraction (to follow the crystallization process and to identify the crystal structure), IR and Raman spectroscopies (to obtain information on the presence of substructural species in solution and in the solid phase, even prior to x-ray-identifiable crystallization), thermal analysis (giving information on the dehydration and/or the decomposition processes of organic molecules in the solid product), transmission electron microscopy (TEM), scanning electron microscopy (SEM), microanalysis (providing information on crystal domains not yet identified by x-ray diffraction, crystal size distribution and shape, and concentration gradients possibly present in the solid particles), ^{129}Xe NMR (to investigate early porous domains [22.147]), XPS (to determine surface composition [22.148]), and gas chromatography (GC)-NMR analysis (to identify silicate species [22.24, 122]).

On the basis of the many systems studied, two processes, called A and B, have been proposed for the crystallization mechanism.

The type A mechanism essentially occurs in highly alkaline medium. In this case, depolymerization of the active silica to yield ultimately monomeric silicate anions was shown to be the essential rate-limiting step. As a result, a small number of negatively charged monomers are formed. They can either condense aluminate species to form aluminosilicate complexes or interact directly with Pr_4N^+ ions, known to order around the preferably Si-rich aluminosilicate units to form stable nuclei. It has also been shown that growing ZSM-5 crystallites accommodate silica in preference to aluminum. Consequently, the nuclei will grow with a relatively fast rate at the expense of the dissolved species in solution, resulting in further dissolution of the gel phase. As silicate species are exhausted, aluminum will be incorporated at the end of the process, resulting in inhomogeneous radial Al distribution through the particles. Condensation processes from low-molecular-weight species in solution was further confirmed by studying silicate species in solution. These species were found to be present in very high concentrations.

In the type B mechanism, a hydrogel is formed from solutions already containing mono- or oligomeric silica (aqueous sodium silicate) or alumina species. Its composition corresponds to that calculated from the ratio of reagents (no rate-limiting depolymerization step). Structure-directing Pr_4N^+ cations are present throughout the gel and can readily interact intimately with the gel species. This, associated with higher Si/Al and Na/Si ratios, leads to fast nucleation and recrystallization of the gel (direct hydrogel transformation or surface nucleation). Indeed, the final product consists of small crystallites (or aggregates of small crystallites) with either homogeneous Al distribution, or even enriched Si outer shell, the dissolved silicate species reacting later [22.139].

22.5.4 Alternative Synthesis Procedures

First pentasil materials, and later other zeolites such as ferrierite, Θ -1, ZSM-39, and ZSM-23, were synthesized from a mixture where the hydroxide ions were replaced by fluoride ions [22.137]. In this mixture the pH was decreased to the acidic region. This new route is particularly favorable for preparation of high-silica materials. Partial substitution of silicon with B(III), Al(III), Ga(III), Fe(III), Ge(IV), or Ti(IV) was also possible.

The degree of substitution decreases with increasing stability of the corresponding fluorocomplexes in the solution. The supersaturation of crystallizing species is lower in the presence of fluoride, resulting in fewer metastable phases and a more regular crystallization rate (formation of large crystals with fewer defects). The new medium enables incorporation of elements that are sparingly soluble in alkaline solution, for instance, Fe(III) or cations such as Ca^{2+} and NH_4^+ .

Use of a mixture of an organic solvent (for instance hexanol), water, template, and an emulsifier [22.140, 149] led to the production of the MCM-type silicoaluminophosphate materials, some of which correspond to previously reported **AIPO** or **SAPO** materials. Among the most interesting materials, MCM-9 was later found to be related to the very large-pore VPI-5 material (18-membered ring pores).

The first reported synthesis of a zeolite in non-aqueous media was the preparation of silica sodalite in the $\text{SiO}_2\text{--Na}_2\text{O}$ –ethylene glycol and $\text{SiO}_2\text{--Na}_2\text{CO}_3$ –ethylene glycol systems [22.9, 150]. Systematic studies in the presence of ethylene glycol, but also of glycerol, dimethylsulfoxide, sulfolane, hexanol or heptanol, and ethanol in the presence of various inorganic cations, led to the formation of hydroxysodalites with various Si/Al atomic ratios, of zeolite BaT, and of kaliophilite [22.122]. Studying the formation of sodalite in the presence of ethylene glycol showed its incorporation in sodalite cavities, suggesting a templating role for this solvent. Attempts to prepare other zeolites without any water in the system, for example, in the presence of organic bases, failed [22.122]. However, synthesis of **ZSM-5** and ferrierite has been reported in the presence of small amounts of water.

22.6 Ion Exchange, Sorption, and Diffusion in Microporous Materials

Ion exchange, sorption, and diffusion are among the most important properties of microporous materials. Indeed, zeolitic materials contain cations to compensate the negative charges of the framework, and these cations can be exchanged partially or fully. Since the cages and channels are of molecular dimensions, the microporous materials show the so-called molecular sieving effect [22.62], allowing certain molecules to enter while excluding others due to their too large size. Once the molecules or ions are adsorbed in the inner pores of these materials, they have to diffuse through the channels and cavities to reach a specific adsorption site or catalytic site, where they can be transformed. In this respect, zeolites can be compared to the active sites of enzymes [22.150].

22.6.1 Ion-Exchange Properties

Zeolites can be considered as solid electrolytes. The ion-exchange properties are well studied, and zeolites are classified following their specificities [22.4, 151].

The ion exchange can be presented as

where cations A and B have charges a and b , respectively, and subscripts “Z” and “S” indicate zeolite and solution, respectively.

The equivalent fractions of the exchanging cations in the zeolite (A_Z) are defined as the ratio of the num-

ber of equivalents of exchanging cation A to the total equivalents of cations in the zeolite, with $A_Z + B_Z = 1$. A similar definition holds for the equivalent fractions in solution.

The selectivity of the zeolite for cation A is expressed by the separation factor α_A

$$\alpha_A = \frac{A_Z B_S}{B_Z A_S}. \quad (22.3)$$

If cation A is specifically preferred by the zeolite, $\alpha_A > 1$.

When the exchange process can be described as a true reversible equilibrium, a thermodynamic equilibrium constant K_a can be defined, and hence the free enthalpy change (ΔG^0), the enthalpy (ΔH^0), and entropy changes (ΔS^0) can be determined.

The ion sieving selectivity does not only depend on the size of the pore apertures but also on the hydrophilic or hydrophobic character of the zeolite; for example, the highly negatively charged framework of zeolite X (with Si/Al varying from 1 to 1.5) prefers smaller cations in the order

while zeolite Y with lower anionic charge (Si/Al = 1.5–3) preferentially takes up larger cations, following the order

Li^+ represents an exception for both zeolites, as this small cation essentially migrates with its first hydration shell.

In order to explain the above-mentioned selectivities, not only the Coulomb interaction between the cations and the framework has to be taken into account, but also the general van der Waals interactions between the ions and the walls of the cavities or channels. In addition, complication arises from the fact that the adsorbed cations do not occupy the same adsorption sites in the zeolite. Indeed, Fig. 22.12 shows the cation sites in the faujasite structure. Cations occupying sites I in the hexagonal prisms and those sites in the sodalite cages (sites I, II', and U) are more hindered for exchange, while those found in the supercages (sites II, III, and IV) are more readily accessible.

The first series for specific exchange in zeolite X seems to follow a relationship with the potential energy (Z/r) of the bare nuclei, a relationship similar to that obtained for the energy of hydration [22.152]. Since the framework negative charge decreases in zeolite Y with respect to zeolite X, larger cations having better interaction with the surroundings are better exchanged. The unexpected role of Li cations can be explained if it is assumed that Li generally migrates with its hydration shell, increasing the effective radius of the cation and decreasing the interaction with the surrounding wall of the cavities.

For exchange of organic cations in hydrophilic zeolites A and X, the following selectivity sequence was obtained [22.153, 154]:

while in the more hydrophobic dealuminated Y or ZSM-5, the sequence is reversed [22.155]. It seems to be clear that Coulomb stabilization prevails in the hydrophilic zeolites, whereas the van der Waals interaction predominates in the hydrophobic–hydrophobic adsorption.

Finally, it has to be emphasized that hysteresis occurs in several exchange processes; i.e., the reverse isotherm does not follow the same profile as the forward process [22.2]. This can be due, for example, to a phase transformation occurring during the ion exchange.

Ion exchange may occur from nonaqueous solutions or in the solid state [22.2, 4, 151, 156, 157].

Solid-state ion exchange may be described by the following equations, depending on whether the starting material is a cation-containing form, such as the sodium form of a zeolite, or the hydrogen (ammonium) form.

Fig. 22.12 The cationic sites of the faujasite framework

The solid-state reaction takes place between a chloride of the cation M and a Na- or H-form of the zeolite:

In a stoichiometric mixture, one may reach complete exchange without residual salt

For Na-zeolite, equilibrium will be obtained similar to in conventional ion exchange. If one starts with the hydrogen (or ammonium) form and continuously removes the hydrogen halide (HCl) in an inert gas stream or high vacuum, the equilibrium may completely shift to the right, resulting in complete exchange [22.156, 157].

22.6.2 Molecular Sieving Properties

The adsorption of gases is characterized by an isotherm (volume of sorbed gas as a function of equilibrium pressure) at constant temperature, an isobar (quantity of gas adsorbed as a function of temperature at constant pressure), and an isostere (identical to a Clausius–Clapeyron relationship (plot of $\log p$ as a function of $1/T$) for

Fig. 22.13 SEM image of calcined rho zeolite (*insert*: high-resolution SEM image for the same sample). (After [22.160], courtesy of Elsevier)

a constant amount of sorbate on the zeolite). The latter provides valuable equilibrium data for design and optimization of gas sorption separation processes [22.158, 159] and for estimation of the differential heat of sorption, which can be used to define more precise contributions to zeolite–sorbate interactions [22.2].

The molecular sieving effect is based on exclusion of molecules larger than the pore apertures. Once the molecule is adsorbed into the channels or cavities, it is *solvated* by the solid framework and a mutual interaction is established between the adsorbate (or adsorbed molecule) and the adsorbent (or the microporous material). The confinement model based on the general van der Waals interaction explains quite adequately the chemical shift variation of ^{129}Xe of adsorbed Xe atoms and of ^{13}C of tetramethylammonium in various zeolites [22.161].

The presence of paramagnetic ions or metal particles greatly influences the ^{129}Xe NMR chemical shift [22.162]. Xe atoms are able to discriminate Pt particles where hydrogen is adsorbed from those covered with water and/or oxygen [22.163, 164]. Moreover, the chemical shift is also sensitive to the number of hydrogen atoms adsorbed per Pt particle [22.162].

Just as in the probe molecule–enzyme interaction, feedback also exists between the adsorbed molecule and the zeolitic framework. In this mutual interaction, both partners are perturbed electronically and sterically. The first report on the change of a zeolitic structure due to adsorption was based on crystallographic

results. It was observed that as-synthesized ZSM-5 zeolite with occluded tetrapropylammonium (TPA) ions had orthorhombic symmetry, while the calcined zeolite became monoclinic [22.165]. This transformation involves only minor changes in atomic position and bond angles and is highly reversible [22.62, 166]. Neutron diffraction data showed a significant change in the pore volume of Ca-exchanged zeolite rho during dehydration, and the lattice volume decreased to ca. 80% of the initial volume [22.167]. An SEM image of a calcined rho zeolite sample is shown in Fig. 22.13 [22.160].

22.6.3 Diffusion Properties

Migration or diffusion of adsorbed molecules through the pores, cages, and channels within the crystals plays an important role in catalysis and selective adsorption/separation; for a review, see [22.168].

Various types of diffusion may be distinguished, such as as molecular diffusion (pore sizes 800–10 000 Å), Knudsen diffusion (10–800 Å), and intracrystalline or configurational diffusion (3–10 Å) [22.169]. The region of configurational diffusion, which characterizes molecular sieves, spans more than ten orders of magnitudes; intracrystalline diffusivities range from 10^{-8} to $10^{-20} \text{ m}^2 \text{ s}^{-1}$. Such restricted molecular diffusion can have a beneficial effect in catalysis. So-called *shape-selective catalysis* is based on the special selectivity obtained by restriction in molecular diffusion [22.169].

As a first approximation, diffusion can be described by Fick's first law, which relates the molar flux J ($\text{mol m}^{-2} \text{ s}^{-1}$) and the concentration gradient $\delta c/\delta x$:

$$J = -D_c \frac{\delta c}{\delta x}, \quad (22.10)$$

where D_c is the diffusion constant.

If one is referring to the true driving force, which is the gradient of the chemical potential $\delta\mu/\delta x$, the molar flux becomes [22.151, 168, 170]

$$J = -B_c C \frac{\delta\mu}{\delta x}, \quad (22.11)$$

where B_c stands for mobility. In general, both D_c and B_c are concentration dependent. The relationship between B_c and D_c is computed by assuming equilibrium between the adsorbed phase (concentration c) and an ideal vapor phase (pressure p and temperature T) as

$$D_c = B_c RT \frac{d \ln p}{d \ln c}, \quad (22.12)$$

with $D_0 = B_c RT$ being the intrinsic diffusivity. D_c approaches the value of D_0 if Henry's law is obeyed, i.e., $d \ln p / d \ln c = 1$.

The intracrystalline transport diffusivities D_c and D_0 are in general different from the self-diffusivity D , which is defined under equilibrium conditions in a system with no concentration gradient.

From the experimental point of view, the change of concentration as a function of time is measured, instead of the concentration gradient. In that case, Fick's second law is applied

$$\frac{\delta c}{\delta t} = D_c \left(\frac{\delta^2 c}{\delta x^2} \right). \quad (22.13)$$

Overall migration of molecules requires their diffusion within the zeolitic crystal (intracrystalline diffusion $\approx r_c^2/D_c$), through the outer layer of the crystallites (surface barrier resistance $\approx r/k_{sb}$), and through the meso- and macropores ($\approx R_p^2/D_p$), where r_c and R_p are the radii of the crystals and the pores, respectively.

Many techniques are devoted to accurate measurement of the various diffusion coefficients. They can be divided into macroscopic and microscopic methods [22.171].

The uptake rate is measured either volumetrically or gravimetrically in the more widely used and experimentally straightforward macroscopic techniques. The change in weight is recorded using a microbalance, and the sorbate pressure is kept constant in the gravimetric method. The volumetric method uses a constant initial amount of sorbate, and the change in pressure is recorded by a sensitive differential pressure transducer as a function of time [22.168].

Another uptake-rate measurement method is the step frequency response method [22.172]. At sorption equilibrium, a zeolite sample is subjected to small (less than 1%) pressure changes brought about by very rapid, square-wave volume perturbations. From the gas pressure response on compression/expansion of the system, intracrystalline diffusion coefficients of small hydrocarbons are determined. The lower limit for the characteristic time is about 1 s.

The chromatographic method and the zero-length-column (ZLC) method are both macroscopic flow methods [22.168, 171]. In the ZLC method, fast desorption of the sorbate with an inert gas occurs from a small amount of zeolitic sample previously equilibrated with the sorbate at known concentration. The intracrystalline diffusion coefficient is obtained from the slope of $\ln(c/c_0)$ plotted as a function of t . The lower limit of the characteristic time is about 7 s.

If large zeolitic crystals of a few hundred microns can be prepared, the macroscopic steady-state membrane technique yields straightforward results for D_c/L^2 , where L is the thickness of the zeolite used. The zeolitic membrane is mounted on a metal plate and sealed with an epoxy resin. On one side of the membrane, a constant sorbate pressure is applied, while the pressure change in the constant-volume cell situated on the other side of the membrane is measured as a function of time.

The microscopic methods are essentially based on NMR [22.173] and neutron diffraction measurements [22.174, 175]. These techniques all measure the self-diffusivity, either indirectly by determining the average time between molecular jumps (NMR relaxation or neutron scattering) or directly as in the NMR pulsed-field-gradient (PFG) method [22.168, 171, 173, 176]. In the indirect methods, the estimated diffusivity depends on the assumed jump length. The PFG method is illustrated in Fig. 22.14 [22.177].

In this experiment, in addition to the strong time- and space-independent magnetic field B_0 , a pulsed field is also applied, increasing linearly with the space coordinate $\Delta B_0 = Gr$. The field gradient G is only applied during two short time intervals of identical duration δ , separated by a time Δ . In the normal spin-echo experiment, using the sequence of a $\pi/2$ and a refocusing π pulse, the attenuation is only due to transverse relaxation effects. If, however, τ is kept constant and either δ , Δ , or G is varied, molecular migration also leads to loss of phase coherence between the individual spins, and hence the intensity of the echo signal decreases. The ratio of the intensity of the echo signal in the presence $I(G)$ and in the absence $I(0)$ of the gradient field is given by

$$-\ln \frac{I(G)}{I(0)} = \gamma^2 G^2 \delta^2 \Delta, \quad (22.14)$$

where γ is the magnetogyric ratio. The self-diffusivity coefficient D is obtained from the slope of $-\ln I(G)/I(0)$ as a function of G . From D , the molecular mean-square displacement $\langle r^2(t) \rangle$ is easily obtained from the Einstein equation

$$\langle r^2(t - \Delta) \rangle = 6D\Delta. \quad (22.15)$$

Depending on the ratio between the root-mean-square displacement $\langle r^2(t) \rangle^{1/2}$ and the mean crystal radius R , either the coefficient of intracrystalline diffusion D_{intra} or the coefficient of long-range (extracrystalline) diffusion may be determined [22.168, 171, 173]. The lower limit of intracrystalline self-diffusivity is on the order of $10^{-12} - 10^{-13} \text{ m}^2 \text{ s}^{-1}$.

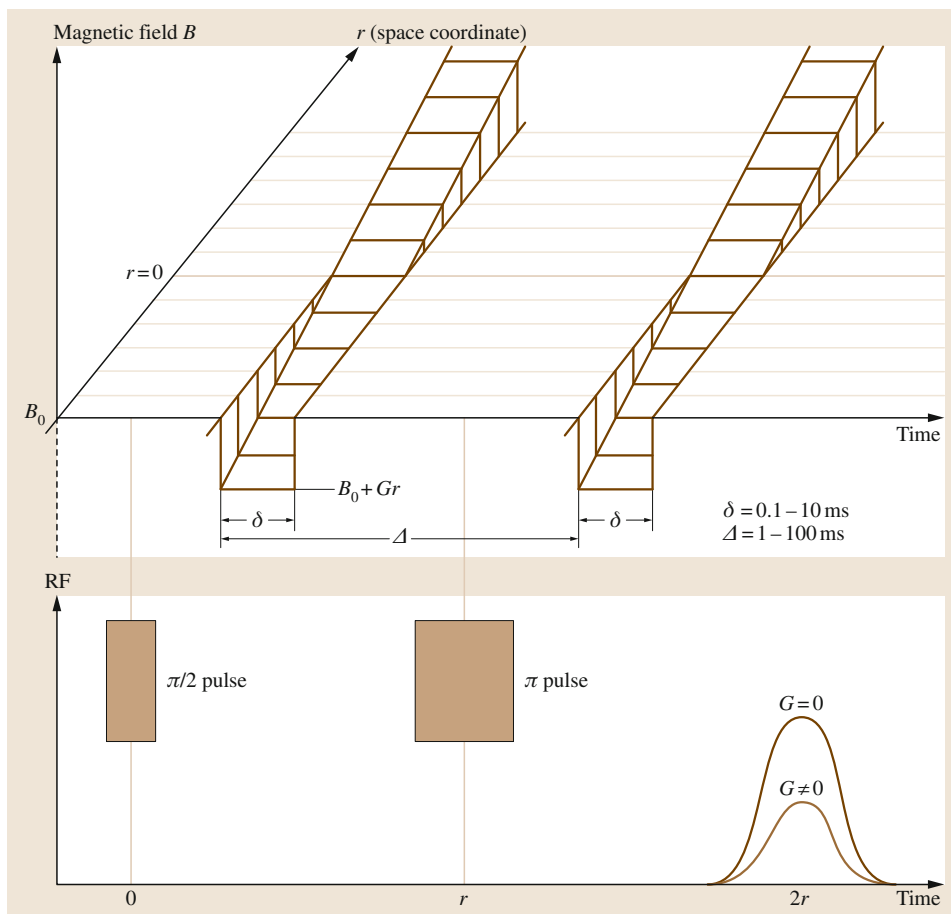

Fig. 22.14 Sequence of radiofrequency (RF) and field gradient pulses used in the NMR PFG method. (After [22.177], courtesy of AIP)

Extra- and intracrystalline diffusion can be readily distinguished by comparing a macroscopic (e.g., the apparent transport diffusivities obtained by volumetric method) and a microscopic (e.g., NMR) method. Indeed, extracrystalline diffusion of methane in natural chabazite depends on the crystal size, while intracrystalline diffusion is constant across the whole range of crystal sizes. Note that, for very large crystal sizes, both methods yield similar values, emphasizing the intracrystalline nature of the determined diffusion coefficients.

NMR tracer desorption measures the exchange rate of the molecules between crystal and surroundings [22.173]. If the measured desorption rate is equal to the intracrystalline diffusivity, no surface energy barrier limits desorption. In some cases, however, desorption rates are substantially reduced, showing the existence of a surface barrier.

Two specific examples are worth mentioning to illustrate molecular diffusion in pores of molecular sizes.

The first one deals with the transport diffusivity of linear alkanes in the potassium form of zeolite T. The mobility of C_4 – C_8 *n*-paraffins decreases with chain length, but for larger chain lengths, the mobility increases from C_9 to C_{12} and reaches a rather high value close to that of C_2 and C_3 molecules [22.168, 178]. For molecules larger than C_{12} the mobility decreases again with chain length. This effect was called the *window effect*: the length of *n*-octane molecule just fits the length of the erionite cage, resulting in entrapment of the molecule leading to low mobility. Molecules that are smaller or larger than C_8 do not fit the erionite cage and preserve their higher mobility. For molecules larger than C_{12} , however, the mobility decreases, as expected, due to the normal chain length effect.

Fig. 22.15 Snapshots of the location of $n\text{C}_4$ (n -butane) and $i\text{C}_4$ (isobutene) within the straight and zigzag channels of ZSM-5. (After [22.179], courtesy of Elsevier) ►

The second example concerns liquid-phase counterdiffusion of aromatic molecules into cyclohexane-saturated NaY. Here, the logarithm of the effective diffusion coefficient is linearly related to the critical molecular diameter, showing that the latter is the predominant parameter in the interaction. The diffusion coefficients vary within five orders of magnitude. This great variation is also the basis of the so-called shape-selective diffusion of molecules.

Molecular modeling methods are also used to study the diffusion of various molecules in the zeolitic channel system. A snapshot of a configurational bias Monte Carlo simulation is shown in Fig. 22.15, concerning diffusion of n -butane and isobutene in the channel network of a ZSM-5 model [22.179].

22.7 Acid–Base Properties of Zeolites

The acid–base properties of zeolites are of paramount importance in catalysis. It is also known that solid acid catalysts involved in the oil and chemical industries assure large economical yield. From the scientific point of view, the development of zeolite-based acid catalysts is also important, since a huge number of acid-catalyzed reactions are known. However, the catalysts used in these processes are very rarely solids that would fit with environmental requirements.

22.7.1 Acidity of Zeolites

A solid acid is able to convert an adsorbed basic molecule into its conjugated acid form. Therefore, the acid site is able to transfer either a proton from the solid to the adsorbed molecule (this type of acid center is called a Brønsted site) or an electron pair from the adsorbed molecule to the solid surface (this type of acidity is called Lewis acidity). Generally, both types of acid sites are present simultaneously in zeolites.

Brønsted acidic sites in zeolites, such as OH groups, should be formed on the surface, and should be able to transfer protons to the molecules adsorbed. For this purpose, OH groups containing mobile protons are required. Surface hydroxyl groups having the above-mentioned properties can be generated in various ways, e.g., direct ion exchange of zeolites with mineral acids

such as diluted HCl, HNO_3 , acetic acid, etc. Using this method, only zeolites with high Si/Al ratio may be transformed to protonic forms. Brønsted acidity can be generated by exchanging the counterions with ammonium or alkylammonium ions followed by calcination [22.2, 180]. Dissociation of water molecules under the influence of the strong electrostatic field of the multivalent cations, as well as reduction of transition- and noble-metal ion-containing zeolites with hydrogen, also provide protic sites.

The simplest way to generate Lewis acid sites is to prepare the metal ionic forms of zeolites, since the metal ions act as Lewis sites. High-temperature heat treatment results in completely dehydrated zeolite (presuming the zeolite itself survives).

Generally, heat treatment influences the state and the location of aluminum in zeolites. Upon heat treatment, Brønsted acid centers are converted to Lewis acid sites, while water is released. When the temperature of treatment is lower or equal to 573 K, essentially Brønsted acid sites are generated by calcinating the ammonium forms of the zeolites. At higher temperatures, however, e.g., at 773 K, dehydroxylation takes place, resulting in the formation of one Lewis site from two Brønsted ones. In so doing, the structure reorganizes and an aluminum ion leaves the framework to compensate the negative charge on the adjacent alu-

minum as AlO^+ . *Jacobs and Beyer* suggested this extra framework AlO^+ species to be the true Lewis acid site [22.181].

Acids with $-\text{H}_0 > 12$, the value referring to 100% sulfuric acid, are regarded as superacids in solution. The strength of Brønsted acids can be increased by chemical modification, for instance, replacing hydroxyl groups for fluoride, e.g., OH in H_2SO_4 resulting in HSO_3F ($-\text{H}_0 = 15$). The second method is mixing a strong Lewis acid to a weaker Brønsted one such as SbF_5 with HF, where the Hammett constant depends on the ratio of the components. This latter method can be easily applied for zeolites. The acidity of Brønsted centers can be enhanced by modification of their local environment by introducing Lewis acid centers at adjacent positions. Superacidity can arise from a synergetic interaction between Brønsted and Lewis acid sites.

The main techniques characterizing the acidity of zeolites comprise temperature programmed desorption (TPD) of preadsorbed bases, particularly ammonia, the indicator method, IR spectroscopy of adsorbed probe molecules such as pyridine or CO, and multinuclear NMR spectroscopy [22.182].

From the TPD pattern the concentration of acid sites can be determined, and the temperature maximum of the desorption peaks characterizes their strength. However, interferences may occur, with nonacidic adsorption sites leading to molecules strongly adsorbed by van der Waals forces.

The disadvantage of the titration method is the restricted accessibility of the acidic sites for basic probe molecules. If bases of suitable size are used, this method resembles the one generally used in solution; i.e., the indicator shows the equivalence in the acid–base couple.

IR spectroscopy examines the variation of the OH stretching frequency in different zeolites or the influence of adsorbed bases on the same stretching frequency. Two major hydroxyl species signals can be identified in zeolites: one with absorption band at 3740 cm^{-1} characterizing terminal defect hydroxyl groups ($\equiv\text{Si}-\text{OH}$), and another for the above-mentioned Brønsted acid site ($\equiv\text{Si}-\text{OHAl}\equiv$) with absorption band in the $3600\text{--}3650\text{ cm}^{-1}$ region.

IR spectroscopy is also able to distinguish between Lewis and Brønsted acid sites using pyridine as probe molecule. Pyridine associated with Lewis acid sites shows a band around 1450 cm^{-1} , while the pyridinium ion vibrates around 1545 cm^{-1} .

Although IR spectroscopy is a valuable technique for identification of different acid sites, it is

unable to yield quantitative results, because the relationship between the integrated intensity of the band and the amount of the species is not firmly established.

Multinuclear NMR identifies either directly the different OH groups by ^1H NMR spectroscopy, or indirectly using ^{13}C , ^{15}N , and/or ^{31}P NMR of adsorbed bases such as pyridine, ammonia, acetonitrile, carbon monoxide, nitrous oxide, and trimethyl phosphine [22.182–186]. In addition, the NMR method yields quantitative data for determination of the concentration of the different species present in the zeolites. ^{15}N NMR of adsorbed pyridine is of particular interest. Large upfield shift is observed upon protonation, and its variation is much larger than the ^{13}C NMR shift for the same molecule. Lewis acidity can also be probed by ^{15}N NMR of pyridine, provided that conditions of slow exchange prevail. For γ -alumina, silica–alumina, and acid-leached calcined mordenite, the chemical shift of the pyridine–Lewis acid pair complex (δ_{L}) could be estimated between -50 and -80 ppm [22.187, 188]. N_2O was also proposed as a base to probe surface Lewis acid sites [22.189]. Indeed, the terminal nitrogen atom is very sensitive to Lewis acidity, while it is only very slightly influenced by Brønsted acid sites. Moreover, this method is able to differentiate between the higher acidity of ZSM-5 and the lower acidity of zeolite HY. In these cases, because of the fast exchange between physisorbed and base–acid pair molecules, only an average ^{15}N NMR line is detected. ^{13}C NMR of carbon monoxide also predominantly probes Lewis acid sites. The NMR line is influenced by the strength and concentration of Lewis acid sites [22.186] to a large extent.

22.7.2 Basicity of Zeolites

The basicity of zeolites is much less well documented. In principle, one can distinguish between Lewis base sites linked to framework oxygen atoms and Brønsted base sites linked to basic hydroxyl groups. The former depends on the negative charge of the oxygen, while the latter depends on the extraframework cation present in the zeolite.

The basicity of zeolites is generally probed by IR of the NH stretching frequency of adsorbed pyrrole [22.190]. The NH stretching frequency decreases with increasing basicity of the sites in the order: Li-, Na-, K-, Rb-, and Cs-zeolite. In addition, it increases with increasing Al content [22.191], i.e., ZSM-5 (MFI) < mordenite (MOR) < L < Y < X.

22.8 Stability and Modification of Zeolite Structures

Since zeolites are widely used in chemical industry, how long a catalyst can remain in steam and how it can be modified to obtain better catalytic properties are relevant issues. Therefore, a great deal of work has been devoted to both the stability and modification of zeolites [22.2, 192–195].

As already discussed, zeolites are metastable solids; therefore, it is quite easy to modify the external surface, or the internal pore volume by pore blocking, create secondary pores, or vary the chemical composition, including isomorphous substitution of Al or Si.

22.8.1 Thermal Stability

The metastable nature of zeolites implies that conversion from one structure to another is possible, in certain cases even at room temperature [22.2]. Loss of intracrystalline water may result in structure collapse to an amorphous phase. Table 22.4 gives the temperature range of stability for various types of synthetic and natural zeolites [22.2].

The different counteranions retain different amounts of water. The water content is quasiconstant for Li^+ , Na^+ , and K^+ in chabazite, while it decreases rapidly as a function of ionic radius for NH_4^+ and Rb^+ . No satisfactory explanation exists at present to justify quantitatively the degree of hydration of the different zeolites. The two categories introduced distinguishing between hydrophilic and hydrophobic zeolites only indicate a tendency for water uptake.

22.8.2 Dealumination of Zeolites

Extraction of Al may lead both to changes in the acidic properties and to the formation of secondary structures. Selective aluminum removal without structure collapse

was first described for clinoptilolite using strong mineral acid [22.196]. Presently, hydrothermal treatment is used in most cases, with or without chemical treatment. The latter may include reaction with mineral acids (HCl , HNO_3 , HF), bases (NaOH), chelating agents ethylenediaminetetraacetic acid (EDTA), acetylacetone (Acac), $(\text{NH}_4)_2\text{SiF}_6$, SiCl_4 vapor [22.197] or CCl_4 vapor [22.198], gaseous COCl_2 [22.199], etc.

Dealuminated zeolite Y (or ultrastable zeolite Y) is widely used as a cracking catalyst, and hence its dealumination is more widely commented. In hydrothermal or steam treatment, the degree of dealumination increases as a function of the steam partial pressure [22.200]. Dealumination leads to zeolites being ultrastable to heat treatment. Note that dealumination is accompanied by significant contraction of the unit cell, and the number of Al atoms remaining can be estimated from the unit cell dimension [22.201]. The process can be followed in detail by, e.g., advanced NMR methods [22.202] (Fig. 22.16).

22.8.3 Formation of Secondary Pore Structure

During dealumination and acid leaching, larger pores (or mesopores) may be found, with diameters ranging from 20 to ca. 250 Å [22.203]. The secondary pores are generally formed during dealumination, while acid leaching is necessary for elimination of the amorphous material deposited in the channels and/or cavities [22.204, 205]. For high-temperature treatments, the pore volume decreases due to partial amorphization of the structure [22.203].

It has been shown not too long ago that the distinction between *small*- and *large*-pore mordenite (**SPM** and **LPM**) is essentially due to the presence of structural

Table 22.4 Approximate classification of some zeolites by their temperature stability as defined by thermal analysis

Temperature range of stability	Zeolite
Ambient to 250 °C	Harmotome, phillipsite, paulingite, heulandite ^a
250–400 °C	Gismondine, yugawaralite, stilbite, brewsterite, stellerite
400–600 °C	Laumontite, faujasite, natrolite, scolecite, mesolite, thomsonite, gonnardite, edingtonite, P, ZK-4
Over 600 °C	Analcime, erionite, offretite, chabazite, mordenite, clinoptilolite, bikitaite, wairakite, dachiardite, merlionite, mazzite omega, A, X, Y, L, ZSM-5
^a changes to heulandite B at 250 °C	

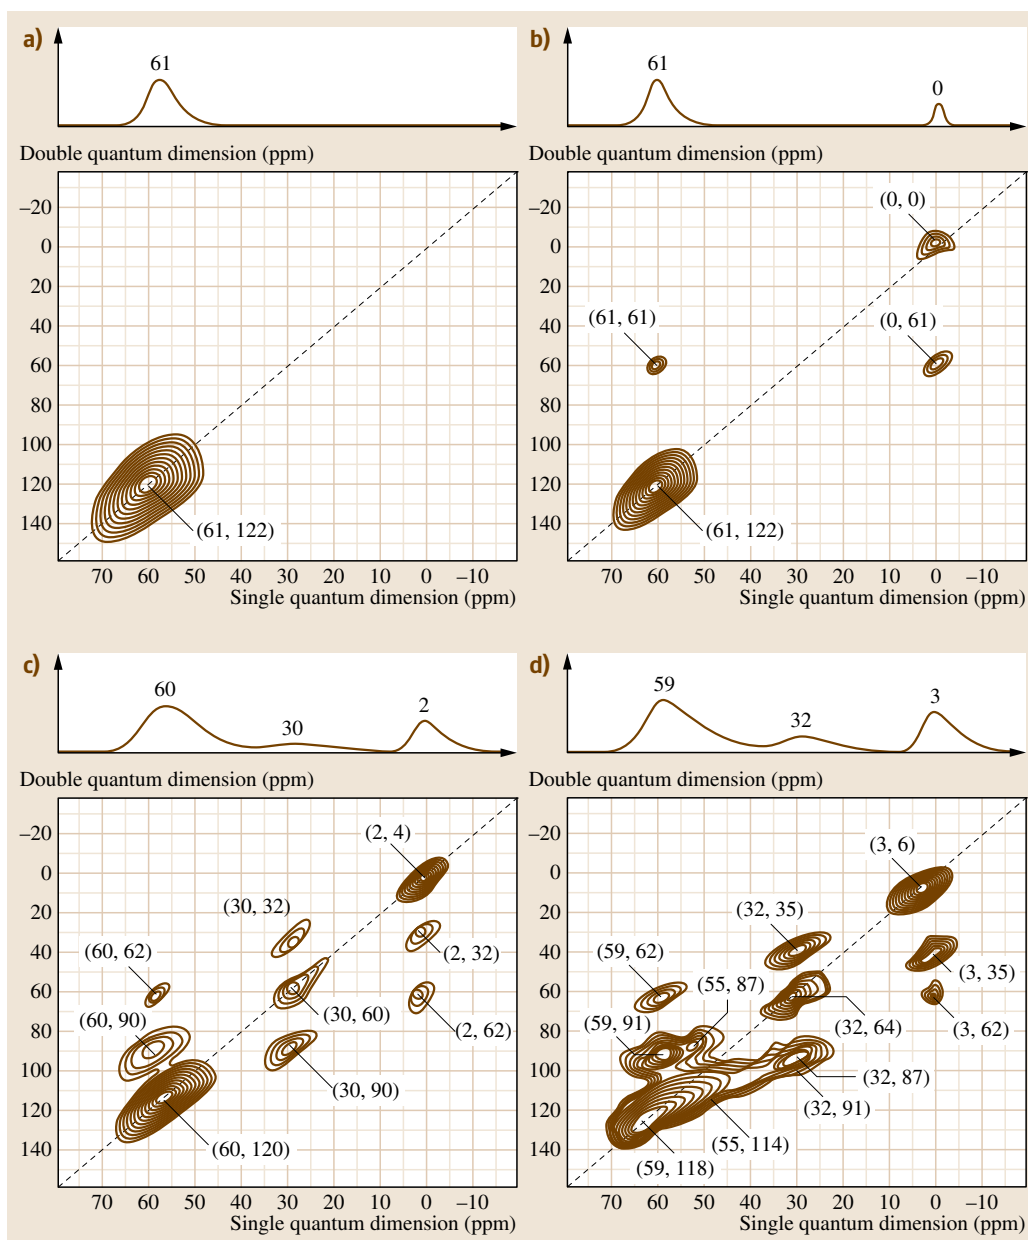

Fig. 22.16a–d ^{27}Al MAS and DQ-MAS (double quantum) NMR spectra of (a) parent HY, (b) HY-500, (c) HY-600, and (d) HY-700 zeolites. One-dimensional ^{27}Al MAS spectra are plotted on top of the two-dimensional ^{27}Al DQ-MAS spectra (calcination temperatures are 500 °C, 600 °C, and 700 °C). All spectra were recorded on hydrated samples at 18.8 T with a 3.2 mm probe at sample rotation rate of 21.5 kHz. (After [22.202], courtesy of Wiley-VCH)

defects along the channel axis c [22.206] in SP morденite. The blocking of the unidimensional channels is caused by a glide plane resulting in successive LPM blocks shifted from each other by $c/2$. Dealumination eliminates the blocking tetrahedral sites, and LPM may be obtained from SPM [22.207].

22.8.4 Isomorphous Substitution

Isomorphous substitution refers to the replacement of silicon or aluminum atoms of the structure by elements with ionic radii and coordination requirements which are compatible with the tetrahedral sites in the

zeolite structure [22.23]. The probability of isomorphous substitution has been discussed on the basis of the simplified version of Pauling's minimum radius ratio [22.208]. Be, B, Cr, Fe, Ga, Ge, etc. have been successfully incorporated in the zeolite structure [22.192]. Indeed, for these cations the ratio between the cation radius (r_c) and the radius of oxygen ion (r_o) satisfies the condition for tetrahedral surroundings, i.e., $0.414 > \rho_s > 0.225$. However, any cation can be occluded in isomorphous positions provided its concentration is low [22.209]. Substitution can be made directly during hydrothermal synthesis or by postsynthetic modifications.

For low Si/Al-ratio zeolites (X, Y, MOR, etc.), framework exchange methods using fluorides and nonaqueous solvents at low temperatures can be used [22.210]. For high-Si/Al zeolites, generally, steam, acid, and/or base treatment is required to create internal OH groups or hydroxyl nests. These hydroxyl groups readily react with metal salts, and the metal ions are incorporated during calcination [22.211, 212].

Incorporation of Al into zeolites from alumina [22.213] has potentially important practical implications, since commercial zeolite catalysts are composed of zeolite crystals embedded in binder matrices that are assumed not to contribute to the catalytic performance.

To control the pore-opening size without affecting the internal pore system of the zeolite, modifying agents with molecular size larger than that of the zeolite pores have to be used, so they cannot enter the pores and interact only with the external surface [22.214]. $\text{Si}(\text{OCH}_3)_4$ is deposited irreversibly on a H-zeolite. The alkoxide groups react with surface hydroxyl groups, and calcination with oxygen removes the residual hydrocarbon, producing silica-coated zeolites [22.194, 214, 215]. The adsorption behavior can be influenced by the degree of SiO_2 deposition on the external surface.

22.8.5 Transition-Metal Ions and Metal Particles in Zeolites

It is well known that transition-metal ions and metal particles are very important catalytic centers. Introduction of these ions and/or particles into zeolites modifies their properties as follows: they (i) can exhibit physical and chemical properties often not found in known complexes, (ii) are often low-coordinated and bind molecules specifically, (iii) can be moved from one sta-

ble position to another when bonded with molecules, and (iv) can induce specific chemical reactions in the sorbed molecules [22.216].

Na^+ and NH_4^+ cations can be exchanged by cations such as Rh^{3+} , Pt^{2+} , Ni^{2+} , Co^{2+} , Cu^{2+} , Re^{3+} (rare earth), etc. Ions of rare-earth elements incorporated into X or Y zeolites produce the widely used cracking catalysts [22.217].

Preparation of active organometallic catalysts within the intracrystalline volume of the zeolite structures is a challenge that is relevant to homogeneous and heterogeneous catalysis as well as to enzyme modeling [22.218].

Size-quantized CdS is easily prepared inside zeolite Y sodalite cages. First, ca. 90% of the Na^+ ions are replaced by Cd^{2+} ions. After calcination, the dry zeolite is treated with H_2S , generating Cd_4S_4 clusters in the sodalite cages [22.148]. The larger supercages remain empty and available for absorption of substrate molecules. The obtained catalyst can be used for photooxidation reactions.

The preparation of metal particles in zeolites involves ion exchange followed by calcination and reduction. Alternative methods may involve the decomposition of complexes, such as metal carbonyls [22.219, 220]. Pt^{2+} or Pd^{2+} ions are introduced by ion exchange by $\text{Pt}(\text{NH})_4^{2+}$ complexes. Calcination, in addition to destroying amine ligands and removing physisorbed water from the zeolite, affects the locations of the metal ions [22.219].

22.8.6 Coke Formation in Zeolites

Carbonaceous residues are inevitable byproducts of most heterogeneously catalyzed organic reactions [22.221]. The term "coke" designates deposits ranging from bulky molecules to heavy polynuclear aromatics. The formation of coke is usually acid-catalyzed, and it can become important on zeolite catalysts. The presence of coke generally leads to deactivation of the catalyst. It is hence of paramount importance to try to avoid coke formation, or if not possible, find a good way of catalyst regeneration.

Coke formed by secondary reaction products either blocks the pores of the zeolite or stays on the outer surface of the crystallites, or both [22.222, 223].

At very low coke content, coke molecules are smaller than the channel intersections, limiting but not blocking access to acid sites. At average coke content, coke blocks access to acid sites. At high coke content,

some it is deposited on the outer surface as well. The mode of deactivation very much depends on the zeolite pore structure, the nature of active sites, and the operating conditions [22.221, 222].

Coke deposits have been characterized by in situ spectroscopic techniques such as IR, UV-Vis, ^{13}C NMR, and electron paramagnetic resonance (EPR) spectroscopy [22.223, 224]. However, the precise composition of the coke can only be obtained when the carbonaceous compounds are recovered from the zeolite and analyzed via GC, ^1H NMR, mass spectrometry, etc.

It seems that coke molecules are formed inside the pores; coke on the outer surface results from its overflow onto the surface of zeolite crystallites [22.222].

22.9 Zeolites as Catalysts

The intrinsic catalytic activity of zeolites was first related to the presence of acid sites in their channels. They are either Brønsted or Lewis sites. Acid sites in zeolites are responsible for their activity in cracking, olefin isomerization (both double-bond migration and skeletal rearrangement), oligomerization, alkylation of aromatics, etc. Use of zeolites as basic catalyst is much less common; indeed, base-catalyzed reactions that have been studied included mainly dehydrogenation of isopropanol to acetone, isomerization of allyl cyanide, and side-chain alkylation of alkylaromatics with olefins or alcohols. In addition to their acid sites, zeolitic catalysts often require another type of active site, a hydrogenation/dehydrogenation component. In order to introduce this function, various methods can be used, such as physical admixture with the hydrogenation/dehydrogenation component, impregnation, ion exchange/adsorption, or vapor deposition. The hydrogenation/dehydrogenation component can be certain noble and transition metals (Pt, Pd, Ni, Co, etc.), metal oxides (ZnO , CuO , Ga_2O_3 , NiO , etc.), metal sulfides (NiS , Co/MoS , etc.), and metal complexes. Zeolites can be made capable to catalyze redox transformation as well. This functionality can be introduced by (i) direct incorporation of elements with changing oxidation states (e.g., titanium ions) during hydrothermal synthesis, or (ii) incorporation by postsynthetic treatments such as impregnation, ion exchange, isomorphous substitution, etc.

As previously described, zeolites are characterized by their unique, uniform pore/channel systems. Separation between molecules of different sizes or po-

At low temperature the retention of coke molecules is essentially due to their low volatility, while at high temperature it is due to trapping [22.222]. On H-ZSM-5 and H-MOR, aliphatic (10–60 ppm) as well as aromatic (120–150 ppm) compounds could be detected on both zeolites during methanol to hydrocarbon conversion [22.221, 224]. While only C-3 and C-4 compounds were identified on H-MOR, a variety of alkanes were entrapped on H-ZSM-5.

Regeneration of zeolites is carried out through coke combustion under air or oxygen flow [22.222]. Coke oxidation, like deactivation by coking, is a shape-selective process. The main difficulty is to limit the detrimental effects of water at high temperature on the active sites of the zeolite.

larities can be achieved by selecting the proper zeolite structure, with the proper chemical properties. Indeed, chemical composition affects the polarity of the inner pore surface of the zeolite, making it more hydrophilic (low $\text{SiO}_2/\text{Al}_2\text{O}_3$) or hydrophobic (low Al_2O_3 content, for instance). Consequently, this can affect the adsorption/desorption properties of molecules on the outer surface, but more importantly inside the pores. However, the main parameters influencing feed or product selectivity are the size of the molecules and of the zeolite channels. If a feedstock contains different types of molecules, some being too large to enter the zeolite pores, only the ones with smaller dimensions or correct shape will be allowed to enter the crystal to react. On the other hand, if a reaction can produce different products, only the product that can diffuse out of the zeolite crystal will be detected. Sometimes, both reactant and product molecules are able to diffuse rapidly in or out of the zeolite crystal. Nevertheless, some selectivity is observed for given products. The reaction intermediates leading to a given molecule can be larger than the space available near the catalytic site, and thus, they may be spatially constrained by the size and geometry of the zeolite cavities. This has been termed transition-state selectivity. Some zeolites of interest have intersecting channels of different size. This is the case for ZSM-5, mordenite, offretite, and ferrierite. Since the smaller channels will adsorb only the smaller molecules while both large and small molecules will enter the larger pores, a new type of shape selectivity can be achieved. This concept is known as the molecular traffic control effect [22.225].

Table 22.5 Commercial refining and petrochemical processes using zeolite catalysts. (After [22.2, 226, 227])

Processes	Catalysts	Remarks
Catalytic cracking	REY, REX, REMY, REMgY, HY high-silica medium-pore zeolites	Selectivity and high conversion (high-octane gasoline)
Hydrocracking	Faujasite (X, Y), mordenite, erionite loaded with Co, Mo, W, Ni, also HY, USY, CaMgY, and HZSM-5	High conversion
Selectoforming	Ni-erionite, Ni-erionite/clinoptilolite	Increase in octane number via LPG production
Hydroisomerization	Pt-mordenite	Converts low-octane pentanes and hexanes to higher-octane products
Dewaxing	Pt-mordenite, ZSM-5, silicalite, other high-silica, medium-pore zeolites (ferrierite)	Low pore and cloud points
Aromatization	Pt, K-L, Ba-L, silicalite, (Pt)Ga,Zn-ZSM-5	Aromatization of C ₆ –C ₈ cuts, aromatization of LPG
Benzene alkylation	ZSM-5	Ethylbenzene (and styrene) production with low by-product yield
Xylene isomerization	ZSM-5	Increase in <i>para</i> -xylene yield
Toluene disproportionation	ZSM-5, mordenite	Production of xylenes and benzene
Methanol to gasoline	ZSM-5, erionite	High gasoline yield with high olefin conversion rate to high-octane rating products
Fischer-Tropsch	Co- or Fe-ZSM-5	Natural gas to gasoline via CO/H ₂
deNO _x	Cu-ZSM-5 (H-mordenite)	Effluents clean-up

In addition to their molecular sieving properties that induce shape-selective effects in catalysis, zeolites can also be considered as small reactors, favoring for instance bimolecular reactions, as ionizing solid solvents or as solid electrolytes.

22.9.1 Zeolites in the Refining and Petrochemical Industry

Zeolites were introduced as catalysts in the late 1950s and early 1960s, in fluid catalytic cracking. This is their largest scale application even today. Numerous other applications in the refining and petrochemical industries have also been developed, including hydrocracking, dewaxing, reforming or dehydrocyclodimerization, deNO_x processes, oligomerization, alkylation, isomerization, methanol transformation to gasoline, and the Fischer–Tropsch process (Table 22.5).

22.9.2 Zeolites in the Fine Chemical Industry

Although the main uses of zeolites as catalysts or catalyst supports remain in the refining and petrochemical industries, more and more applications are being developed in the intermediate and fine chemicals area.

Actually, experiences gained in the refining and petrochemical areas with zeolite catalysts are being applied to other organic reactions involving fine chemicals. The accumulated knowledge allows enhancement of activity and selectivity and stabilization of the active catalytic sites in zeolite cavities. Replacement of homogeneous catalysts by heterogeneous materials often operated in fixed bed avoids problems due to corrosion of equipment, or separation of the catalyst from the products.

The major applications in this new field are proton or Lewis-acid-catalyzed reactions, using acidic zeolite materials, taking advantage of their shape-selective properties. Other functionalities can also be introduced, and acid–base properties can be modulated either during the hydrothermal synthesis, for instance, by introduction elements other than Si and Al in the zeolite framework, or by postsynthetic modifications, such as dealumination, ion exchange, impregnation, etc. This allows preparation of tailor-made catalysts by modulating the zeolite properties or by combining the zeolite with other catalyst sites, to achieve the best performance.

Reactions performed on zeolite catalysts involve double-bond isomerization, skeletal isomerization, dehydration, dehydrogenation, aromatic ring substitution

(halogenation, acylation, alkylation), isomerization of aromatics, selective hydrogenation, and selective oxida-

tion. This area has been reviewed several times [22.228–232].

22.10 Some Special Applications of Zeolites

Although the ion-exchange properties of zeolites have been well documented in relation to catalysis and molecular sieving, very few practical uses as ion exchangers have emerged [22.2]. A major technical barrier to zeolite use as ion exchanger is in their apparent lack of compatibility with column use. Synthetic zeolites have sizes which are too small (0.1–10 μm) to allow reasonable liquid transport through a bed of particles [22.2]. Therefore, granulated synthetic or ground natural zeolite rocks such as clinoptilolite or mordenite are preferred for column use. Another major reason preventing wide use of zeolites as ion exchangers is their inherent instability at low pH. The limit of acid resistance of low Si/Al-ratio zeolites is at pH 3–4. The growing awareness of the environmental damage created by the use of polyphosphate-containing detergents caused detergent manufacturers to seek less hazardous replacements [22.2]. The function of polyphosphate is to enhance the cleaning efficiency of detergents by removing Ca^{2+} and Mg^{2+} ions from washing water to prevent their precipitation by surfactants. Zeolite A has proved to be a suitable substitute, and its current application as a detergent builder represents a major success in direct use of zeolites as ion exchangers [22.233].

When spent nuclear fuel elements are removed from a nuclear reactor they are stored under water in ponds [22.2]. The pH of the water is 11.4 with respect to NaOH and Na_2CO_3 . Pond storage allows thermal and radiation cooling to take place prior to reprocessing. During the storage period a build-up of fission products – essentially $^{137}\text{Cs}^+$ and $^{90}\text{Sr}^{2+}$ – occurs in the pond water. Zeolites, such as mordenite and clinoptilolite, are used to decontaminate the effluent.

There is a constant need to remove heavy metals and ammonia from waste waters. Release of heavy metals into waste water is one of the most worrying pollution problems, since its effects on life may be particularly serious in plants and animals (mainly fish), and humans are also affected through the food chain [22.234]. Nitrogen pollution stems from municipal and industrial waste waters via washout of natural and artificial fertilizers, and seepage and runoff of liquid livestock wastes, effluents from aquaculture systems, and from food pro-

cessing plants [22.235]. Natural zeolites, clinoptilolite, phillipsite, and chabazite, are particularly useful to selectively eliminate ammonia [22.2, 236, 237] and heavy metals, such as Cd^{2+} , Pb^{2+} , Zn^{2+} , Cu^{2+} [22.2, 235], and partially Cr^{3+} [22.234].

In agriculture, natural zeolites such as clinoptilolite, phillipsite, and chabazite act as neutralizers of low pH of soils, traps for harmful heavy metals, and effective carriers of herbicides, fungicides, and insecticides [22.2, 235]. In husbandry, pigs consuming clinoptilolite show beneficial weight gain and are less subject to disease [22.2]. Moreover, natural zeolites such as clinoptilolite, chabazite, mordenite, erionite, and phillipsite actively adsorb volatiles (ammonia, carbon dioxide, hydrogen sulfide, and mercaptans) and have a strong deodorizing effect. In the diets of calves and poultry, zeolites act, in addition to the above-mentioned benefits, as veterinary hygiene agents by inhibiting embryonation of worm eggs and protozoa.

Every chemical laboratory in the world has a bottle of 4A beads for use as a general-purpose drying agent [22.2]. The organic liquids are generally dried on Linde 3A or 4A [22.2, 238]. For drying of gases, zeolites A, X, and Y are also used. CoCl_2 plays the role of an indicator: it is blue at low water content (tetrahedral Co^{2+}), while it is pink at high water content (octahedral Co^{2+}). Natural gas is dried on Linde 4A, 5A, and natural zeolites. Larger crystallites have longer lifetime. In order to dry gases containing polymerizable monomers, Linde 4A is used first to adsorb the monomers and then Linde 3A for dehydration.

Elimination of sulfur-containing gaseous species such as H_2S /COS or CH_3SH from natural gas and biogas is of paramount importance [22.238]. General use is made of Linde 5A, X, natural zeolites, or zeolites impregnated with Fe_2O_3 [22.238]. Liquid hydrocarbons are desulfurized by zeolite impregnated with CuSO_4 . Silanes are cleaned of PH_3 and AsH_3 on AgA zeolite, of ethylene on Linde 4A, POCl_3 on high-silica zeolite, and of HCl, HF, and SO_2 on H-mordenite [22.238]. Hydrogen is purified of nitrogen on Ca-mordenite, and the residual amount of nitrogen can be as low as 1 ppm [22.238]. Nitrogen is purified by eliminating oxy-

gen, methane, carbon monoxide, and carbon dioxide with the help of zeolites. For air purification, charcoal is used in combination with zeolites, impregnated or not with bactericides (Ag, KMnO_4 , etc.). Natural zeolites are used for air refreshing in freezers of airplanes or in cars. Various zeolites are used for deodorizing sewers, toilets, freezers, etc. Zeolites are also used to adsorb methane (firedamp) in coal mines or carbon monoxide in sealing equipment.

The dangerous isotopes of Cs^+ and Sr^{2+} are eliminated by ion exchange with zeolites. The adsorption properties of zeolites help to extract tritium from waters used in this process. Tritium is adsorbed in the form THO on zeolites Linde 5A and X or zeolite exchanged with Ag^+ [22.233, 238]. Heavy water D_2O is adsorbed on zeolite X. Radioactive iodine is eliminated using faujasite in its hydrogen- or Ag^+ -exchanged form, or using Ag-mordenite. The radioactive noble gases (Ar, Kr, Xe) are adsorbed on zeolite A or mordenite, which can then be vitrified under pressure or fixed by silicate cement [22.238].

The mobile cations in zeolites are apt to contribute to the ionic conductivity in batteries. The conductivity is dependent on the nature of the cation and the degree of hydration [22.238]. The anode is generally composed of a zeolite containing Li^+ , Na^+ , or K^+ . The cathode is a CrO_3^- , P^- , FeCl_3^- , Cl^- , or S-containing zeolite [22.239]. In the presence of organic electrodes, the zeolite is used for its dehydration properties. In dry battery, zeolite eliminates impurities (peroxides) and impedes passivation of the anodes.

Various applications are already in use in the food industry. Zeolite saturated with CO_2 gives instantaneous carbonation of aqueous preparations. Beer is stabilized with NaA and LiX, which adsorb proteins responsible for further degradation [22.238]. Dealkoholization of beer is achieved using silicates. Decaffeination is also performed with the help of dealuminated zeolite Y [22.240]. Fatty acids of comestible oil are eliminated on zeolite X. Also, everyday use of toothpaste reminds us of the utility of zeolites, as they are included as polishing and anticorrosion agents [22.241].

Zeolites are also used as supports for enzymes or antibodies [22.238]. Glucose oxidase is fixed on zeolite 4A and zeolite X. Coenzymes have been stabilized on 4A. The thermal stability of trypsin is greatly enhanced when adsorbed on zeolite 4A. Zeolite treatment is, however, not beneficial for all enzymes, as, e.g., β -galactosidase is deactivated in presence of zeolites.

The best known procedure for separation of *n*-paraffins from isoparaffins involves adsorption on zeolite 5A, from which the latter are excluded by virtue of their larger effective kinetic diameter [22.2]. Another large-scale molecular sieving separation is that of enriching gases from air (oxygen, nitrogen, and inert gases) [22.2, 238]. This can be carried out cryogenically, but new pressure sieving processes at near-ambient temperature are progressively being used to generate oxygen and nitrogen. Natural clinoptilolites and mordenites are used with success in portable pressure sieving oxygen generators for use in hospitals or as home oxygen supplies for patients with respiratory problems [22.2]. Separation of inositol and sorbitol has recently been realized on Ca-zeolite X. First sorbitol and second inositol are adsorbed from a mixture [22.242]. Release with the help of a desorbing agent yields firstly inositol and secondly sorbitol. Use of zeolites in chromatographic separation and quantitative determination is also beneficial [22.2, 238]. The amount of N_2O in blood has been determined using zeolite 5A. Capillary columns impregnated with zeolite 5A or X have high performance.

Conjugated polymers, such as doped polyacetylene, polyaniline, and polypyrrole, have potential applications based on their conducting properties, ranging from lightweight batteries, antistatic equipment, and microelectronics to speculative concepts such as *molecular electronic* devices [22.243]. Pyrrole can be polymerized within the cavities of faujasite and the unidimensional channels of mordenite. Polymerization required the presence of intrazeolite oxidants, such as ferric or cupric ions. Intrazeolite heteroaromatic polymer chains represent host-stabilized one-dimensional molecular conductors or molecular wires [22.243]. Zeolites are also used as polymers protecting against degradation by ultraviolet radiation [22.238, 244].

The textile industry also uses zeolites as additives to synthetic fibres (polyesters, polyamides, polyacrylonitriles, etc.). They protect them from degradation (Cu-zeolite), have a bactericidal effect (Ag, Cu-A, X or Y), an antistatic effect (with Fe_2O_3), or a deodorizing function, and help fixation of dyes [22.238].

The paper industry uses zeolites as fillers to give more density to paper [22.238].

Zeolites also favor adhesion of polymers onto steel; for example, polyethylene coated with Ba-mordenite and Ag, Zn, or Sn-A zeolite has better adhesion to steel [22.245].

22.11 Conclusions

We hope that this chapter has convinced the reader that zeolites and related substances are very versatile materials. Many varieties can be found in nature, and these as well as structures not found in our environment can be synthesized with relative ease. Their framework can be modified without great difficulty, which means they can be tuned for particular applications. Applications are numerous, ranging from molecular sieving to catalytic applications. The latter are of out-

most importance from oil refining to fine chemical industries. Active sites that can be generated in/on the framework are coupled with shape-selective effects, which is very useful in high atom-efficiency processes, which is one of the driving forces for constructing new frameworks with pore dimensions in the mesoporous range. This requirement keeps this area active today and will continue to do so in the foreseeable future.

Porous Anod

23. Porous Anodic Aluminum Oxide

Qiaoling Xu, Guowen Meng

Porous anodic aluminum oxide (AAO) is one of the typical self-organized fine structures with cylindrical pores of uniform diameter arranged in a hexagonal array. AAO has been commonly used as a template for synthesis of nanostructures with a variety of materials. In this chapter, we first describe the preparation of AAO templates with various pore structures, such as straight, branched, and step-shaped pores. Then, we focus on the use of AAO with different pore structures as templates for construction of nanostructures with various architectures, including one-dimensional (1-D) nanostructures and nanoheterostructures with linear and complex shapes.

23.1 Background

Anodic aluminum oxide (AAO) template, which is prepared by electrochemical anodization of aluminum in an acidic electrolyte, is one of the typical self-organized fine structures with a nanohole array. AAO templates contain cylindrical pores of uniform diameter arranged in a hexagonal array with pore densities as high as 10^{11} pores/cm². AAO templates are sold commercially, but only a limited number of pore diameters are available. However, Masuda and coworkers [23.1] established a two-step anodization process for fabrication of AAO templates with a broad range of pore diameter (5–267 nm). The dimensions of AAO templates can be easily tailored during the two-step anodization process. The pore diameters of AAO templates can be adjusted by varying the composition and concentration of the acidic electrolyte solution as well as the temperature and voltage of the anodization. The template thickness is dependent on the anodization time, with longer anodization resulting in thicker templates.

Compared with ion-track-etched membranes (e.g., polycarbonate membrane), inorganic AAO templates show advantages of high stability at high temperature and homogeneous pore distribution. AAO has been commonly used as a template for synthesis of one-dimensional (1-D) nanostructures with a variety of materials. In the early 1990s, Martin and coworkers [23.2, 3] pioneered use of AAO templates in synthesis of metal and polymer tubules, rods, and wires by electrochemical or electroless deposition. From then on, AAO templates were typically used for fabrication of a series of 1-D nanostructures of metals [23.4, 5], semiconductors [23.6, 7], polymers [23.8–10], carbons [23.11, 12], and other materials by different techniques including electrochemical deposition, the sol-gel technique, electroless deposition, and chemical vapor deposition (CVD). As well as for synthesis of 1-D nanostructures with single-component materials in AAO templates, progress has been made towards

the synthesis and design of more complex, multicomponent 1-D nanostructures, i.e., nanoheterostructures, in such templates. These nanoheterostructures contain heterojunctions between various combinations of metals, semiconductors, carbon, and polymers, having nanoscale 1-D morphology. The formation of 1-D heterojunctions has led to materials with unique properties and multiple functionalities not realizable in single-component structures that are useful for a wide range of applications [23.13–16].

Fabrication inside AAO templates is an ideal way to produce nanostructures with predesigned diameters and lengths, because the diameters and lengths of the nanostructures formed inside the nanochannels of AAO templates can be tuned by adjusting the pore diameter and the thickness of the templates, respectively. Nanostructures filled in the nanochannels of AAO templates can also replicate the morphologies of the nanochannels. Previously reported architectures created inside AAO templates were all linear shape,

until Xu et al. [23.17] reported the construction of Y-shaped carbon nanotubes (CNTs) in AAO templates with Y-branched pores. Later, Meng and coworkers [23.18] developed a rational approach for creating AAO templates with complex-shaped pores and fabricated a series of complex-shaped nanowires (NWs) and nanotubes (NTs) inside these templates. The complexity of such nanostructures may facilitate applications of these structures as complex nanoelectronics circuits and nanoelectromechanical systems.

In this chapter, we focus on the use of AAO templates with different pore structures for construction of nanostructures with various architectures. In Sect. 23.2, preparation of AAO templates with a variety of pore structures, including straight, branched, and step-shaped pores, is discussed in detail. In Sect. 23.3, we summarize the creation of 1-D nanostructures and nanoheterostructures with linear and complex shapes in AAO templates with various pore structures.

23.2 Preparation of AAO Templates

AAO templates are usually achieved by two-step anodic oxidation of aluminum in acidic electrolytes, as follows. High-purity Al foils ($\approx 99.999\%$) are degreased in acetone and then ultrasonically cleaned in ethanol and deionized water for several minutes. Then, the aluminum foils are annealed in vacuum at 450–550 °C for 4–5 h to enhance the grain size of the metal and to obtain homogeneous conditions for pore growth over large areas. Subsequently, the aluminum foils are mounted on a copper plate that serves as the anode and exposed to an acidic solution in an electrochemical cell. Anodization is conducted under constant potential in the acidic electrolyte. Oxalic acid solution is commonly used. The first-step anodization of the aluminum foil in oxalic acid solution is performed in 0.3 M solution at 8–10 °C under constant voltage in the range of 40–72 V_{DC} for 8 h. Then, the resulting anodic aluminum layer is removed in a mixed solution of phosphoric acid (6 wt %) and

chromic acid (1.8 wt %) at 60 °C. Different processes for the second-step anodization are carried out to construct AAO templates with different pore architectures (see below). After anodization, the remaining alumina is removed in saturated SnCl₄ solution. Subsequently, the pore bottoms are opened by chemical etching in 5 wt % aqueous phosphoric acid solution.

23.2.1 AAO Templates with Straight Pores

The second-step anodization for producing AAO templates with straight pores is carried out under the same conditions as in the first step. The thickness of the AAO template can be tuned by controlling the duration of the second-step anodization. The arrangement of the alumina pores is determined by the applied voltage, temperature, and electrolyte type and concentration. If special self-ordering conditions are used to anodize the

Table 23.1 AAO templates with different pore arrangements achieved under different self-ordering conditions (with permission from [23.19], © American Chemical Society (2002))

Electrolyte	Interpore distance (nm)	Inner-wall thickness (nm)	Pore diameter (nm)
H ₂ SO ₄ (25 V, 0.3 M)	66.3	7.2	24
(COOH) ₂ (40 V, 0.3 M)	105	9.1	31
H ₃ PO ₄ (195 V, 0.1 M)	501	54	158.4

aluminum, AAO templates with different pore arrangements can be achieved (Table 23.1).

23.2.2 AAO Templates with Branched Pores

Not only the thickness and pore arrangement of the AAO templates can be varied; also, the shape of the channels of the AAO template can be controlled. By reducing the anodization voltage in the second-step anodization, AAO templates with complex-shaped pores can be achieved; for example, Y-branched and multiple-branched pores can be achieved by reducing the anodization voltage once, while multiple generations of branched pores can be achieved by reducing the anodization voltage more than once. Second-step anodization processes for constructing branched pores are described below.

AAO Templates with Y-Branched Pores

For fabrication of AAO templates with the simplest branched pores of Y-branched pores, where one stem of the pore is divided into two branches, the second-step anodization is firstly performed to create primary stem pores under the same conditions as those in the first step. Then, the anodization voltage is reduced by a factor of $1/\sqrt{2}$ to form Y-branched pores. Figure 23.1 shows a scanning electron microscopy (SEM) image of the cross section of an AAO template with Y-branched pores. The stems and branches of the nanochannels can be clearly observed in the inset.

Fig. 23.1 SEM image of an AAO template with Y-branched nanochannels; the *inset* shows a close-up of the Y-branched nanochannels. The *dashed line* indicates the interface of the stems and branches (with permission from [23.20], © American Institute of Physics (2004))

AAO Templates with Multiple-Branched Pores

In the second-step anodization for creating nanochannels with a predetermined number of branches inside the AAO template, an anodizing voltage (denoted as V_s) is applied to form stem channels with large diameter (denoted as D_s), and then the anodizing voltage is reduced to a small value V_b to create the desired number (n) of branched channels of smaller diameter (denoted as D_b).

Based on the fact that the original total top-view area of the AAO template will not change during the whole anodization process, the original area of every stem channel ($(\pi/4)D_s^2$) equals the total sum of the areas of the n branched channels that divide from the same stem channel: $n(\pi/4)D_b^2$. Thus, the relationship between D_s and D_b can be expressed as

$$D_s^2 = nD_b^2. \quad (23.1)$$

The pore cell diameter (D) is proportional to the anodizing voltage (V) [23.18, 21],

$$D = kV, \quad (23.2)$$

where k is a constant. Combining (23.1) with (23.2), V_b for creating a predetermined number (n) of branched channels from a single stem channel can be calculated,

$$V_b = \frac{1}{\sqrt{n}} V_s. \quad (23.3)$$

After the initial anodization for the stem pores of an AAO template with multiple-branched pores, the template is cleaned in deionized water to remove oxalic acid solution remaining in the pores and the barrier layer at the pore bottom is thinned by immersing the samples in 5 wt% phosphoric acid solution at 31 °C for 30–70 min. Then, the anodizing voltage is reduced by a factor of $1/\sqrt{n}$ to create multiply branched (n branches) pores based on (23.3). If the voltage is reduced slowly, the stem pores are divided into branched pores gradually. On the contrary, the stem pores will be divided abruptly with sharp interfaces. It should be noted that, if the anodizing voltage for branched pores is lower than 25 V, sulfuric acid solution should be used as the electrolyte.

AAO Templates with Multiple Generations of Branched Pores

After the initial anodization for primary stem pores, the anodizing voltage is reduced by a factor of $1/\sqrt{n}$ ($n \geq 2$) to create the first-generation multiple-branched

pores, and subsequently by a factor of $1/\sqrt{m}$ ($m \geq 2$) to generate the second-generation multiple-branched pores from each of the first-generation multiple-branched pores. Further generation of branched pores can be created by sequentially reducing the anodizing voltage by a factor of $1/\sqrt{l}$ ($l \geq 2$). After any prior anodization, the samples should be washed in deionized water to clean acidic solution remaining in the pores. It is noted that, if the subsequent anodizing voltage is lower than 25 V, the anodization should be conducted in sulfuric acid solution at the same temperature as used previously.

23.2.3 AAO Templates with Step-Shaped Pores

The second-step anodization for AAO templates with step-shaped pores is performed under the same conditions as for the first step to create partial nanochannels. Then, the anodized sample is immersed in phosphoric acid solution to widen the existing pores. Subsequently, another anodization is carried out under the same conditions as in the previous step to create smaller-diameter channels of step-shaped nanochannels. Figure 23.2

Fig. 23.2 SEM image of the cross section of step-shaped nanochannels of an AAO template (with permission from [23.22], © Institute of Physics (2006))

presents a SEM image of the cross section of an AAO template with step-shaped nanochannels, clearly showing the large-diameter channels connected with the smaller-diameter channels.

23.3 Nanostructures Constructed in AAO Templates

AAO with uniform cylindrical pores can serve as an ideal mold for construction of nanostructures, such as 1-D nanostructures and nanoheterostructures. By adjusting the pore diameter and the thickness of the AAO template, the resulting nanostructures can have controllable diameters and lengths. More importantly, these nanostructures actually conform to the shape of the AAO template. Thus, nanostructures with linear and even more complex shapes (e.g., branched and step shapes) can be achieved by appropriately designing the shape of the nanochannels of the AAO template.

23.3.1 One-Dimensional Nanostructures

AAO with uniform and dense pores is commonly used as a template for synthesis of 1-D nanostructures, including NWs and NTs. 1-D nanostructures of various materials, such as metals, semiconductors, and nonconducting and conducting polymers, can be constructed in the nanochannels of AAO templates. The diameters of the 1-D nanostructures are determined by the pore size of the template.

Nanowires (NWs)

NWs of various materials can be constructed inside the nanochannels of AAO templates by various approaches, such as electrodeposition, electroless deposition, chemical vapor deposition (CVD), and the sol-gel process.

Electrochemical deposition is commonly used for synthesis of NWs in AAO templates. It is accomplished by coating one face of the template with a metal film for use as a cathode for electroplating. Electrochemical deposition offers marked advantages over other methods for synthesis of 1-D nanostructures because it does not require expensive instrumentation, high temperatures, or low vacuum pressures. This method is also not time-consuming, since nanomaterials grown via this approach have a high growth rate. Using this method, NWs of magnetic Fe, Co, and Ni [23.23, 24], metallic Zn [23.25], Ag [23.26], and Cu [23.27], as well as semiconducting CdS [23.28] have been deposited inside AAO templates.

The drawback of electrochemical deposition methods is that the material to be deposited must be both easily reduced and conductive. Meanwhile, modification of the metal layer on the templates makes the

experiment complicated. Thus, other techniques, such as electroless deposition, CVD, and the sol-gel process, have been developed for fabrication of materials that are poor conductors and not easily reduced to be deposited into the nanochannels of AAO templates. Xu et al. [23.29] reported an electroless deposition approach for fabrication of metallic NWs of pure metals (e.g., Au, Pt, Pd, Cu, Ni, and Co) and their alloys, by infiltrating aqueous solutions of metal chloride salts into Au-coated AAO template with Al foil on its outside edge. The formation of the metallic NWs is ascribed to the redox reactions of two galvanic cells where the Al foil acts as the anode. CVD methods have been used for synthesis of semiconducting NWs of SiGe alloy [23.30], Si [23.6, 31], and Ge [23.32] in AAO templates, where a metal catalyst (e.g., Au) is firstly electrochemically deposited in the nanochannels of the AAO template, then semiconducting NWs are grown by pyrolysis of source gas (e.g., silane and germane) under metal catalysis in the nanochannels. In addition, Miao et al. [23.33] reported fabrication of single-crystalline TiO₂ NWs inside the straight pores of an AAO template by a cathodically induced sol-gel method.

Nanotubes (NTs)

CNTs were one of the first reported 1-D nanoscale materials to be successfully synthesized using a variety of methods. Typically, the AAO-template-assisted approach provides an effective route for synthesis of ordered CNT arrays. It has been reported that uniform CNT arrays can be formed in nanochannels of AAO templates by CVD [23.34, 35].

Electrodeposition is also an important method for fabrication of NTs. Metal [23.36, 37], metal alloy [23.38], semimetal [23.39], semiconductor [23.40], and oxide [23.41] NTs have been reported to be prepared by electrodeposition in nanochannels of AAO templates. Yang et al. [23.39] reported fabrication of BiNTs by electrodeposition inside the nanochannels of an AAO template coated with a thin mesh-like Au layer onto one planar surface side. They demonstrated that the wall thickness of the BiNTs could be tuned by adjusting the thickness of the Au layer and the current density during electrodeposition. Resistance-temperature measurements revealed that BiNTs showed semiconducting electronic transport behavior, and the resistance of BiNTs with thinner walls showed greater temperature dependence than that of BiNTs with thicker walls.

The conventional sol-gel template process involves immersing an AAO template into a precursor sol, followed by gelation inside the pores. The driving force

in this technique is capillary action. This approach has been commonly used for synthesis of NTs made from oxides such as TiO₂, WO₃, ZnO, and SiO₂ in AAO templates [23.42, 43]. The internal diameters of the NTs can be adjusted by varying the concentration and viscosity of the initial sol as well as the immersion time. Kovtyukhova et al. [23.44] reported a *surface sol-gel* method for fabrication of SiO₂ NTs in AAO templates. This method involves repeats of a two-step deposition cycle in which adsorption of a molecular precursor and the hydrolysis step are separated by a post-adsorption wash. The *surface sol-gel* method allows fine control over the thickness of the NTs. Wu and coworkers [23.45] reported an improved sol-gel method for fabrication of Eu₂O₃ NTs in AAO templates. This method involves immersing the AAO template in a precursor sol, after which the template is taken out of the sol and sintered in a tube furnace. During the sintering process, the sol inside the nanochannels of the AAO template is changed into gel by condensation reactions, and the gel is further turned into Eu₂O₃ nanocrystallites. Via this approach, the same group also prepared Y₂O₃:Eu NTs by using AAO as template [23.46].

Atomic layer deposition (ALD) has been developed for synthesis of NTs in AAO templates. This method is based on successive, surface-controlled reactions from the gas phase to produce thin films and overlayers in the nanometer range with perfect conformality and process controllability. For synthesis of inorganic NTs, ALD is superior to the other approaches in terms of versatility and wall thickness control. Lee et al. [23.47] reported fabrication of Ru NTs in an AAO template by ALD. The NTs had diameter of 50 nm and aspect ratio of 10. The wall thickness of the Ru NTs could be precisely controlled from 13 to 23 nm by adjusting the number of ALD cycles. Farhangfar et al. [23.48] reported growth of high-aspect-ratio (≈ 300) ZnS NTs inside the pores of AAO templates by ALD at low temperature. The diameter (30–200 nm), wall thickness (10–60 nm), and length (up to several tens of micrometers) of the NTs could be precisely tailored by a combination of electrochemical and ALD techniques. Pitzschel et al. [23.49] first utilized ALD to coat the internal pore walls of the AAO template with conformal layers of an oxide, then ferromagnetic Fe₃O₄ NTs of 10 nm wall thickness and 10–30 μm length were prepared.

23.3.2 Complex-Shaped 1-D Nanostructures

The 1-D nanostructures formed in AAO templates discussed above are all linear in shape. By predesigning

the morphology of the nanochannels of the AAO templates, nanostructures with more complex shapes can be achieved. In the following, we focus on the synthesis of branched and step-shaped nanostructures by using AAO templates with correspondingly shaped nanochannels.

Y-Branched and Multiple-Branched Nanostructures

Among the branched nanostructures constructed inside branched nanochannels of AAO templates, Y-branched ones are the simplest. Xu et al. [23.17] first reported construction of Y-branched CNTs inside an AAO template with Y-branched nanochannels using CVD. The fabrication process of the Y-branched CNTs is as follows. Firstly, a Y-branched nanochannel AAO template is synthesized via a two-step anodization process. Then, a small amount of cobalt catalyst is electrochemically deposited in the bottom of the template channels and the catalyst is reduced at 600 °C for 4–5 h under carbon monoxide flow. Finally, Y-branched NTs are grown by pyrolysis of acetylene at 650 °C. They considered that the resulting well-aligned Y-branched CNTs with controllable length and diameter of the stem and branches have potential in nanoelectronics. Further research revealed that the Y-branched CNTs show intrinsic nonlinear transport and reproducible rectifying behavior at room temperature [23.50], further confirming that these Y-junction NTs represent new heterojunctions for use in nanoelectronics.

By using AAO templates with Y-branched nanochannels, Y-branched semimetallic and metallic NWs can also be created via electrochemical deposition. Tian et al. [23.20] reported fabrication of Y-branched BiNWs embedded in AAO templates by electrochemical deposition, with stems 80 nm in diameter and branches 50 nm in diameter. Current–voltage measurements revealed that the parallel Y-branched BiNWs exhibited characteristics of conventional metal–semiconductor junctions. Mahima et al. [23.51] reported construction of Y-branched Pt NWs in AAO templates, which showed unique electrocatalytic activity for formic acid and ethanol oxidation (two important reactions for microfuel cells). Yang et al. [23.52] reported synthesis of Y-branched CuNWs and NTs by using AAO with Y-branched nanochannels via electrodeposition, with an Au layer sputtered onto the planar surface of the stem-channel side of the Y-branched AAO template. For synthesis of Y-branched CuNTs, the Au layer must be thin enough to leave the pores open and cover only the top-view surface of the pore walls, while for fabrication of Y-branched Cu NWs, the Au layer must

be thick enough to cover the pores completely. Figure 23.3a shows an SEM image of the stem roots of Y-branched CuNTs with stem-tube outer diameter of about 70 nm. Figure 23.3b shows a side-view SEM image of a bundle of Y-branched CuNTs, clearly showing the Y-shaped topology of the NTs. Figure 23.3c,d shows transmission electron microscopy (TEM) images of Y-branched CuNTs with tube-wall thicknesses of about 10 and 20 nm obtained inside the Y-branched nanochannels of an AAO template, with the stem surface side coated with Au layers of about 20 and 30 nm thickness, respectively. In situ x-ray diffraction investigation demonstrated that the thermal expansion of the Y-branched CuNTs and NWs was temperature dependent and that the thermal expansion coefficient of the stem of the CuNTs and NWs was higher than that of the branches.

By using AAO with Y-branched nanochannels as a template, Xu et al. [23.53] demonstrated fabrication of not only Y-branched metallic NWs but also Y-branched conducting polymer NWs by electrochemical deposition. Figure 23.4a shows an SEM image of electrodeposited Y-branched Au NWs after removing the AAO template. The diameters of the stems and the branches of the NWs are 80 and 50 nm, respectively, being consistent with those of the stem and the branches of the template channels. By an electrochemical polymerization process, Y-branched polypyrrole (PPy) NWs can be formed inside the channels of an AAO template. This process is accomplished in an electrolyte solution containing pyrrole under a positive potential. Figure 23.4b shows an SEM image of the resultant Y-branched PPy NWs after template removal.

It is known that a metal layer can be coated on either side surface of AAO templates with straight or Y-branched nanochannels prior to electrodeposition of NWs and NTs. However, for branched templates having nanochannels with more than two branches, the metal layer has to be sputtered onto the stem channel side of the templates to make the stem and the branches well connected, because the NWs or NTs electrodeposited inside the AAO nanochannels usually have different lengths. By using a three-branched AAO template with its stem channel side coated with a gold layer, three-branched Au NWs have been achieved by electrodeposition, as shown in Fig. 23.4c.

By using AAO templates with branched nanochannels, Meng and coworkers [23.54] constructed metallic NWs with predesigned branched architectures by electrodeposition. Firstly, they created AAO templates with nanochannels having a predetermined number of

branches, such as two- (or upside-down Y-), three-, and four-branched nanochannels by reducing the applied anodizing voltage multiple times during the second-step

anodization of the aluminum (Fig. 23.5a). Then, metal NWs were electrodeposited in the branched nanochannels of the AAO template with the stem side coated

with a metal layer as electrode (Fig. 23.5b). Using such nanochannel-confined electrochemical deposition, Y-branched Au NWs were constructed, as shown in Fig. 23.5c,d. The diameter of the stem segment and the branches of the Y-branched Au NWs were about 50 and 35 nm, respectively. By using similar approaches, two-, three-, and four-branched Ni NWs were also created, as shown in Fig. 23.5e–j. The stem and branch diameters of the two-, three-, and four-branched Ni NWs were 90 and 55 nm, 120 and 50 nm, and 125 and 50 nm, respectively.

Xu et al. [23.29] recently developed a porous AAO-template-assisted galvanic deposition approach for fabrication of branched metallic NWs, by infiltrating aqueous solutions of metal chloride salts into an Au-coated native AAO template with Al foil on its outside edge. The formation of the metallic NWs can be ascribed to the redox reactions of two galvanic cells where the Al foil acts as the anode. Y-branched Au NWs have been constructed by infiltrating aqueous HAuCl₄ solution into an AAO template with Y-branched nanochannels. Figure 23.6a shows a low-magnification SEM image of a bundle of Y-branched Au NWs after template removal. The interface between the larger-diameter stems and the smaller-diameter branches can be clearly observed. The Y-branched junctions are obvious in the high-magnification image shown in Fig. 23.6b. The diameters

of the stems and branches are about 80 and 50 nm, respectively.

Multiple Generations of Branched Nanostructures

By using AAO templates with tree-like multigeneration branched nanochannels, Meng et al. [23.18] constructed multigeneration branched nanostructures. AAO templates with the simplest multigeneration branched nanochannels, in which each generation divides into two branches, were fabricated. Typically, four generations of two-branched complex channels were obtained by sequentially reducing the applied anodizing voltage four times during the anodization, each time by the same factor of $1/\sqrt{2}$. Four-generation Y-branched CNTs could be achieved by depositing CNTs in the four-generation Y-branched channels via CVD. Figure 23.7a (left) shows an SEM image of a large bundle of four-generation Y-branched CNTs obtained after template removal, with four parallel interfaces showing where each of the four generations of Y-branching takes place. Figure 23.7a (right) shows a schematic of the architecture formed inside the template. High-magnification images of each of the interfaces (Fig. 23.7b–e) clearly reveal the corresponding Y-branches. The diameters of the primary stems and the branches depend on the corresponding anodizing voltages, while the length of each branch is controlled

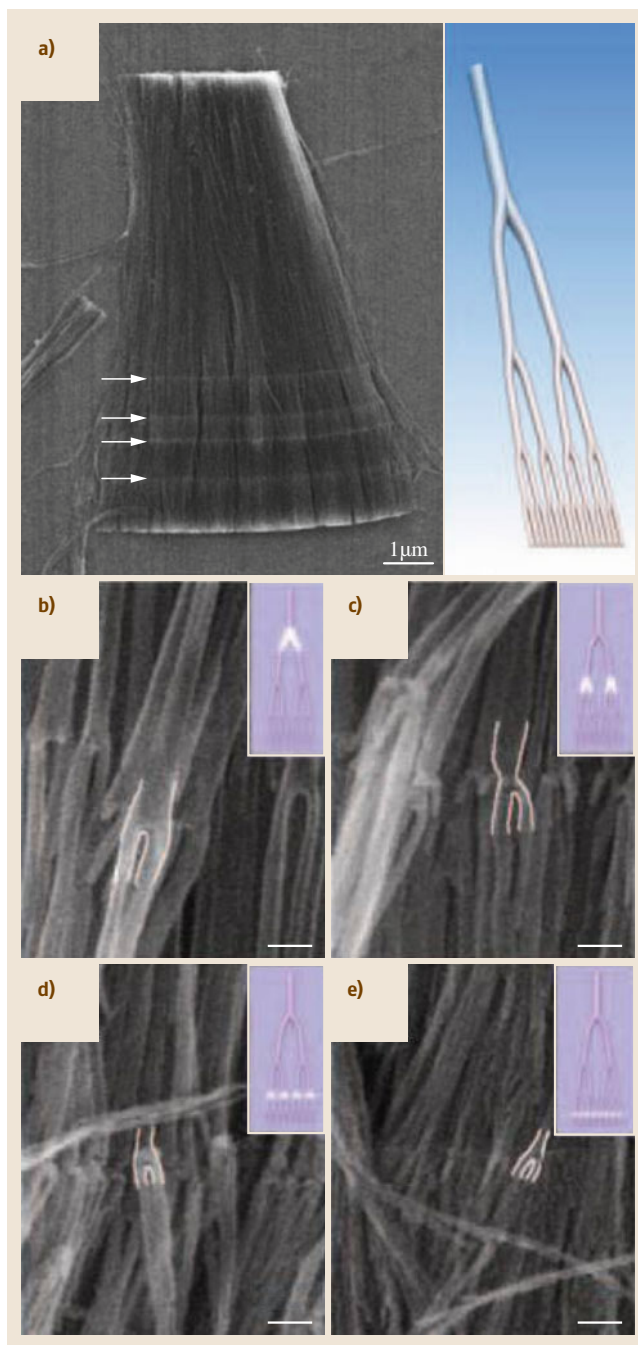

Fig. 23.7 (a) *Left*: Low-magnification SEM image of four-generation Y-branched CNTs, with the four parallel interfaces indicate by white arrows. *Right*: Structure of typical four-generation Y-branched CNTs. (b–e) High-magnification images from each interface clearly revealing the corresponding Y-branches and the decreasing diameter of the branched nanotube segments, showing the first (b), second (c), third (d), and fourth (e) Y generations. The Y-junction is contoured by white lines for clarity. *Insets at top right* show schematics of the whole architecture with the specific junction highlighted in white. goal can be achieved by reducing the anodizing voltage in steps, by factors of $1/\sqrt{2}$ and $1/\sqrt{n}$ sequentially, consecutively generating Y-shapes and n -branched pores in the template. Continuing this approach, more complicated architectures, such as a single stem dividing into multiple branches each of which further subdivides into multiple branches, can be created. Meng et al. [23.18] reported the construction of two-generation branched CNTs, with each generation having three branches. AAO templates with three-branch-three-subbranch tree-like channels were created by sequentially reducing the applied anodizing voltage by a factor of $1/\sqrt{3}$. Using AAO with such tree-like branched channels as templates, CNTs with three-branch-three-subbranch morphology have been constructed via CVD. Figure 23.8a shows an SEM image of CNTs with three-branch-three-subbranch morphology, where two levels of multiple branching are shown. The primary stem first splits into three branches, each of which further splits into three subbranches. The high-magnification SEM images of the two interfaces (Fig. 23.8b,c) reveal the junctions, showing the branching and the diameter reduction as the branching occurs. These branched NTs could be used to build large supramolecular constructs for applications such as drug delivery, nanoscale separation, and fundamental diffusion studies, and also as complex nanoelectronics circuits and nanoelectromechanical systems.

Step-Shaped Nanostructures

Using AAO templates with other complex-shaped nanochannels, such as step shape, step-shaped nanostructures can be constructed. Tian et al. [23.22] reported fabrication of step-shaped BiNWs inside step-shaped nanochannels of AAO templates by electrodeposition. The current–voltage characteristics of the parallel uniform BiNWs showed conventional metal–semiconductor junction behavior.

independently by the anodization time for each corresponding pore segment generation.

A combination of Y-shapes and multiple branches can lead to a wealth of new nanoscale architectures. This

Yang et al. [23.52] reported synthesis of step-shaped CuNWs and NTs using AAO templates with correspondingly shaped nanochannels via electrodeposition (Fig. 23.9). To obtain NWs, the coated Au layer must be thick enough to fully cover the nanopores of the step-shaped AAO templates. Figure 23.9 shows a schematic and a TEM image of the step-shaped CuNWs, clearly showing that the large-diameter segments of the NWs are well connected to the small-diameter segments. In situ x-ray diffraction investigation demonstrated that the thermal expansion of the step-shaped CuNTs and NWs was temperature dependent and that the thermal expansion coefficients of the large-diameter segments of the CuNTs and NWs were greater than that of the small-diameter segments.

23.3.3 Nanoheterostructures

Nanoheterostructures can be synthesized inside nanochannels of AAO templates by various synthetic approaches, such as sequential electrodeposition, some combined techniques, etc. In the following, the fabrication of two kinds of nanoheterostructures (i.e., segmented and core/shell nanoheterostructures) in AAO templates is demonstrated in detail.

Segmented Nanoheterostructures

Sequential electrodeposition is commonly used for synthesis of segmented nanoheterostructures. This method has been used to fabricate metal–polymer heterostructures in AAO templates. Park and coworkers [23.55] reported synthesis of segmented nanorods made of Au hydrophilic blocks and PPy hydrophobic blocks that behave as mesoscopic amphiphiles in the AAO template by sequential electrodeposition. In a typical experiment, Au–PPy nanorods were prepared by electrodeposition of gold into the AAO templates, followed by electrochemical polymerization of pyrrole, then removal of the AAO template. The amphiphilic structures had pseudoconical shape because of a difference in diameter between the Au (large) and polymer (small) sections. They could assemble into three-dimensional bundle- and tubular-shaped microscale architectures.

Sequential electrodeposition also can be applied for synthesis of segmented metal–semimetal nanoheterostructures in AAO templates. Yang and coworkers [23.56] reported fabrication of heterostructures of NTs and NWs of metal Cu and semimetal Bi by sequential electrodeposition of the two materials inside nanochannels of an AAO template with an Au layer thin enough to leave the pores open. Segmented het-

eroheterostructures of CuNTs and BiNWs (CuNT-BiNW) were achieved by electrochemical deposition of Cu first, then Bi in the nanochannels of the AAO template with one side coated with an Au layer which was thin enough to leave the pores open and cover only the top surface of the pore walls. Similarly, if the electrodeposition sequence was changed to Bi first, then Cu, segmented heterostructures of BiNTs and CuNWs (BiNT-CuNW)

Fig. 23.12 Procedure for preparation of metal NTs and the proposed mechanism of metal NT growth (with permission from [23.57], © Wiley-VCH (2005))

could be achieved. Figure 23.10a shows SEM images of the electrodeposited CuNT segments. It can be clearly observed that the CuNTs have closed caps on the top. BiNW segments were subsequently deposited on the CuNTs to form CuNT–BiNW heterostructures, as shown in Fig. 23.10b. The junctions between Cu and Bi can be clearly observed. The light-contrast segment and the dark-contrast segment are CuNT and BiNW, respectively. The SAED patterns (insets in Fig. 23.10b)

indicate that the CuNT is polycrystalline, while the BiNW is single crystalline. I – V curve measurements on these two kinds of heterostructures (Fig. 23.11) revealed that the CuNT–BiNW heterojunction arrays are metal–metal junctions, while the BiNT–CuNW heterojunction arrays showed metal–semiconductor electronic transport behavior.

Electrodeposition can be used for fabrication of segmented nanoheterostructures of other materials in

Fig. 23.13 Schematic illustration of synthesis of segmented CdS-BiNWs: (a) sputtering a thick gold layer, (b) electrodeposition of BiNWs, (c) sensitization of channel wall, (d) chemical bath deposition of CdSNWs, (e) removal of the Au layer (with permission from [23.61], © Elsevier (2008))

AAO templates; For example, *Liu et al.* [23.13] prepared segmented Pt-Ru, Pt-Ni, and Pt-RuNi nanorods by sequential electrodeposition of the metals into the nanochannels of AAO templates. They found that the segmented nanorods were catalytically active for room-

temperature electrooxidation of methanol in acidic solution. *Zhang et al.* [23.58] synthesized segmented Sb-BiNWs inside nanochannels of AAO templates by sequential electrodeposition using two different electrolytes. The segmented Sb-BiNW arrays showed resistive switching behavior that may find applications in metal-semiconductor field-effect transistors. Using a single bath, Sb-Bi [23.59] and Bi-BiSb [23.60] superlattice NWs have been prepared in AAO templates by pulse electrodeposition.

Using a modified electrochemical deposition technique, *Lee et al.* [23.57] fabricated multisegment Au-Ni NTs in AAO templates. A typical fabrication process is shown in Fig. 23.12. Ag nanoparticles were first immobilized on the pore walls of the AAO template by spontaneous reduction of Ag^{I} by Sn^{II} , which is a modification of the previously established sensitization-preactivation process of AAO prior to electroless deposition of metals. Then, sequential electrodeposition of Au and Ni in the AAO template resulted in multisegment Au-Ni NTs. It is believed that the Ag nanoparticles immobilized on the nanochannel surfaces play a key role in the growth of the metallic NTs, enabling preferential electrodeposition of metal along the nanochannel surfaces.

Segmented heterostructures can also be achieved by methods combining electrodeposition with other techniques. *Yang et al.* [23.61] reported fabrication of segmented CdS-BiNWs in AAO templates via a method combining electrodeposition with electroless deposition. In a typical process (Fig. 23.13), BiNWs are first electrodeposited inside the nanochannels of the AAO template with a thick Au layer sputtered on one side surface. Then, the nanochannels of the AAO template are activated by Sn^{2+} and Pd^{2+} . The Pd^{2+} is deoxidized by Sn^{2+} via the reaction $\text{Sn}^{2+} + \text{Pd}^{2+} = \text{Pd} + \text{Sn}^{4+}$, leading to Pd nanoparticles attached to the channel walls of the AAO template. The Pd nanoparticles serve as seeds for subsequent heterogeneous nucleation and

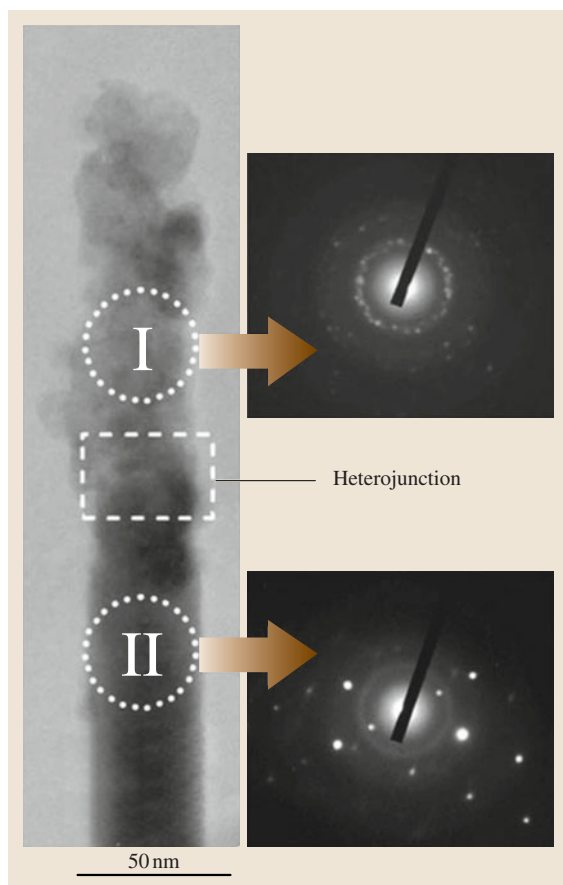

Fig. 23.14 A TEM image with SAED patterns of segmented CdS-BiNWs (with permission from [23.61], © Elsevier (2008))

growth of CdSNWs. When the AAO template is immersed in a mixed solution of CH_3CSNH_2 and CdCl_2 , CdSNWs are deposited in the AAO template via the reactions $\text{CH}_3\text{CSNH}_2 \rightarrow \text{CH}_3\text{CN} + \text{H}_2\text{S}$ and $\text{CdCl}_2 + \text{H}_2\text{S} \rightarrow \text{CdS} + 2\text{HCl}$. Figure 23.14 shows a TEM image of the resulting segmented CdS–BiNWs. SAED patterns taken from the segmented NWs reveal that the CdSNW segment is polycrystalline whereas the BiNW segment is single crystalline. Measurements of the resistance–temperature relationship (Fig. 23.15) reveal that the CdS–BiNW heterojunctions display semiconductor–semiconductor behavior.

Han et al. [23.62] reported synthesis of two-segment CdSNW–CNT and three-segment CNT–CdSNW–CNT heterostructures inside nanochannels of AAO templates by a method combining electrodeposition with CVD. Figure 23.16 shows the fabrication procedure for the segmented nanoheterostructures. Two-segment CdSNW–CNT heterostructures were achieved by first electrodepositing CdSNWs in the nanochannels of an AAO template with one side coated with a silver layer as electrode, and then growing CNTs in the remaining empty channels via CVD. Three-segment CNT–CdSNW–CNT heterostructures were obtained by adding a procedure to selectively etch part of the deposited CdSNWs before chemical vapor deposition of the CNTs. Figure 23.17a shows a top view of the CNTs. Figure 23.17b and c show SEM images of a bundle of CdSNW–CNT and CNT–CdSNW–CNT heterostructures, respectively. The close-up view of the CdSNW–CNT heterojunctions in Fig. 23.17d clearly shows that the CNT and CdSNW are well connected.

Fig. 23.15 Temperature dependence of the resistance of a segmented CdS–BiNW array (with permission from [23.61], © Elsevier (2008))

EDS spectra (Fig. 23.17e,f) reveal that the light- and dark-contrast parts in Fig. 23.17b,c are CdSNW and CNT segments, respectively. The TEM image of a single CdSNW–CNT junction in Fig. 23.17g shows good connection between the CdSNW and CNT. The SAED pattern (inset in Fig. 23.17g) indicates that the NW is single-crystal CdS with hexagonal structure. The high-resolution TEM image of the CdSNW–CNT junction in Fig. 23.17h shows that the CNT is closely ended at the CdSNW tip and that good adherence is achieved between the CdSNW and CNT. Electronic transport

measurements reveal that the CdSNW–CNT heterojunctions show ohm-like behavior.

Xu et al. [23.29] used the porous AAO-template-assisted galvanic deposition approach for fabrication of segmented metallic NWs consisting of different metals or alloys with distinct properties, by sequentially infiltrating corresponding aqueous solutions of metal chloride salts into the same piece of Au-coated native AAO template with Al foil on its outside edge. After sequential infiltration of HAuCl₄ and NiCl₂ aqueous

solution into the nanochannels of the AAO template, two-segment Au–Ni NWs were obtained. Figure 23.18a shows an SEM image of the resulting two-segment Au–Ni NWs, clearly showing an interface between the two segments with different contrast. Figure 23.18b shows a TEM image of an individual two-segment Au–Ni NW. The dark-contrast segment is single-crystalline Au NW, whereas the light-contrast segment is polycrystalline Ni NW (Fig. 23.18c,e). The lattice-resolved image taken at the junction interface of the Au and Ni segments in

Fig. 23.18 (a) Side-view SEM image of two-segment Au-Ni NWs, with a black dashed line showing the interface of the two segments having different contrasts. (b) TEM image of part of the segmented NW near the junction area, along with SAED patterns taken from (c) the Au segment and (e) the Ni segment; (d) lattice-resolved image of the Au-Ni interface (with permission from [23.29], © American Chemical Society (2009))

Fig. 23.18d reveals that Au(111) plane is nearly parallel to Ni(111) plane. Using such an approach, multisegment metallic NWs with individual segments having distinct properties also could be achieved via multiple sequential infiltrations; for example, three-segment Au-Ni-Au NWs could be synthesized by sequentially infiltrating HAuCl_4 , NiCl_2 , and HAuCl_4 aqueous solutions into the nanochannels of the AAO template.

Core/Shell Nanoheterostructures

Sequential electrodeposition is a common approach to create core/shell nanoheterostructures in AAO templates. This method was used to produce core/shell conducting polymer NT/metal NT heterostructures in AAO templates. Conducting polymer NTs were firstly synthesized inside the nanochannels of the AAO template by an electrochemical polymerization method from an electrolyte containing the corresponding monomer. Then, metal NTs were electrodeposited inside the nanochannels as shells around the preformed conducting polymer NTs. Core/shell polyaniline (PANI) NT/Au NT [23.63] and PPy NT/Ni NT [23.64] nanoheterostructures have been synthesized by such an approach. Figure 23.19 shows a typical fabrication process for core/shell PPy NT/Ni NT heterostructures. Electrochemical polymerization was performed to deposit PPy NTs inside the AAO template (Fig. 23.19a). The Ni NTs were synthesized outside the PPy NTs by electrodeposition (Fig. 23.19b). After removal of the

AAO template, core/shell PPy NT/Ni NT heterostructures were obtained (Fig. 23.19c). It was demonstrated that the Ni shells of the resultant core/shell nanoheterostructures had an anisotropic ferromagnetic nature with maximum coercivity and remanent-saturation magnetization when applying a magnetic field along the direction parallel to the tubes.

By the sequential electrodeposition method, Yang and coworkers [23.65] synthesized semimetal/metal coaxial nanocables in AAO templates. Figure 23.20 shows the fabrication process for the nanocables. Cable shells were first electrodeposited on the interior walls of the nanochannels of an AAO template coated with a mesh-like Au layer covering the top-view surface of the pore walls but still leaving the pores open; then, the cavities of the shells were filled by a second electrodeposition to obtain cable cores. This fabrication process has been used to demonstrate fabrication of Cu shell/Bi core (Fig. 23.21) and Bi shell/Cu core (Fig. 23.22) nanocables. Figure 23.21b shows a TEM image of a single Cu shell/Bi core nanocable with the core and shell clearly identified. The core and shell of the nanocable can be clearly distinguished from the cable end, where the core sticks out of the shell (Fig. 23.21c). The lattice-resolved image and SAED pattern (Fig. 23.21a) reveal that the preferred growth direction of the BiNW core is along the [003] orientation. Figure 23.22 shows SEM images of Bi shell/Cu core nanocables with the same outer diameter but differ-

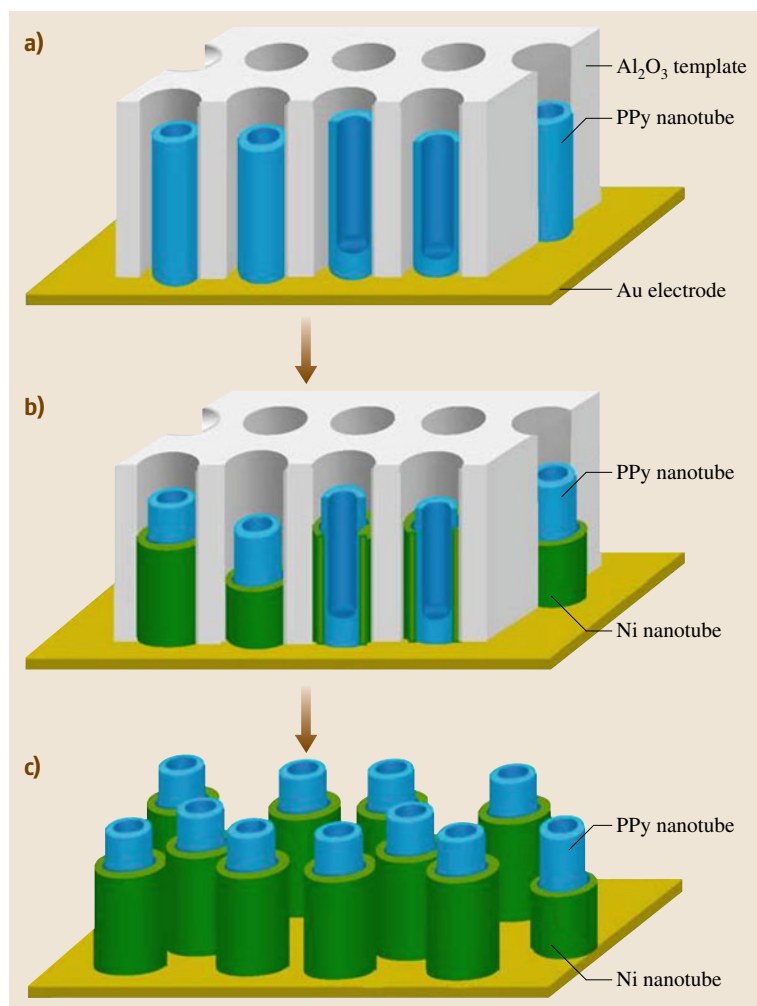

Fig. 23.19 Schematic of the synthesis of the core/shell PPy NT/Ni NT nanoheterostructures (with permission from [23.64], © American Institute of Physics (2007))

ent shell thicknesses and core diameters. The diameter of the cable core and the thickness of the cable shell can be tuned by modulating the thickness of the sputtered Au layer. As shown in Fig. 23.22, Bi shell/Cu core nanocables with thinner shells and thicker cores could be achieved when a thinner Au layer was coated on one planar surface side of the AAO template.

Except for preparation of core/shell conducting polymer/metal and semimetal/metal nanoheterostructures, sequential electrodeposition has been used to fabricate core/shell metal/metal nanoheterostructures; for example, ordered core/shell Cu/Ni nanocables were synthesized in an AAO template by sequential electrodeposition [23.66]. However, the two-step electrodeposition using two different electrolytes for

deposition of corresponding materials in the AAO templates makes the experiments complicated. Thus, a one-step electrodeposition method, using only one electrolyte, has been developed for construction of core/shell nanoheterostructures in AAO templates. Synthesis of core/shell Cu/Ni [23.67] and Ni/TiO₂ [23.68] nanocables has been reported using this technique.

By combining electrodeposition with other synthetic approaches, core/shell nanoheterostructures of metal or semiconductor/oxide have been achieved; for instance, core/shell Co/TiO₂ nanocables were fabricated by deposition of TiO₂ NTs inside nanochannels of AAO templates via a sol-gel technique followed by electrodeposition of Co NWs into TiO₂ NTs [23.69]. By a combination of atomic layer deposition (ALD) and

Fig. 23.20 Schematic for synthesis of nanocables consisting of two materials via electrodeposition: (a) sputtering a mesh-like Au layer on one planar surface side of the AAO template, (b) electrodepositing one material as the shells (marked in red) of the cables, (c) etching the caps on top of the deposited shells and sputtering a thick Au layer at the bottom of the shells, (d) electrodepositing another material as cores (marked in blue) of the cables inside the earlier deposited shells, (e) removal of the AAO template (with permission from [23.65], © American Institute of Physics (2008))

Fig. 23.21 (a) High-resolution TEM image of Cu shell/Bi core nanocable, taken from the dashed circle and rectangle marked in (b), the inset is the SAED pattern. (b,c) TEM images of the middle (b) and end (c) segment of one nanocable (with permission from [23.65], © American Institute of Physics (2008))

Fig. 23.22a–c Bi shell/Cu core nanocables with the same outer diameter of 75 nm but different shell thicknesses and core diameters. The Bi shell thicknesses and Cu core diameters are (a) 15 and 45 nm, (b) 20 and 35 nm, and (c) 25 and 25 nm, respectively (with permission from [23.65], © American Institute of Physics (2008))

electrodeposition, nanocables consisting of a Ni core and a Fe₃O₄ shell separated by a silica spacer layer have been synthesized in AAO templates [23.70]. ALD is used to conformally deposit the shells (including the inert layers), whereas electrodeposition furnishes the core. Yang et al. [23.71] reported a combinatorial method of electrodeposition and chemical etching for fabrication of core/shell InSb/Al₂O₃ nanocables. InSb NWs were first electrodeposited in the nanochannels of an AAO template. Then, the AAO template embedded with InSb NWs were immersed in aqueous NaOH solution for different periods of time to partially remove the AAO template. Finally, core/shell InSb/Al₂O₃ nanocables were obtained. The obtained InSb NW core was single crystalline along the [100] direction, whereas the Al₂O₃ sheath was amorphous. Figure 23.23 shows SEM images of core/shell InSb/Al₂O₃ nanocables after chemically etching for different times, revealing that the Al₂O₃ shell becomes thinner and shorter with increasing etching time.

In addition, a supercritical fluid inclusion process has been developed for synthesis of core/shell heterostructures in AAO templates, where the NT is first deposited onto the channel walls of the AAO templates and subsequently filled with core material to form core/shell heterostructures. Using the supercritical fluid inclusion processes, magnetic core/shell Ge/Co [23.72],

Fe₃O₄/Co, and Co/Fe₃O₄ [23.73] nanocables have been achieved in nanochannels of AAO templates.

23.3.4 Complex-Shaped Nanoheterostructures

By using AAO templates with complex-shaped nanochannels, heterostructures with corresponding complex shapes can be constructed. Meng et al. [23.74] recently demonstrated fabrication of various branched two-segment NW/NT and three-segment NT/NW/NT heterojunctions in AAO templates with branched nanochannels. These heterostructures were achieved by a combinatorial process of electrodepositing NWs within the branched channels of AAO templates, selectively etching part of the electrodeposited NWs, and growing NTs on the ends of the NWs. The NW segment can either be made of a single material or consist of several subsegments of different materials (metals, alloys, or compound semiconductors), while the NT segment can be made from carbon, silicon, or silica; the two end NT segments in the NT/NW/NT architecture can comprise the same or different materials. These branched hybrid nanoarchitectures suggest the potential for fabrication of large-scale three-dimensionally interconnected multifunctional nanocircuits, nanodevices, and nanosystems.

23.4 Conclusions and Outlook

Preparation of AAO templates with a variety of pore structures, including straight, branched, and step-shaped pores, has been discussed in detail. We then focused on construction of a number of nanostructures including NTs, NWs, and nanoheterostructures in AAO templates with different pores. These nanostructures replicate the morphologies of the nanochannels of the AAO template, resulting in nanostructures of various shapes.

More recently, several AAO templates with novel pore structures have been achieved; for example, Lee et al. [23.75] delaminated a single as-prepared anodic film into a stack of well-defined nanoporous

AAO sheets by pulse anodization. Lim et al. [23.76] reported fabrication of two-layer mild-hard AAO templates with different pore sizes and the same pore distance by a three-step anodization process. Future developments will continue to rely on engineering of the pore structures of the AAO template. The most important area is use of these AAO templates with novel pores for synthesis of novel architectures. Assembling the nanostructures in AAO templates into multifunctional nanodevices and nanosystems may have fascinating applications in future nanotechnology.

Porous Silico

24. Porous Silicon

Paolo Bettotti

Porous silicon (PS) is a nanoporous material obtained by electrochemical etching of crystalline silicon. Since its discovery in the mid 1950s it has been investigated as an active material in a number of research fields. The complexity of silicon electrochemistry, which is not yet completely understood, enables fine-tuning of etched nanoporous structures from the scale of a few nanometers up to tens of microns in a nearly continuous way (Sects. 24.1, 24.2). Historically, porous silicon was investigated for its bright visible luminescence and the possibility of realizing efficient silicon-based light emitters. Later, the shaping of complex photonic crystal (PC) structures led to porous silicon returning to the limelight in the form of silicon-based photonics. In fact, compared with other fabrication technologies (such as physical or chemical deposition methods), electrochemical etching has some fundamental advantages: it is a cheap and fast method that does not require complex facilities; it allows fabrication of complex structures with extremely high optical quality, composed by hundreds of layers; and moreover it enables etching of huge-aspect-ratio (>100) structures in a short time (Sects. 24.3–24.6). Lastly, applications of porous silicon in optical sensing

and drug delivery have maintained interest in porous silicon as an extremely lively field.

Porous silicon (PS) is a porous material obtained by electrochemical etching of silicon. It was discovered during the 1950s [24.1], but it was not considered a material of interest until the early 1970s, when researchers underlined its porous nature [24.2]. Since then, the number of publications has steadily increased to the present day. Porous silicon has attracted a great deal of interest because of its many applications. In 1971, the discovery of the porous structure of electrochemically etched silicon opened the way to applications of this layer as an insulator in so-called *full isolation by porous ox-*

idized silicon (FIPOS) technology [24.3]. A strong effort was focused on the general electrochemical behavior of silicon and to find a model to describe the enormous variety of porous structures attainable with the electrochemical fabrication method [24.4–9]. Nearly 20 years later, *Canham* discovered that PS shows strong visible luminescence if illuminated with a blue or ultraviolet light source [24.10]. Since then, interest in PS has grown exponentially because of the intriguing possibilities of fabricating efficient silicon-based light-emitting devices.

24.1 Basics of Porous Silicon Electrochemistry and Formation Models

Semiconductor electrochemistry is a complex topic, and, concerning Si, some fundamentals are not yet fully understood. In this chapter we try to introduce the reader to the basic processes behind silicon dissolution in HF-containing media. In this chapter, we simply review the basics of Si electrochemistry. More in-depth treatises can be found in the literature [24.11, 12].

Different formation models have been proposed since the discovery of PS, but an exhaustive model able to correlate all possible etching conditions and PS morphologies is still lacking.

PS is generally etched in aqueous hydrofluoric acid (HF) solutions. Often, solutions have surfactants added or are mixed with another solvent (such as alcohols, dimethylsulfoxide (DMSO) or dimethylformamide (DMF)). Such additions reduce surface energies and improve wettability, so that pores are readily filled by solvent. Moreover, hydrogen that evolves during etching can be efficiently extracted without the formation of bubbles that would otherwise induce pore inhomogeneities and surface roughness.

24.1.1 Chemical Dissolution Model

A general mechanism for the chemical dissolution of silicon in dilute HF has been proposed by various authors [24.13–15]. The main step is the weakening of Si-hydride-terminated surface bonds by holes injected

from the bulk silicon. This favors nucleophilic attack of fluorine anions on Si–Si bonds and dissolution of the semiconductor. The reaction steps are reproduced in Fig. 24.1. Holes are required at the silicon surface to bias the Si–H bond. This allows the fluorine ion to substitute a hydrogen atom (Fig. 24.1a). The substituted Si atom becomes more reactive and undergoes other substitutions (Fig. 24.1b–d) up to complete silicon dissolution (Fig. 24.1e).

In the case of an oxidized surface, it is believed that fluorine anions firstly remove the oxide, leaving a Si–H-terminated surface, followed by dissolution proceeding as described above.

This is a very general mechanism that does not account for many of the reactions actually encountered. Moreover, at large current densities, it has been proved that a nonnegligible contribution to the dissolution is due to anodic oxidation [24.16].

It is important to note that, during the reaction, hydrogen evolves (Fig. 24.1c) [24.17]. This process can strongly influence the final result of the etching. In fact, if hydrogen is not readily removed from the pores, it can form bubbles that stick onto the pore walls. The etch rate and pore structures are thus modified, and the properties of the resulting PS samples can differ from the expected ones.

PS is composed by a columnar array of silicon nanowires aligned along preferred crystalline directions

Fig. 24.1a–f Steps of a generalized chemical dissolution model. Silicon surface is assumed to be passivated by hydrogen. (a) Under proper bias holes diffuse from the bulk to the surface weakening the Si–H bonds, (b) fluoride ions substitute hydrogen atoms, (c) subsequent nucleophilic attacks produce hydrogen evolution and bring to the complete dissolution of Si superficial atoms (d,e). (f) Similar reactions on different Si atoms gives rise to a complete dissolution

Fig. 24.2 (a) I - V curve for p -type silicon. The junction is forward biased. Solid line indicates the behavior in the dark. If the sample is illuminated the reverse current increases (dashed line). (b) n -Type silicon shows the behavior of a reverse biased junction. In the dark (dashed curve) the anodic current is determined by the doping level. If minority carriers are generated by illumination, the behavior is similar to the p -type case. Black arrows indicate the effect of increasing illumination

(generally $\{100\}$, but also $\{113\}$). Pore sizes from a few nanometers to tens of micrometers can be realized. Pore size varies in a complex way, depending on both the silicon doping content and etching conditions.

24.1.2 I - V Curves

Figure 24.2 shows the I - V curves for both p -type (Fig. 24.2a) and n -type (Fig. 24.2b) silicon substrates. The point where the current passes through zero is the open-circuit potential (OCP). The left side of the graphs shows the cathodic behavior, while at potential higher than the OCP, the curve indicates the anodic behavior, where the silicon can be oxidized and dissolved. Clearly these behaviors deviate from that of an ideal Schottky diode and are dominated by two current peaks (j_{ep} and j_{ox}). j_{ep} is called the electropolishing limit and indicates the maximum current that permits production of a porous structure. The exact position of this peak – in terms of both current and potential – strongly depends on the solvent composition and substrate type. Above j_{ep} the process proceeds in two steps: initially the electrode is oxidized, then the oxide is dissolved directly by HF (in this range, the dissolution valence changes from 2 to 4 [24.18]). This is the maximum current density that allows the formation of PS structures; in fact, etching performed using currents larger than j_{ep} produces complete dissolution of the Si. PS samples fabricated using currents near j_{ep} have extremely high porosity, and are extremely difficult to handle because of their fragility. Usually, such high-porosity PS samples require carefully controlled drying processes that minimize the stress induced in the porous sponge by solvent evaporation. In fact, the capillary pressure that develops during solvent evaporation is strong enough to

collapse PS walls. The easiest way to achieve this result is to wash the sample in solvents with low surface tension (such as pentane or isopropyl alcohol), but in the case of extremely high-porosity layers, more complex approaches (such as supercritical drying) are sometimes required. Thus, fabrication of complex devices composed by multilayers requires currents well below this limit.

While in p -type substrates holes are the majority carriers, being readily available at the semiconductor–electrolyte interface, for n -type substrates they are the minority carriers and a surplus of carriers has to be generated by illuminating the backside of a biased sample. Absorbed photons generate electron–hole pairs that are separated by the sample bias and driven towards the interfaces.

24.1.3 Porous Silicon Formation Mechanisms

The formation of nanoporous silicon (with length scales in the range of a few nanometers) is considered a quantum phenomenon and does not depend on the type (i. e., doping or crystal orientation) of the substrate [24.19]. Meso- and macroporous structures show much richer behavior, and both silicon type and etching conditions determine the final porous structure. Here, we review the most important models that try to describe PS formation.

In all cases the growth of a stable PS layer requires that the dissolution takes place at the interface between PS and bulk silicon. In other words, the process is self-limiting, and the already formed PS layer is inert to HF etching (or, at least, must dissolve at a much slower rate). This assumption is experimentally confirmed and is supported by the fact that Si nanostruc-

Fig. 24.3a,b Common geometries for PS electrochemical cells. **(a)** The most common case. The sample is sealed between two cells: one filled with HF, and the other with a conductive liquid solution

tures are depleted of carriers and thus cannot contribute to electrochemical etching.

The first model to try to describe such porous structures postulated the presence of a space-charge region (SCR) parallel to the silicon–electrolyte interface [24.20, 21]. This SCR layer prevents anodic dissolution of the already formed porous layer, because the walls in between adjacent holes are completely depleted of carriers. Due to the reduced radius of curvature and the enhanced electric field, the SCR thickness is strongly reduced at the pore tip. The resultant field distribution induces strong anisotropy in the etching, and pores with extremely high aspect ratio can be realized [24.22]. The main difference between *p*- and *n*-type substrates lies in the fact that, in *p*-type Si, the holes are the majority carriers, while in *n*-type Si, they either have to be generated by suitable illumination or forced to flow by exploiting breakdown mechanisms that permit hole tunneling through the SCR. This model describes the types of structures realized in low-doped substrates, but fails to describe many other cases where the SCR model does not apply; For example, the SCR model cannot explain why pores grow along well-defined crystal directions, nor the

complex dependence on *I*–*V* conditions required to obtain the same pore modulation at different length scales (which is not linear, as would be predicted by the SCR model) [24.23].

More recently, the so-called current burst model was presented [24.24, 25]. In this scheme, the silicon dissolution proceeds through a stochastic mechanism that includes various concurrent processes: spatially localized oxide formation and oxide etching together with oscillating current bursts that start on these oxide bumps depending on the etching conditions [24.26, 27]. This model is able to semiquantitatively describe all the possible PS structures and can be used to recover simplified models such as the SCR and the *Lehmann formula* [24.18]. More in-depth reviews about PS formation models can be found in [24.28, 29].

The PS growth rate is heavily dependent on both silicon properties and etching conditions. Etch rates can range from a few Å/s [24.30] to hundreds of nm/s [24.31]. *p*-Type Si shows an etch rate that is linearly dependent on both HF concentration and current density, whereas *n*-type Si is linear only under proper illumination. Sublinear conditions are found if etched in the dark and for high current density, because the reaction is limited by hole diffusion. More data can be found in [24.32].

It is worth underlining that there is not a simple model able to comprehensively describe PS etching, thus each PS study and application has to be carefully optimized by checking the existing literature and, eventually, optimizing the method to achieve the desired results.

PS is usually etched in electrochemical cells made of plastic materials (such as Teflon or polyvinylchloride (PVC)). Two main geometries are encountered, as sketched in Fig. 24.3. In the simplest case, the backside of the sample is in contact with a metallic electrode, while a platinum working electrode immersed in HF solution closes the circuit. The other cell type is composed by a double liquid contact. Here the sample is sealed between two cells: one filled with HF, and the other with a conductive liquid solution.

24.2 Other Etching Methods

PS can also be obtained under nonanodic conditions. In particular, three methods have been explored so far and are briefly described here. The first method is called *stain etching* and was developed during the

mid 1980s. Stain etching is based on the OCP and addition of oxidant species to produce an autocatalytic effect. Typical etching solutions are composed by a HF/H₂O/HNO₃ mixture (although other oxidants

Fig. 24.4a–c Schematic of typical structures achievable by metal-assisted Si etching. **(a)** Isolated metal dots produce a porous structure similar to that obtained by using anodic etching. **(b)** By increasing the metal coverage on the Si surface, both pores and Si pillars can be obtained. **(c)** Under proper values of metal coverage, columnar structures can be etched

have also been proposed in the literature). PS dissolution proceeds following the formation of both localized anodic and cathodic regions on the surface of PS. Some reaction mechanisms have been proposed, based on HNO_3 reduction [24.33]. This reaction requires an incubation time that depends on both the solution composition and Si doping concentration [24.34]. Because of the random nucleation of surface-active sites, porous structures produced by this method are neither spatially homogeneous nor applicable for fabrication of complex

structures (e.g., no pore modulation is possible). Nevertheless, considering its simplicity, stain etching can be used in niche research applications to study effects related to patterned surfaces [24.35].

A second nonanodic method to fabricate PS relies on the use of a metal catalyst. A noncontinuous metal film deposited on the Si surface acts as a cathode and promotes strongly enhanced Si dissolution in the regions covered by the metal itself [24.36, 37]. Thus, the pore size, shape, and density can be defined by the deposition of an appropriately structured metal layer, as shown in Fig. 24.4. A comprehensive review of this method can be found in [24.38].

Finally, the third nonelectrochemical method to obtain PS is based on reactive-ion etching (RIE) to form so-called *black silicon* (BS). BS was discovered in the mid 1980s as an unwanted side-effect of Si RIE processes [24.39]. Essentially, if RIE conditions are properly controlled, the competitive reactions of Si etching and passivation can be promoted or inhibited to give rise to either perfect Si etching (the so-called vertical-walls regime) or the creation of Si needles that resemble a porous structure. Recently, an interesting application of PS etched in the BS regime was proposed for photovoltaic applications [24.40]. In fact, a PS multilayer etched to form BS was found to have a very low reflection coefficient over a wide spectral range (3000–300 nm) and could be of interest for enhancing the efficiency of Si-based photovoltaic devices.

24.3 Porous Silicon Structural Properties

PS can have characteristic length scales ranging from a few nanometers to tens of micrometers in a nearly continuous way [24.41]. As a rule of thumb, larger macropores are obtained in low-doped substrates and concentrated HF solutions [24.42, 43], although many exceptions can be found in the literature.

While etching in alkaline solutions is highly anisotropic and strongly dependent on crystal orientation, HF shows very weak dependence of etch rate on silicon orientation and is considered to be an isotropic etchant. The strong etching anisotropy found in meso- and macropore formation is due to the different rates at which holes reach the solid–liquid interface along different crystalline directions. In fact, after nucleation of a pore site, the establishment of a SCR produces an increase of the etch rate along the $\langle 100 \rangle$ direction.

If side-pores nucleate along a direction different from $\langle 100 \rangle$, they grow at a rate

$$v_{\text{sp}} \propto i_{\text{sp}} \cos \delta, \quad (24.1)$$

where v_{sp} is the speed of growth, i_{sp} is the current at the side-pore tip ($i_{\text{sp}} \ll i_{\text{MP}}$, where i_{MP} is the flux of holes that reach the bottom of the main pore), and δ is the angle between the $[100]$ direction and the side-pore growth direction (Fig. 24.5). This means that the growth rate of side-pores is lower, because a small current of holes reaches their surface and because their growth direction is not parallel to the carrier flux. The main pore grows faster and efficiently collects the majority of the carriers. The net effect is increased spacing between the tips of pores growing along $[100]$ and termination of lateral ones.

Fig. 24.5a,b The anisotropic PS formation mechanism is due to the different hole currents that reach the pore tips. (a) Pores parallel to the $\langle 100 \rangle$ direction collect carriers more efficiently. Side-pores are etched at slower speed because of this shielding effect. Moreover, their oblique growing direction moves these side-pores away from the bottom interface, meaning that they collect even fewer holes. Finally, they cease to grow. (b) SEM image showing an example of side-pore growth. The angle between the pore growth directions is 54° , corresponding to the angle between the $\langle 100 \rangle$ and $\langle 113 \rangle$ crystalline directions

This simplified model works well with large ($> \mu\text{m}$) macropores, which grow only perpendicular to the sample surface. Instead, submicrometer pores can be forced to grow preferentially along oblique directions. However, under such conditions, branching occurs and three-dimensional PS structures are realized. The final PS structure is heavily dependent on the details of the etching conditions. Nevertheless, oblique pores preferentially grow along $[100]$, $[113]$, and $[110]$ directions [24.44, 45], whereas the interface between the PS layer and the bulk silicon is always parallel to the contact electrode.

During the initial etching time, a thin transition layer develops. In this layer, pores do not grow in a steady-state regime and with a regular structure, rather trying to arrange themselves to form a porous structure compatible with the etching conditions. The very first layer is homogeneously etched away, leaving a rough surface. Here pores start to grow. Generally, there are more nucleation sites than allowed by the etching conditions, and most of these initial pores stop growing after some tens of nanometers. Holes are thus collected by neighboring pores, which increase their size and define the correct PS structure (Fig. 24.6).

For this reason the size of the pores at the surface is generally smaller than that of the bulk pores, and estimates of pore size and density obtained by electron microscopy surface images can give incorrect results.

One of the main differences between p - and n -type silicon is the reduced anisotropy of the etching process in p -type substrates. In fact, the high concentration of holes in p -doped semiconductor favors chemical etching (corrosion process) and induces substantial lateral

enlargement of pore size during etching. Experimentally it was found that this problem can be greatly reduced by using an aprotic solvent (such as DMF and DMSO) [24.46]. By using such a solvent, it is possible to obtain high-aspect-ratio porous samples also in p -type substrates.

Macroporous silicon usually has pore shapes from round to square-like with rounded edges. On n -type substrates, the pores are generally more rounded, while on p -type, due to the reduced anisotropy of the etching mechanism, complex-shaped structures can be realized starting from a simple geometrical pattern [24.47].

Etching of an unstructured silicon sample produces a random pore size distribution. Given a certain resistivity of the sample, pore sizes can be tuned within

Fig. 24.6 The first superficial layer of a PS sample has a pore distribution that markedly differs from that representing the steady growth condition. This thin layer reflects the high density of nucleation sites. Most of these pores stop growing after a few tens of nanometers, and the carriers are collected by neighboring pores that increase in size. (a) A thin superficial layer is completely etched away during the PS formation, (b) transition layer, (c) steady-state pore growth region

Fig. 24.7 (a) Flowchart of the process steps required to induce a predetermined pore array geometry: (1) deposition of a dielectric mask resistant to HF etching, (2) lithographic step to open the mask and expose the required silicon area, (3) etch pit definition, usually achieved by wet anisotropic chemical etching of the underlying silicon (using KOH or TMAH), (4) the lithographed pattern is finally transferred into the silicon substrate by electrochemical etching. (b) SEM image demonstrating the efficiency of the etch pits in the definition of the pore nucleation sites. With proper etching conditions, high-aspect-ratio submicrometer pore sizes can be obtained even in lattices with much larger periods

a certain range to obtain growth of regular pores but with different sizes. There are no rules to predict the size of this tunable range, because it is strongly dependent on the interplay of required pore sizes, etching conditions, and sample resistivity.

Porous samples with ordered pore geometry are obtained by inducing a surface structure that defines the pore site nucleation. Figure 24.7 illustrates this process:

1. A dielectric mask (usually SiO_2 or Si_3N_4) is deposited on top of the silicon sample.
2. A lithographic step is used to define the required geometrical lattice that has to be transferred into the silicon.
3. After the opening of the mask, alkaline silicon etching (generally using KOH or tetramethylammonium hydroxide (TMAH)) is used to form etch pits.
4. The tips of these inverted pyramids act as pore nucleation sites because the SCR at these tips is greatly reduced and the etching proceeds much faster at the bottom of the etch pits, starting an anisotropic etching mechanism.

Other processes can be used to determine the area to be porosified; For example, different etching properties resulting from silicon illumination can be used to spatially localize the area where PS is to growth. Also, localized ion implantation can be used to change the substrate resistivity and exploit the different etching properties of those localized areas.

It is important to remember that the final PS structure depends in a nontrivial way on all the etching parameters used during its formation. Only a few general rules are generally verified; in particular, the pore size and growth rate increase with both current density and HF concentration. However, fine-tuning of

many critical parameters (pore density, PS porosity, pore separation, surface pore roughness, etc.) has to be determined based on the actual etching conditions and cannot be easily extrapolated from literature data.

Nevertheless, the two general trends underlined above make PS a very interesting material because of the possibility to etch high-quality nanoporous multilayered structures using a fast and easy method. In fact, as described in more detail in Sect. 24.7.2, if the current is modulated during etching, highly complex porosity profiles can be achieved, while maintaining optical-quality interfaces between each layer. Thus, Si electrochemistry is a unique method for fabrication of high-quality multilayers, and no other deposition method can compete with it for the fabrication of complex porous structures. One of the most striking features of Si electrochemical etching is its self-limiting property: once a PS layer is formed, electrochemical etching proceeds only at the interface between PS and the underlying, unetched bulk Si. The already porosified layers are not affected by the electrochemical etching. This is because the porous layer is depleted of carriers and electrochemical etching cannot proceed further (although, during the fabrication of complex samples composed by hundreds of layers, the slow, direct chemical etching of silicon by HF has to be taken into account and compensated for).

Crystallographic analysis has shown that Si preserves its crystalline nature even in nanoPS, where the solid scaffold is composed by an interconnected network of Si wires [24.48, 49]. After anodization, PS retains its crystalline structure with a small lattice expansion (of the order of 10^{-3} – 10^{-4}). The PS surface achieves values from a few tens of m^2/cm^3 for macroporous samples up to nearly $600 \text{ m}^2/\text{cm}^3$ [24.50].

24.4 Light Emission from Porous Silicon

Nanoporous Si attracted much attention after the discovery of its efficient light emission under ultraviolet (UV) illumination. Since this discovery, a huge number of works tried to describe the origin of the luminescence, and different models were proposed (e.g., the hydrogenated amorphous silicon model [24.51], surface states model [24.52], surface hydrides model [24.53], defect models [24.54], and siloxene model [24.55]).

Spectroscopic analysis shows that both the valence-band maximum and the conduction-band minimum shift with respect to bulk crystalline Si, enlarging the material bandgap [24.56, 57]. Different models have been proposed to try to describe the origin of the luminescence. The quantum confinement model was the first proposed to describe the origin of the luminescence and is today well accepted as the most probable mechanism. Light emission originates from the extremely small nanocrystals (a few nanometers in size), where quantum effects enlarge the bandgap of the silicon nanocrystals (Si-nc), shifting the optical transitions towards the visible part of the spectrum. The reliability of the quantum confinement model is supported by its ability to describe a number of experimental facts, such as

the relaxation of the momentum-conservation rules and the photoluminescence (PL) shift depending on the size of the PS nanostructures [24.58–61].

One of the most interesting features of PS is the tunability of its light emission [24.62]. The current density used for sample preparation directly affects the size of the silicon nanostructures and, consequently, their optical properties. Higher currents produce layers with greater porosity, smaller Si nanostructures, and thus blue-shifted PL emission. The energy of the emitted photons is directly linked to the Si-nc size and clearly shows a spectral shift of the emission that can be modeled by quantum confinement (blue-shift for smaller Si crystallites). Figure 24.8 shows a typical PL band of a PS sample. In this case, the PL sponge was sonicated in an ultrasonic bath, and the obtained nanocrystals were dispersed in liquid. The PL properties were monitored over time for many days. Sample aging produces a strong reduction of the emission intensity and a blue-shift of the PL peak. Both of these facts can be ascribed to surface oxidation of Si nanoparticles. Thus, light emitted from nanoPS can be tuned from the near-infrared (corresponding to the bulk Si bandgap of 1.1 eV) to the green and, in some cases, the blue part of the visible spectrum. These emissions are found to be generated by different mechanisms [24.63–66], as demonstrated also by the fact that the lifetimes of excited states differ by orders of magnitude [24.67]. The most interesting emission band is the so-called S-band, which covers roughly all the visible spectrum and is the only one that can be excited in electroluminescence experiments. This emission has a rather large bandwidth due to inhomogeneous broadening that arises from the wide size distribution of the Si-nc composing the nanoPS. Its center of mass depends on the porosity, while its intensity shows a threshold-like behavior, and it is recognized that a minimum porosity has to be achieved for efficient light emission to appear [24.68]. External quantum efficiency (EQE) values up to a few percent have been reported in the literature in as-etched samples [24.69, 70]. Spectroscopic analysis suggests that the light emission mechanism in nanoPS is the same as for bulk semiconductor, apart from an energy shift of the optical transitions due to quantum confinement effects [24.67].

It is worth remembering that PS is an extremely complex system, and its light emission depends on

Fig. 24.8 PL spectra of Si nanocrystals obtained by sonication of PS. The typical PS PL red band shows a marked intensity decrease together with a blue-shift (emphasized by the gray dotted arrow). Both processes can be ascribed to surface oxidation of Si nanoparticles (data courtesy of Dr. E. Froner)

the details of the fabrication process and sample history. The optical properties of PS show dependence on sample aging and sample posttreatment (e.g., sur-

face stabilization process, controlled surface oxidation, etc.); For example, in properly stabilized samples, EQE greater than 20% has been reported [24.71].

24.5 Thermal and Electrical Properties

Electrical transport in PS was a matter of intense investigation during the 1990s, but its deep nature remains unclear. A number of models have been proposed, differing in both transport path and mechanism [24.72–75].

Because of carrier depletion, the resistivity of PS is nearly five orders of magnitude higher than that of intrinsic silicon. This high resistivity can be due either to bandgap enlargement and consequently to a reduced probability of thermal activation of carriers or to a high concentration of trap states (with activation energy on the order of 0.5 eV [24.76]). The deep origin of the transport mechanisms remains unclear, and both PS preparation conditions and temperature determine which model better describes the carrier transport [24.77]. Characterization of PS–metal diodes demonstrated the existence of two junctions: one at the metal–PS interface, and a second one at the PS–bulk Si interface. Moreover, the I – V curves mainly depend on the Si bulk properties and not on the type of metal [24.78, 79].

A number of works have tried to elucidate the electrical conduction mechanisms by analyzing PS con-

duction in alternating-current (AC) conditions. A more in-depth review of these arguments can be found in [24.80].

Because of its structure, PS possesses very low thermal conductivity (two to three orders of magnitude smaller than that of bulk Si) that is inversely proportional to the PS porosity (from $\approx 1 \text{ W(mK)}^{-1}$ for 40–60% down to $\approx 0.04 \text{ W(mK)}^{-1}$ for 90% porosity [24.81]), thus opening new perspectives in the field of thermal insulation of microsystems; For example, a PS layer was used in the fabrication of a complementary metal–oxide–semiconductor (CMOS)–compatible thermopile with high sensitivity [24.82].

It is of interest to note that the possibility of controlling the PS structure from nanometer up to micrometer scale enables the use of PS in the fabrication of phononic crystals, i. e., periodic structures able to control phonon propagation and thus the flow of thermal energy [24.83, 84]. Phononic crystals are a rather new research field, and advanced PS applications in thermal insulation and thermoelectrics should be expected in the coming years.

24.6 The Role of the Surface

The (chemical, optical, mechanical, and electronic) properties of porous silicon depend strongly on the state of its surface. The surface of as-etched PS is covered by Si–H bonds. Silicon hydrides are not stable under environmental conditions and are gradually substituted by other types of bonds; in particular, the PS surface is oxidized when exposed to air, and a thin layer of silicon oxide grows over time and stabilizes the PS surface [24.80].

Aging of PS luminescent samples is a well-known effect: after etching, the Si surface is passivated by Si–H bonds, which tend to be substituted by more stable Si–O bonds in ambient air at room temperature. As shown in Fig. 24.8, the photoluminescence band blue-shifts, due to a decrease of the Si-nc size because of

their conversion into a silicon oxide layer that passivates the PS surface [24.85].

Stabilization methods are of great importance, not only for the electrooptical properties of PS, but also for its application in (bio)sensing and even in passive optical devices. Many attempts have been made to stabilize the PS surface to either improve its optical properties or stabilize them.

Three main surface stabilization techniques have been developed and can be classified as follows: oxidation, hydrosilylation, and thermal carbonization.

Native oxide takes a long time to form, and it is difficult to control the extent of the reaction. Rather, faster and highly controlled oxidation can be induced either electrochemically [24.67] or thermally [24.86].

The thermal method is the most common, because of its better control over the oxide properties and extent of oxidation. Moreover, thermal oxide generally has better electrical properties than anodic oxide [24.15]. PS oxidizes even at 300 °C (backbone oxidation [24.87]). The degree of oxidation depends on the initial PS conditions (porosity) and oxidation conditions (process duration, temperature, and atmosphere composition). At higher temperatures, oxidation proceeds faster and to a more complete extent. The volume expansion subsequent to oxide formation reduces the PS porosity; too strong an oxidation process, performed at high temperature or for a long time, could lead to PS sintering and the formation of nonporous glass.

Recently, an extremely efficient method was proposed to achieve very good control over surface stabilization, being based on high-pressure water vapor annealing [24.88, 89]: the PS is placed in a pressure-resistant container and heated to 150–300 °C. Using this method, the luminescence properties of PS are strongly enhanced and stabilized. In fact, samples stabilized using this method show the highest external quantum efficiency ever reported for PS samples [24.71].

It is of importance to note that PS oxidation greatly modifies the surface wettability from hydrophobic to hydrophilic. Control over surface wetting properties is of fundamental importance for many PS applications.

Apart from pure oxidation methods, other thermal treatments have been investigated. In particular, we briefly describe two recently proposed methods to modify PS and increase its stability. The first process is based on thermal carbonization of PS surface by thermal treatment in acetylene atmosphere [24.90].

Thermally carbonized PS shows increased chemical resistance in hazardous environments (such as KOH and even HF/ethanol solutions) [24.91]. Two main drawbacks of thermal carbonization are: the complete quenching of the PS luminescence properties, and its CMOS incompatibility.

The second method relies on PS surface nitridation performed by a rapid thermal annealing process [24.92, 93]: PS samples are annealed for a few minutes at 600 °C in N₂ atmosphere. A great advantage of this method compared with the other thermal treatment is the fact that the refractive index of the PS is left unchanged, so that the optical properties of multilayer structures are preserved.

Other methods of PS surface passivation use pure chemical reactions that either substitute the hydride surface terminations with Si–C bonds (hydrosilylation reaction) or directly functionalize the oxidized PS surface. A number of research groups are working on this topic to develop different reaction mechanisms. The most common are based on hydrosilylation mediated by either light or Lewis acid [24.94, 95]; recent bibliography on this topic can be found in [24.96].

These methods enable the attachment of a number of organic substituents that endow the PS surface with specific functional reactivity. Moreover, while a PS surface oxide layer induces strong modification of the optoelectronic properties, a thin monolayer of organic molecules has a much lesser effect, while retaining a good surface passivation function. For these reasons, chemical methods are very attractive if PS is to be used as a sensing medium or in biorelated experiments.

24.7 Applications of Porous Silicon

24.7.1 Porous Silicon Light-Emitting Diodes

It is known that a Si *p–n* junction emits light under both forward- and reverse-bias conditions. The first and most encouraging results on PS-based light-emitting diodes (LEDs) were obtained using liquid electrodes to contact the device [24.97, 98]. Luminescence originates from an electrochemical reaction at the surface of PS: free carriers are injected either from the PS to the electrolyte or in the opposite direction, depending on whether oxidation or reduction processes are involved. In the former case, the electroluminescence (EL) decreases with time because of the increasing thickness of the oxide layer on

the Si surface [24.99], while if reduction is considered, no PS oxidation takes place and the EL does not degrade with time [24.97]. The use of a liquid junction poses strong limitations on real applications, and alternative solutions have been investigated.

The simplest solid contacts were deposited on PS using thin metal layers [24.100] or transparent semiconductor materials [24.101]. Because of the poor contact between PS and conductor materials, high turn-on voltages (≈ 10 V) and low efficiency ($\approx 10^{-5}$) were found. Improved EL was achieved in metal-implanted PS samples [24.102, 103] and in devices that make use of conductive polymer electrodes [24.104–106]. In

fact, polymers deposited by spinning or electrochemical growth on PS permeate through the pores and produce a better electrical contact.

A different approach relies on the use of heterojunctions composed by a crystalline semiconductor and PS [24.107, 108]. High-efficiency devices have also been fabricated using amorphous silicon ($\eta \simeq 0.1\%$ and voltage-tunable spectra also obtained) [24.109] and silicon carbide [24.110].

Improved light emission efficiency from PS-based LEDs was also achieved by fabrication of optical cavities (see Sect. 24.7.2 for more details) [24.111]. To be appealing in real applications, PS LEDs must be realized by a fully CMOS-compatible fabrication process. This is a complex task, because the fragile porous structures have to be preserved during all the fabrication steps that lead to the realization of the final device. A lot of effort has been invested to try to optimize the process flowchart, and some applications have been demonstrated [24.112, 113].

24.7.2 Porous Silicon-Based Photonic Crystals

The most widely exploited use of PS is in the fabrication of photonic crystals (PCs). PCs are a broad class of passive optical devices based on interferometric or diffractive filters. The properties of Si electrochemical etching (strong anisotropy and self-limitation) together with the physical properties of bulk Si (high refractive index, and transparency in the range 1500–1600 nm, the so-called third telecommunication window) make PS an ideal material to develop high-quality photonic structures. Moreover, Si is the leading material in electronics, thus the development of PS optical devices compatible with CMOS technology will boost their implementation in the development of next-generation optoelectronic integrated devices.

PCs are composed by dielectrics structured over a length scale comparable to the wavelength with which they have to interact. Often, they are composed by periodic patterns, and their optical properties can be described by a band structure model, very similar to the one used to describe electrons in an atomic potential [24.114]: in a semiconductor, the periodic potential is defined by the atomic lattice, whereas in a PC it is the periodicity of the material dielectric function that defines an *effective* potential for photons. Here, we review only the fundamental characteristics that make PCs of interest for optical applications and that are of interest to describe PCs fabricated in PS.

Light propagation into structured material is heavily modified by diffraction phenomena, and photons impinging on the material are allowed to propagate only if their energy falls within permitted bands. In some cases, two bands are separated by a forbidden energy range where photons cannot propagate (so-called bandgaps).

The bandgap can be of different dimensionality depending on the number of directions in which the material is structured: periodicity along one dimension (a multilayer filter) forbids photon propagation only along the direction perpendicular to the periodicity itself. Bandgaps in two-dimensional (2-D) periodical systems can extend over a plane, while three-dimensional (3-D) periodicity (e.g., in opals) can forbid light propagation in all directions (light trapping).

The analogy with the semiconductor band diagram can be extended to the description of defect states: a defect in a semiconductor lattice is formed when an impurity breaks the atomic lattice periodicity. In PCs, a defect is an element that breaks the dielectric lattice periodicity. Defect states are highly localized in space and show a flat band, highly delocalized in k -space.

Photonic band dispersion is used to exploit another interesting phenomenon: the speed of light in a homogeneous dielectric medium scales with the material refractive index ($v = c/n$, where v and c are, respectively, the speed of light in the medium and in vacuum and n is the material refractive index). On a band diagram, the speed (group velocity) of light propagating through the material is represented by the first derivative of the band dispersion ($v_g = \partial\omega/\partial k$, where ω is the frequency of the photonic mode and k is the wave vector). Thus, the minimum and maximum points are regions of slow light propagation. Also, defects with flat-band dispersion describe a narrow energy range of slow propagation speed. This slow-light regime is of extreme interest because of the prolonged interaction time between photons and matter (e.g., being used to enhance optical nonlinearity).

One-Dimensional Photonic Crystals

One-dimensional (1-D) PCs (1-DPCs) are filters composed by multilayered structures (also called a distributed Bragg mirror, DBR). Their use as antireflection coatings was discovered well before the development of PC theory [24.115]. The simplest multilayer filter is composed by two alternating materials with optimized refractive indexes and physical thicknesses. Without entering into details that can be found elsewhere [24.116], we describe here the basic equations that rule the optical response of the most common configuration. In fact, the

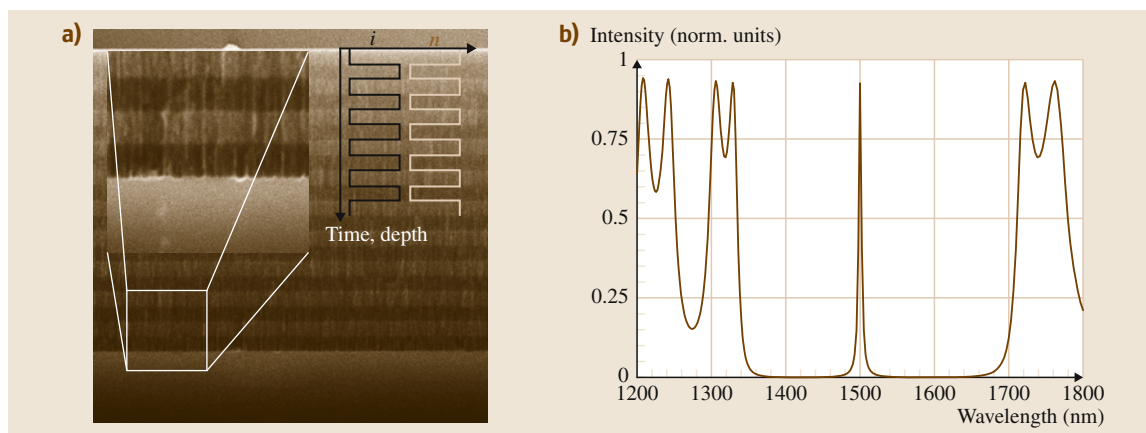

Fig. 24.9 (a) SEM cross-section of a PS multilayer. Bright and dark layers indicate low- and high-porosity layers, respectively. The inset is a zoomed view of the bottom layers that outlines single pores. The superimposed graph is a pictorial view of the modulated current profile used to etch the sample (black line) and of the corresponding refractive index profile (white line). (b) Transmission spectra of a similar structure simulated using a transfer-matrix code. The narrow peak at the center of the spectra is due to the insertion of a defect that breaks the periodicity of the porous lattice

width of the high-reflectivity stop band is maximized if the layer thicknesses satisfy the $\lambda/4n$ condition. The reflectivity (R) response will be centered at λ and depends on the number of periods

$$R = \left(\frac{1 - (n_H/n_L)^{2m} (n_H^2/n_s)}{1 + (n_H/n_L)^{2m} (n_H^2/n_s)} \right)^2, \quad (24.2)$$

where n is the refractive index of the layer, m is the number of layer and subscripts H, L and s refer, respectively, to the high, low and substrate surrounding the filter and $2N$ is the number of periods. The stop-band width ($\Delta\omega$) is proportional to the refractive index contrast between the layers and is equal to

$$\Delta\omega = \omega \frac{4}{\pi} \arcsin \left(\frac{n_H - n_L}{n_H + n_L} \right). \quad (24.3)$$

These 1-D PCs can be fabricated using deposition processes (such as chemical vapor deposition (CVD), physical vapor deposition (PVD)-like, or coating techniques). However, these methods require complex facilities and long deposition times to obtain a few tens of layers. In PS, such filters can be fabricated in a few minutes, obtaining samples with extremely high optical quality. In fact, the proportionality between the etching current and the refractive index exhibited by nanoPS is used to transfer a periodical current profile into a periodic refractive index variation of the PS. After characterization of the etching rates (which are usually on the order of $\mu\text{m}/\text{min}$) and of the layer porosity, it

is possible to design a DBR with the required optical response.

High-quality PCs require each layer to be modeled as a homogeneous material, thus the pore size should be much smaller than the wavelength. Considering a realistic case of a PS DBR with a stop band centered between 800 and 1500 nm, a single DBR layer has a thickness of less than 200 nm. Only nanoPS satisfies these requirements and can be used to realize high-quality 1-D PCs for the visible/near-infrared (NIR) range.

The electrochemical etching method allows the possibility to continuously tune the refractive index of the layer from that of bulk silicon down to the value of 1.3 of an extremely high-porosity layer. Nevertheless, this wide range cannot be used for fabrication of complex multilayer structures composed by tens of layers. In fact, a layer of extremely low porosity acts as a diffusion barrier for the HF solution, so that the concentration of HF changes with sample depth, as does the porosity. Moreover, extremely high-porosity layers have poor mechanical stability and have to be handled with great care: even the solvent drying and the capillary pressure developed can collapse the porous sponge. As a rule of thumb, indexes between 1.5 and 2.5 permit etching of complex filters made up of some tens of layers.

A critical parameter that determines the optical quality of a PC is the flatness of the interfaces. To minimize the roughness of these regions, good ohmic contact between the wafer and the backside electrode has to be established. The back of the wafer is usually im-

planted at high doses (on the order of 10^{19} atoms/cm³) followed by deposition of a thick aluminum layer.

Scanning electron microscopy (SEM) cross-section imaging of a multilayered PS sample is shown in Fig. 24.9a, while Fig. 24.9b shows a simulation obtained by a transfer-matrix code for a similar structure but with a defect layer (cavity) added. As also described below, by breaking the periodicity of an otherwise perfect lattice, photonic states are allowed inside the bandgap.

PS 1-D PCs with extremely complex structures have been fabricated, permitting analysis of complex optical phenomena; For example, PS DBRs have demonstrated the optical analog of Bloch oscillations [24.117], light localization, and necklace states [24.118].

Higher-Dimensional Photonic Crystals

2-D PCs can be realized in macroPS. The lattice geometry is defined prior to the etching by a lithographic step as previously described. MacroPS is an ideal system to study the optical properties of PCs; in fact, it can exploit both the high Si refractive index and the very high aspect ratio of the macroPS pores that permits the fabrication of nearly ideal 2-D PCs [24.119]. Figure 24.10 shows two examples of macroPS. Both samples initially had the same filling factor. In the triangular sample, the pore size was enlarged after etching by applying a few cycles of thermal oxidation and oxide removal. Lattice parameters from micrometers [24.120] down to the sub-micrometer range [24.121] have been demonstrated in the literature. In general, large and smooth pores are easily etched in low-doped substrates, and for fixed lattice constant, a certain flexibility in pore size can be achieved by modifying the etching parameters. Reduction of the lattice parameter to the (sub)micrometer scale is required to obtain a bandgap of $1.55\text{ }\mu\text{m}$, which is of great interest for integrated photonics.

The fabrication of high-quality PCs becomes extremely difficult with the shrinkage of the pore size. This is because some effects occur to reduce the quality of the etched structures. A first important parameter to control is the surface pore roughness, to avoid unwanted scattering effects. While on large macropores the effect of roughness can be neglected (a smooth pore has a surface roughness on the order of a few nanometers), it becomes of greater importance for small, submicrometer-size pores. Moreover, etching parameters that allow etching of smooth, submicrometer pores have to be carefully controlled and show strong dependence on substrate type and doping concentration. Thus, great control over the substrate used is also required [24.121]. Only a few experimental results demonstrating the

Fig. 24.10 (a) Bird's-eye view of a macroPS sample with square symmetry (scale bar: $10\text{ }\mu\text{m}$). (b) SEM top view of a triangular lattice of pores (scale bar: $1\text{ }\mu\text{m}$)

achievement of the control over etching required to fabricate silicon-based PCs for applications in the $1.55\text{ }\mu\text{m}$ range have been published [24.122, 123].

Larger macropores with a bandgap in the mid-to far-IR range (pore diameter $> \mu\text{m}$) do not require such highly controlled etching conditions. Moreover, once the lattice geometry is fixed, the pore diameter can be adjusted by modifying the solvent concentration or etching current. One-dimensional PCs made of nanoPS do not suffer from those limitations, because the nanopores are much smaller than the wavelength and behave as an effective medium. The intermediate regime, which is the most interesting for applied integrated photonics, requires good knowledge of silicon electrochemistry and long optimization processes.

Three-dimensional PCs are the most intriguing structures: ideally they are able to localize a photon inside a tiny volume and keep it for a long time. Their realization is a formidable task, and, excluding opals, only a few other examples have been proposed in the literature. Generally, all of them are fabricated using state-of-the-art nanofabrication technologies. The first Si-based 3-D PC was the so-called *yablonovite* and did not rely on an electrochemical process. Instead, it was realized using a focused ion beam technique to etch holes with the proper orientation into bulk silicon. Yablonovite was the first structure to demonstrate the realization of a high-quality 3-D PC with a bandgap in a wavelength range compatible with integrated optics applications. Some years later, the so-called *woodpile* structure was proposed and fabricated. This PC is composed by alternate layers of silicon sticks, each rotated by 90° with respect to the previous one [24.124]. While yablonovite shows a complete three-dimensional bandgap (no photonic states are allowed along any direction), the woodpile bandgap is limited to some spatial directions, and it is thus not able to confine photons completely in 3-D space.

Fig. 24.11 SEM image of a 3-D macroPS sample: holes interconnecting adjacent pores can be seen on the vertical pore walls (scale bar: 1 μm)

The fabrication of a 3-D PC by an electrochemical method is a formidable task. As already noted, under certain conditions, a variation of the etching current is reflected by a pore size variation [24.125]. This is true at the nanoscale but can also be transferred to macropores. Thus, a 2-D lattice etched with proper modulation of the current forms a 3-D porous medium. Unfortunately, the pore size cannot be varied too much, and only a slight index variation can be achieved along the vertical profile. Moreover, the effect is highly nonlinear with etching conditions, and a suitable current profile has to be found with a trial-and-error approach [24.23]. Nevertheless, it was demonstrated that, after proper thermal treatment and subsequent oxide removal, an interconnected 3-D PC could be fabricated in macroPS [24.126]. An SEM image of such a sample is shown in Fig. 24.11.

24.7.3 Optical Sensing

PS is an excellent material to fabricate optical sensors. In fact, it possesses important characteristics such as:

1. Very high-quality optical structures can be etched in PS.
2. It offers high specific surface area, which can be tuned over a wide range.
3. It enables the achievement of rather high refractive index contrast (much higher than 1) even in 1-D PCs.
4. PS fabrication is based on a simple and fast etching method.
5. It can be chemically functionalized in a number of ways to make it stable and give it chemical specificity to particular analytes.

All of these are key requirements for a sensor device and are seldom found together in materials other than PS.

The great majority of the works that exploit PS in optical sensors rely on the use of PC structures. The presence of unknown analyte is detected by changes in optical properties induced by binding events.

Porous silicon microcavities have been investigated since the late 1990s [24.127, 128]. Generally, these works rely on spectral shifts of resonances induced by changes in refractive index. Extremely high sensitivity has been achieved (a limit of detection for refractive index change down to 10^{-6} has been demonstrated [24.129]).

Apart from the optical response, other physical parameters can be monitored using PS-based sensors. Here, we briefly discuss some of these alternative approaches.

As discussed in Sect. 24.7.1, PS shows bright visible PL if irradiated with UV light. PL quenching can be correlated to the presence of bound molecules that, by activating energy-transfer mechanisms, reduce the PL efficiency [24.130]. Unfortunately, PL quenching is generally an irreversible process, thus only disposable devices can be obtained from PS.

Electrical conductivity is another parameter subject to changes due to interaction with the environment. Sub-ppm sensitivity to NO_2 has been demonstrated [24.131]. The main limitations of PS-based sensors are their limited reversibility and hysteresis in the sensor optical response due to degradation processes (due to either aging or irreversible contamination), although improved reversibility was found in oxidized PS samples [24.132].

24.7.4 Drug Delivery Systems

PS possess many properties that make it an interesting material for biological applications. Following the pioneering work of *Canham* [24.133, 134] that demonstrated the biocompatibility of PS, many other groups have investigated the use of PS as a material in biosensing, drug delivery, and tissue engineering.

The pore size tunability provided by electrochemical etching allows the realization of optical structures with optimized sensitivity to particular molecule sizes. Thus, while nanoPS can be used to detect complementary DNA strands [24.135], macroPS structures can detect immunoglobulin G (IgG) or other, larger molecules [24.136].

Recently, PS has received great attention due to the possibility of its use as a drug delivery system or as a biodegradable marker. There is growing interest in the development of biodegradable smart materials that are

able to transport and deliver a drug payload in a well-controlled manner in vivo [24.137].

24.7.5 Oxidized Porous Silicon

PS is easily oxidized at low temperature. Sample porosity (pore wall thickness) and oxidation conditions (such as temperature, time, and atmosphere composition) determine the degree of the oxidation process. The same can be controlled to a very high level; in fact, high-porosity layers can be fully oxidized at temperature of 500 °C, while at higher temperatures the PS layer is sintered and porosity is reduced to low values.

Oxidized PS (OPS) has found applications as a sacrificial layer [24.138–140]. An OPS layer is easily removed by HF and can, thus, be used to fabricate free-standing structures, as sketched in Fig. 24.12. The process exploits the electrochemical etching selectivity of silicon areas with different doping concentrations. Initially, the layer to be rendered free-standing is subject to lithography to define the structures of interest (Fig. 24.12a). A subsequent etching process is used to expose the underlying substrate that will be rendered porous (Fig. 24.12b). The PS is then etched and finally removed, leaving suspended structures (Fig. 24.12c,d). The PS underetching shown in Fig. 24.12c can be used to obtain a silicon-on-insulator (SOI)-like structure, if the PS regions merge and no bulk silicon remains in between.

The dielectric properties of PS make it an ideal electrical insulating material. Since the early 1970s, NTT and Sony have developed methods that make use of PS as an insulating layer in integrated cir-

Fig. 24.12a–d Flowchart illustrating the process steps required to obtain free-standing structures using OPS as a sacrificial layer. (a) lithographic step to define the area to be porosified, (b) etching of the dielectric mask, (c) etching of PS area, (d) removal of the porous layers

cuits (ICs) [24.141]. OPS has found application as an electrical insulator in bipolar ICs and was used in commercial products developed in the first half of the 1980s [24.142]. Here, a silicon chip is implanted with different dopants and concentrations to form p – n junctions. After electrochemical etching, they are laterally isolated by OPS regions.

The extremely low refractive index achievable in OPS, together with the high material homogeneity and reproducibility, raised interest in its use as low-index cladding in waveguide (WG) structures. OPS can be fabricated with index as low as 1.1, and values around 1.2 are routinely achieved. Thus, use of OPS as low-index cladding in WG-based structures has been proposed and demonstrated [24.143, 144].

24.8 Conclusions

PS is an intriguing material that finds applications in a number of research fields.

Si electrochemistry offers a fast, simple, and fully CMOS-compatible fabrication method. The etching process allows the realization of porous structures with extremely complex profiles, with typical length scales that span from nanometers to hundreds of micrometers. Moreover, etched structures have very high quality, thus enabling detailed characterization of the properties of samples. NanoPS has been used to deeply understand the physical properties of Si-based nanostructures: both light emission and transport properties have been analyzed in depth using PS. Later, the development of

the photonic crystal field further drove use of PS in nanophotonic applications, leading to great achievements concerning the demonstration of optical analogs of electronic phenomena and the realization of complex PC elements. At the same time, PS has also found applications in the development of high-sensitivity, multi-parametric sensors. During recent years, use of PS in biological applications has become a lively research area thanks to its optical properties and biocompatibility.

The great flexibility of PS suggests that further developments can be expected in the coming years and that PS will remain in the limelight of nanostructured materials for a long time to come.

Organic Nanomaterials

25. Organic Nanomaterials

Huanli Dong, Wenping Hu

Nanomaterials, notable for their extremely small feature size, have the potential for wide-ranging industrial, biomedical, and electronic applications. Organic nanomaterials, with the utility of weak noncovalent interactions for the design and self-assembly of molecules one by one into desired structures, give the potential advantages of constructing building blocks using synthetic chemistry at multiple levels, and open the *bottom-up* route for synthesis of organic and polymeric nanostructures; for example, self-assembly of organic molecules with the assistance of noncovalent interactions, such as hydrogen bonding, electrostatic interactions, and pi-stacking, provides a powerful strategy for synthesis of molecular nanostructures, which have been attracting particular attention since the 1990s as a *bottom-up* paradigm of nanosciences, and discrete nanoparticles with controlled chemical composition and size distribution are readily synthesized. However, the assembly of well-defined nanostructures in large areas, the tuning of noncovalent interactions for efficient assembly, and the dynamics and model of the self-assembly process remain challenging and demanding tasks. There is still a long way to go to achieve true mastery of the art. It will be attractive to find a simple, efficient, and controllable way to produce organic nanomaterials in large areas (mass production) as well as to bridge their applications in organic optoelectronics. fact, organic nanomaterials have been projected as active components in optoelectronic devices recently, not to mention the great efforts invested in manipulating their morphologies and tailoring their functions. The overall aim of this chapter is to bring together science and applications on organic nanomaterials with emphasis on synthesis and preparation, processing, characterization, and applications of organic nanomaterials that enable novel or enhanced properties or functions, including experiments and applications.

25.1 Preparation/Synthesis of Organic Nanomaterials

The development of facile, mild, and universal construction strategies is a prerequisite to further investigation of organic nanomaterials. Most of the present approaches to inorganic nanomaterials are not applicable for organic ones due to the lower melting and

sublimation points of organic and polymeric materials. However, some fruitful attempts have been developed during the past couple of years based on the characteristics of organic and polymeric materials. Judging from the phase state for the preparation/synthesis of organic

nanomaterials, the various methods can be divided into solution processes, vapor processes, and other special techniques such as supercritical and/or ionic liquid methods. Certainly, the methods also can be divided into template and template-free processes depending on whether they use a template or not during the preparation process. Here, we divide the methods into solution processes, vapor processes, and other methods.

25.1.1 Solution Processes

Solution processing is an effective method for growth of organic nanomaterials, mainly including templating, electrochemistry, recrystallization, solvent-exchange, dip-coating, and drop-casting methods, surface-assisted solvent–vapor annealing, etc., which usually require materials with good solubility.

Template Method

The template method represents a straightforward route to fabricate organic nanomaterials by forcing the target molecules into the template to grow desired nanomaterials according to the patterns of the templates, e.g., anodized aluminum oxide (AAO) templates. Probably, *Possin* was the first to use this technique to prepare

semiconductor nanowires in the 1970s [25.2], and *Martin* extended this technique and first put forward the term *template synthesis* in the 1990s [25.3,4]. Now the commonly used templates include but are not limited to ordered porous membranes prepared with AAO, but also silica and nanochannel glass, etc. [25.5]. Li and coworkers fabricated C₆₀ nanotubes with this method by an easy dip-and-dry procedure, in which they dipped the AAO templates repeatedly into a C₆₀ solution, and evaporated the solvent during the intervals between dipping. Owing to its versatility, this approach should be a promising route toward a variety of nanotubes (i.e., polymer and inorganic and organic compounds) and should be applicable to any compound that can be dissolved in a membrane-compatible solvent. Especially, this method could be a general technique for thermopolymerization and in situ polymerization under shape and size control, as shown in Fig. 25.1 [25.1].

Zhao et al. reported the preparation of perylene nanotubes [25.6] by repeatedly immersing a porous alumina template (Whatman Ltd., Anodisc 13, quoted diameter 200 nm) into a saturated perylene solution for 2 min for every cycle and allowing the solvent to evaporate in air during the intervals. After 20 cycles, the templates were perylene-laden and heated to 240 °C for 10 h under a nitrogen atmosphere and then cooled to room temperature. The surface layer of the membrane was removed by polishing with 1500-grit sandpaper, and then the sample was fixed to a piece of copper tape. Field-emission scanning electron microscopy (FESEM, JEOL JSM-6700F) images of the as-prepared template-synthesized perylene nanotubes after complete removal of the alumina template by etching it away with 6 M aqueous sodium hydroxide are given in Fig. 25.2. It can be clearly seen that the nanotubes are arranged in a continuous, parallel, and well-ordered way with monodispersed diameters (ca. 200 nm), lengths (ca. 60 μm), and wall thicknesses (ca. 25 nm) at quite high density (about $2.6 \times 10^9 \text{ cm}^{-2}$). The diameters and lengths of the nanotubes correspond well to the diameter of the pores of the membrane and the thickness of the template used (60 μm). After application of alkaline corrosion to the aluminum oxide membrane, the nanostructures in the pores of the membrane remained, which makes this method more suitable for fabricating nanotubes from small organic molecules that are not sensitive to the inorganic alkali.

It is well known that polymers and small organic molecules are attractive materials for (opto)electronics due to their chemically tunable optical and electronic properties as well as their potential for low-cost fab-

rication of flexible or large-area devices. In particular, pentacene has shown tremendous promise for thin-film transistor (TFT) applications, with reports of hole mobilities approaching $1 \text{ cm}^2/(\text{V s})$ for TFTs fabricated on flexible substrates. Barrett et al. [25.7] reported on convenient synthesis of pentacene nanotubes by the method of melt-assisted template wetting and on electrical contacting of single tubes. Briefly, pentacene powder is placed on an alumina pore array and heated above its melting point under an inert atmosphere. As a result of the high surface energy of the alumina membrane, a thin surface film will rapidly cover the pore walls in the initial stages of wetting, forming nanotubes with well-defined wall thicknesses. Figure 25.3a shows a scanning electron microscopy (SEM) image of an array of pentacene nanotubes following partial dissolution of the alumina template in aqueous NaOH. The density of nanotubes (109 per template) demonstrates the efficiency of the melt-assisted wetting process for high-yield preparation of these novel one-dimensional (1-D) nanostructures. Figure 25.3b shows a high-magnification image of the back side of part of the membrane shown in Fig. 25.1a. The large number of protruding nanotubes indicates almost complete filling of the template during melt injection, confirming formation of $60 \mu\text{m}$ -long tubes. Histogram analysis of tube diameters and wall thicknesses measured using SEM yielded mean values for the tube outer diameter ($d \approx 350 \text{ nm}$) and wall thickness ($w \approx 40 \text{ nm}$).

Template-Free Method

The template-free method is usually called self-assembly, which is the fundamental principle which generates structural organization on all scales from molecules to galaxies. Self-assembly can occur spontaneously in nature, for example, in cells (such as the self-assembly of the lipid bilayer membrane) and other biological systems, as well as in human-engineered systems. It usually results in the increase in internal organization of the system. Molecular self-assembly is the assembly of molecules without guidance or management from an outside source. There are two types of self-assembly, intramolecular self-assembly and intermolecular self-assembly, although in some books and articles the term self-assembly refers only to intermolecular self-assembly. Intramolecular self-assembling molecules are often complex polymers with the ability to assemble from the random coil conformation into a well-defined stable structure (secondary and tertiary structure). An example of intramolecular self-assembly is protein folding. Inter-

molecular self-assembly is the ability of molecules to form supramolecular assemblies (quaternary structure). A simple example is the formation of a micelle by surfactant molecules in solution. Certainly, self-assembly can be also classified as either static or dynamic. Static self-assembly is when the ordered state occurs when the system is in equilibrium and does not dissipate energy. Dynamic self-assembly is when the ordered state requires dissipation of energy.

Almost everything has the inclination for self-assembly. Molecular self-assembly in liquid solutions is a strategy for nanofabrication that involves designing molecules and supramolecular entities. The assembly of organic molecules into nanostructures with defined morphologies needs driving forces from the molecules themselves, including hydrogen bond, $\pi-\pi$ stacking van der Waals contact, etc. Sometimes, the self-assembly process also requires induction from the surroundings, such as interactions between the organic molecules and the solvents or auxiliaries. The use of noncovalent interactions for self-assembly is widely ap-

plied for preparation of organic nanomaterials. Usually, covalent interactions (bonds) hold the atoms together with large bond energies of the order of $\approx 10^2$ kcal/mol. Compared with covalent interactions, noncovalent interactions are much weaker. However, the cumulative energies of noncovalent interactions can be huge; For

example, huge numbers of small noncovalent forces drive the spontaneous folding or unfolding of proteins and nucleic acids. Moreover, the weak noncovalent interactions (hydrogen bonding, π -stacking, electrostatic interactions, van der Waals forces, etc.) can be tuned with the design of molecules so that molecules can self-assemble one by one into desired architectures. This gives the potential advantages of constructing building blocks using synthetic chemistry at multiple levels, and opens the *bottom-up* route for synthesis of organic nanomaterials; For example, Jiang et al. [25.8] used anthracene and its series derivatives (Fig. 25.4) to demonstrate a simple way to cast-assemble nanowires of organic semiconductors through tuning of the intermolecular noncovalent interactions by molecular design. The tuning of intermolecular interactions could be achieved by:

1. Decreasing intermolecular hydrophobic interactions by linking hydrophilic side-chains to anthracene rings
2. Increasing intermolecular interaction for self-assembly with the assistance of hydrogen bonds
3. Enhancing molecular π - π interaction by increasing the conjugated dimension of the compounds.

Attractively, nanowires and microwires of organic semiconductor (**3**) could be prepared by cast assembly efficiently and simply [25.9]. Due to the merits of cast assembly, these nanowires/microwires could be synthesized in large quantity and large scale at low cost. Transmission electron microscopy (TEM) images of individual nanowire/microwires and their corresponding selected-area electron diffraction pattern indicated that the whole nanowires/microwires are single crystals. Precise size-controlled nanowires and ultralong microwires with length reaching several millimeters were obtained by carefully adjusting the concentrations of (**1**) in cast solutions (Fig. 25.4). Control experiments and the growing process of microwires in solution monitored in situ by optical microscopy suggested that the formation mechanism of nanowires/microwires was a crystallization process. Moreover, the nanowires/microwires showed no substrate or solvent dependence and were orientation controllable. Highly reproducible and sensitive photoresponse characteristics were observed in these nanowires/microwires. Fast and reversible photoswitches based on multiple or individual nanowires/microwires were fabricated via the *multi times gold wire mask moving* technique with switch ratio of over 100.

25.1.2 Vapor Processes

Vapor deposition is a facile and feasible method for preparing nanomaterials and has achieved great success in fabricating inorganic 1-D nanostructures, polymeric thin films, and inorganic–polymer nanocomposites; For example, the physical vapor transport technique is a general method to produce high-quality nanocrystals. It is usually carried out in a quartz tube by sublimating high-purity compounds at a high-temperature zone, carrying the vapor with an inert gas, and then recrystallizing the compounds at a low-temperature zone of the tube [25.10]. This approach is widely used for oligomers and small-molecular-weight organic semiconductors; For example, *Tang et al.* [25.12] synthesized nanocrystals of copper phthalocyanine (CuPc) by the physical vapor transport technique (Fig. 25.6). A quartz tube was inserted in a two-zone horizontal tube furnace. CuPc powder was placed at the high-temperature zone and vaporized at 425 °C. Vapor of CuPc was then carried by high-purity Ar gas flowing from the high-temperature zone to the low-temperature zone at a rate of 200 sccm. Purple fuzz-like products, which were found to be CuPc nanoribbon crystals later (Fig. 25.6), were obtained on a substrate at the low-temperature zone (150 °C).

For vapor deposition, the degree of saturation is the predominant factor in controlling the morphology and dispersity of the products, and it should be possible to process most solid materials into 1-D nanostructures by maintaining the vapor saturation at a low level [25.11]. Several techniques have been adopted to control the local supersaturation in the preparation of organic 1-D nanomaterials by vapor deposition; For example, *Yao* and coworkers reported an adsorbent-assisted physical vapor deposition (PVD) method. Adsorbents such as neutral aluminum oxide or silica gel, used widely in column chromatography, were introduced into the PVD method to control the degree of saturation, considering that there should exist an adsorption–desorption equilibrium between the adsorbents and the organic sources. A series of single-crystalline 1-D organic nanostructures were prepared with this method [25.11, 13]. Figure 25.7a,b shows typical SEM and TEM images of tris(8-hydroxyquinoline)aluminum (Alq3) nanowires. The selected-area electron diffraction (SAED) pattern shown in Fig. 25.7c reveals that the Alq3 nanowires are single-crystalline structures with preferential growth along the $[10\bar{1}]$ direction, which is also testified by the x-ray diffraction (XRD) patterns. The length and diameter of the nanowires prepared with this method

can be well controlled by varying the deposition conditions, such as time and temperature. The results of analogous experiments and thermogravimetric analysis (TGA) measurements displayed in Fig. 25.7d indicate that the addition of adsorbents is indispensable in improving the uniformity of the nanowires. It can be observed that the adsorbents decreased the sublimation temperature and slowed the weight loss of Alq3 remarkably, through which the degree of saturation and the uniformity can be readily controlled. In contrast, the introduction of sodium chloride, which does not adsorb, hardly affects the slope of the TGA plot. No

catalyst was used and no droplet was found at the top, so the growth of the 1-D materials prepared with this

method should be controlled by the vapor–solid (VS) process [25.14].

25.2 Properties of Organic Nanomaterials

Great attention has been drawn to nanomaterials due to their size, confinement, surface, and quantum tunneling effects, etc.. These effects result in unique properties of nanomaterials superior to those of their bulk counterparts; For example, owing to the phenomena of charge transfer and Frenkel excitons, their optoelectronic properties are more complicated than those of inorganic nanomaterials, which results in many difficulties in research of organic nanomaterials. Fortunately, rapid development in the understanding of organic nanomaterials is underway due to researchers' great efforts.

25.2.1 Structure and Morphology

Controllable synthesis is a key task for nanoscale science, and the morphologies of inorganic nanostructures have been successfully controlled by choosing appropriate materials and changing the synthesis methods. How-

ever, the morphology control of organic nanomaterials has met with limited success. The commonly used strategy to modulate the organic nanostructures is to slightly alter the molecular structures in a series of derivatives; For example, Zang and coworkers have prepared either nanobelts or nanospheres by using two different derivatives of perylene diimide [25.14, 15]. Nanobelt structures have been fabricated for an n-type semiconductor molecule (Fig. 25.8), *N,N'*-di(propoxyethyl)perylene-3,4,9,10-tetracarboxylic diimide (PTCDI) [25.14]. The short alkyloxy side-chain not only affords effective π – π stacking in polar solvents for self-assembly but also provides sufficient solubility in nonpolar solvents for solution processing. As revealed by both atomic force microscopy (AFM) and electron microscopies, the nanobelts have an approximately rectangular cross-section, with typical thickness of about 100 nm and width in the range of 300–500 nm. The length of the nanobelts ranges from 10 to a few tens of micrometers. The highly organized molecular packing (uniaxial crystalline phase) has been deduced from the measurement of electron diffraction and polarized microscopy imaging. The detected optical axis is consistent with the one-dimensional stacking of the molecules.

An obvious effect of side-chain substitutions on the morphology of self-assembly of perylene diimide molecules was also found with two derivatives modified with distinctly different side-chains: *N,N'*-di(dodecyl)-perylene-3,4,9,10-tetracarboxylic diimide (DD-PTCDI) and *N,N'*-di(nonyldecyl)-perylene-3,4,9,10-tetracarboxylic diimide (ND-PTCDI). Due to the different side-chain interference, the self-assembly of the two molecules results in totally different morphologies in aggregates: one-dimensional (1-D) nanobelts versus zero-dimensional (0-D) nanoparticles (Fig. 25.9). The distinct morphologies of self-assembly have been obtained from both solution-based processing and surface-supported solvent–vapor annealing. The nanobelts of DD-PTCDI fabricated in solution can feasibly be transferred to both polar (e.g., glass) and nonpolar (e.g., carbon) surfaces, implying high stability of the molecular assembly (due to the strong π – π stacking). Compared with the emission of ND-PTCDI aggregate, the emission of DD-PTCDI aggregate was significantly red-shifted (ca. 30 nm) and the emission

Fig. 25.9 Molecular structures of DD-PTCDI and ND-PTCDI and SEM images of their self-assembled structures. (After [25.15], courtesy of American Chemical Society (2006))

quantum yield decreased about three times, primarily due to the more favorable molecular stacking of DD-PTCID. Moreover, the aggregate of DD-PTCDI shows a pronounced absorption band at longer wavelength, whereas the absorption of ND-PTCDI aggregate is not significant in the same wavelength region.

The facile fabrication of nanostructures with well-defined shapes and uniform sizes from stilbazolium-like dyes was reported [25.16]. Stilbazolium-like dyes (1) and (2) (Fig. 25.10) with different substituents were synthesized with the intention of exploring the possible influence of the substituent on the shape and therefore the optical properties of the resulting nanostructures. The self-assembly of the target molecules was induced by solvent exchange. Figures 25.10a and 25.10b display SEM images of compounds (1) and (2), respectively, assembled in nonsolvents. It can be seen that changing the substituents influenced the mor-

phology of the aggregates significantly. As shown in Fig. 25.10c, molecule (1) consists of a strong electron-withdrawing moiety *N*-methylpyridinium (Nmpd) and a strong electron-releasing group *N*-methylpyrrole (Nmpr) connected by a conjugated system. For molecule (2), two weaker electron-releasing groups, 4-hexadecyloxyphenyl (4Hop), are connected to the Nmpd moiety. In addition, (1) is a planar molecule, so strong donor–acceptor interactions are the main driving force for the aggregation of (1) and induce the formation of 1-D nanostructures. In comparison, (2) is a nonplanar molecule with weak donor–acceptor interactions. There are two long flexible alkyl side-chains on the ionized pyridine ring, and therefore (2) is a typical amphiphilic molecule bearing a hydrophilic head (ionized pyridine ring) and two long and flexible hydrophobic arms (alkyl chains), which will drive the molecules to form H-aggregates with monodisperse spherical morphologies as shown in Fig. 25.10c.

Fig. 25.11 Schematic representation of the formation processes of nanoscale materials of compounds *o*-, *m*- and *p*-bis(iminopyrrole)benzene, respectively. (After [25.17], courtesy of R. Society Chemistry (2010))

Besides those from derivatives with different substituents, nanostructures were also tuned between spheres, wires, and cubes via the self-assembly of three isomeric molecules of bis(iminopyrrole)benzene with the same substituents on different positions [25.17]. Although all three isomeric precursors, *o*-, *m*-, and *p*-bis(iminopyrrole)benzene, present similar strong multiple hydrogen-bonding interactions for molecular aggregation, distinctly shaped nanostructures were obtained. As shown in Fig. 25.11a, the two iminopyrrole (IP) groups in the *o*-isomer are 60° open-armed. Therefore, two monomers can embed into each other to form a dimer via quadruple hydrogen bonds, which act as the basic units for the formation of spherical structures. In contrast, the configurations of *m*- and *p*-isomers, with two IP groups open-armed at an angle of 120° and 180°, respectively, determine that each molecule connects with two others via hydrogen bonds, forming chain-like structures. Also determined by molecular configuration, the chain of the *m*-isomer is zigzag shape (Fig. 25.11b), while that of the *p*-isomer is almost linear (Fig. 25.11c). These chains are the actual building blocks for the solid states of the two isomers to form square wires and cubes, respectively. It is the different interactions for aggregate stacking at the supramolecular level caused by the isomeric molecular structures that are responsible for the different morphological evolution.

25.2.2 Absorption and Emission Properties

During the past several years, the unique optoelectronic properties have also sparked widespread investiga-

tion of hierarchical self-assembly of organic building blocks achieved by the induction of noncovalent intermolecular interactions. Besides exploration of synthetic strategies, much effort has also been made to investigate the unique properties of the organic nanomaterials obtained by molecular aggregation in the nanostructures. As mentioned above, it was found that the optical and electronic properties of organic nanomaterials are fundamentally different from those of their inorganic counterparts, because the intermolecular interactions in organic materials are basically of weak types, such as hydrogen bonds, $\pi-\pi$ stacking, van der Waals contacts, and charge-transfer (CT) interactions; For example, the size-dependent optical properties of organic nanoparticles, which are similar to but cannot be explained by the so-called quantum confinement effect observed in inorganic semiconductor quantum dots, were first observed in perylene nanocrystals and reported by Nakanishi and coworkers [25.18]. They prepared perylene microcrystals with different sizes from about 50 to about 200 nm using the reprecipitation method. Their excitonic absorption peaks were found to shift to the high-energy side with decreasing crystal size; that is to say, the shifts from that of the bulk crystal were about 500 and 1420 cm^{-1} for 200 and 50 nm microcrystals, respectively. Moreover, strong fluorescence from the free-exciton energy level in the microcrystals was observed even at room temperature, which is not usually observed in bulk crystals. Fu and Yao synthesized nanoparticles of 1-phenyl-3-((dimethylamino)styryl)-5-((dimethylamino)phenyl)-2-pyrazoline (PDDP) ranging from tens to hundreds of nanometers using the reprecip-

itation method. Their excitonic transitions responsible for absorption and emission, as compared with those of dilute solution, have been investigated as a function of nanoparticle size. They found that **PDDP** nanoparticles possess a special size dependence in their optical properties (Fig. 25.12). They identified an extended **CT** state stemming from **PDDP** molecules closely stacking in nanoparticles and observed its shift to the high-energy side with decreasing nanoparticle size due to exciton confinement. At the same time, the molecular $\pi-\pi^*$ absorption of the nanoparticles was also blue-shifted, accompanied by an almost unchanging $n-\pi^*$ absorption as a result of the reduced overlap of the pyrazoline ring π orbital and decreased intermolecular interactions. Moreover, **S1** and **CT** states were in equilibrium in the nanoparticles, and the probability of fluorescence from **S1** increased with decreasing nanoparticle size.

As mentioned above, an adsorbent-assisted **PVD** method was developed by Yao and coworkers for the preparation of crystalline **1-D** organic nanomaterials. In very recent work, they extended this method to binary doped systems. 1,3,5-Triphenyl-2-pyrazoline (**TPP**) and rubrene were chosen as the model compounds, which were fabricated into uniformly doped crystalline nanorods and nanowires by adsorbent-assisted **PVD**; For example, binary doped organic nanowires were prepared with the above-mentioned adsorbent-assisted **PVD** method. A blue light emitter, 1,3,5-triphenyl-2-pyrazoline (**TPP**), and rubrene, a good orange dye used as the dopant in host-guest organic light-emitting diodes (**OLEDs**) with good transport property, were chosen as the model compounds, which were fabricated into uniformly doped crystalline nanorods and nanowires using the adsorbent-assisted **PVD** method [25.20]. The doping content was tuned by changing the molar ratio of the two sources.

Figure 25.13a–c shows fluorescence microscopy images of the binary nanostructures with various doping contents. The homogeneous emission color from all of the nanorods/wires in each sample testified that rubrene crystal grains were dispersed uniformly into the **TPP** matrices. The binary nanowires also show waveguide properties, which is proven by the microarea fluorescence microscopy of a single nanorod in Fig. 25.13c. It is revealed by the fluorescence microscopy images that the emission color evolves from blue to orange with the increase of rubrene content, and more importantly, white emission can be achieved when a proper **TPP**-to-rubrene molar ratio (100 : 1) is adopted. The tunable emission can also be observed from the evolution of the fluorescence spectra of the nanostructures with the

Fig. 25.12 Ultraviolet (UV)-visible absorption spectra of **PDDP** nanoparticle dispersions in water with different sizes: 20 nm, (b) 50 nm, (c) 105 nm, (d) 190 nm, and (e) 310 nm. (m) The spectrum of the **PDDP**/ethanol solution (1.0×10^{-5} mol/l). (After [25.19], courtesy of American Chemical Society (2001))

change of rubrene content shown in Fig. 25.13d. For comparison, doped amorphous thin films were also prepared using the coevaporation technique. The colors of the doped films are not stable because of the oxidation of rubrene. In contrast, the emission colors of the binary nanowires are very stable, which was ascribed to the crystallinity of rubrene. In the amorphous films, the emission of **TPP** can be quenched almost completely at 4% rubrene doping content, which is caused by the higher energy-transfer efficiency. In contrast, the emission of **TPP** cannot be quenched completely even when the dopant content was as high as 20% in the doped nanowires. Both the color stability and the incomplete quenching are essential to the realization of white-light emission.

In general, the fluorescence efficiency of organic chromophores decreases in the solid state, as a result of concentration quenching, even though they show high fluorescence efficiency in solution. However, a phenomenon named aggregation-induced enhanced emission (**AIEE**) was reported in recent years, in which enhanced emission instead of fluorescence quenching was observed in the solid state for some fluorophores [25.21–23]. As we know, solution investigations have made great contributions to the fundamental understanding of luminescence processes at molecu-

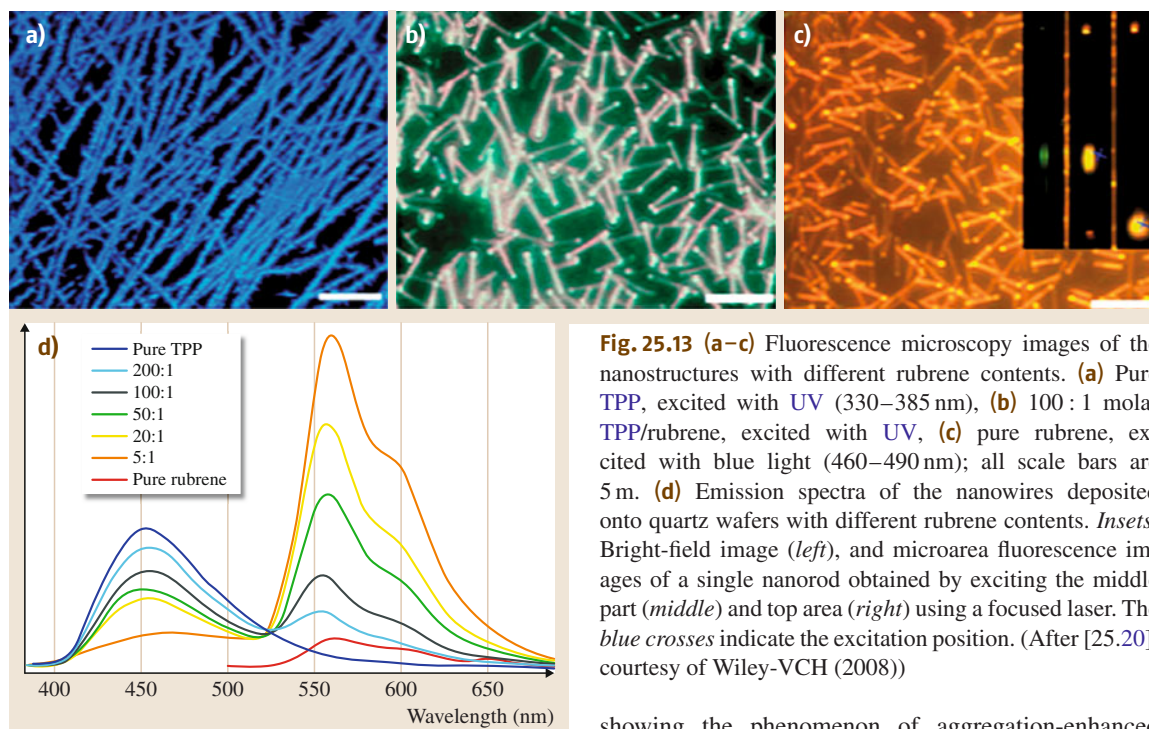

Fig. 25.13 (a–c) Fluorescence microscopy images of the nanostructures with different rubrene contents. (d) Emission spectra of the nanowires deposited onto quartz wafers with different rubrene contents. *Insets*: Bright-field image (left), and microarea fluorescence images of a single nanorod obtained by exciting the middle part (middle) and top area (right) using a focused laser. The blue crosses indicate the excitation position. (After [25.20], courtesy of Wiley-VCH (2008))

lar level. The conclusions drawn from dilute-solution data, however, cannot commonly be extended to concentrated solutions; For example, luminescence is often weakened or quenched at high concentrations, a phenomenon widely known as *concentration quenching*. A main cause for the quenching process is mechanistically associated with the *formation of aggregates*, which is probably why the concentration quenching effect has frequently been referred to as *aggregation-caused quenching (ACQ)*. However, in 2001, Tang et al. discovered an uncommon luminogen system in which aggregation worked constructively rather than destructively as in conventional systems [25.21, 22]. They found that a series of silole derivatives were nonemissive in dilute solutions but became highly luminescent when their molecules were aggregated in concentrated solutions or cast into solid films. Since the light emission was induced by aggregate formation, they termed the process as *aggregation-induced emission (AIE)*.

A series of conjugated polymers that show enhanced light emissions in the solid state have been developed in recent years, examples of which include poly(1-phenyl-1-alkyne)s and poly(diphenylacetylene)s (Fig. 25.14) [25.24, 25]. These polymers fluoresce when dissolved and emit more intensely when aggregated,

showing the phenomenon of aggregation-enhanced emission (AEE). A common structural feature for these polymers is that each of their repeat units contains phenyl rotor(s) and an olefin stator. This is similar to tetraphenylethene (TPE), a well-known AIE luminogen [25.26]. In TPE, the olefin stator is surrounded by phenyl rotors and the restriction of intramolecular rotation (RIR) process is known to account for its AIE effect. In the polymer systems, the intramolecular rotations of the phenyl rotors are already partly restricted at molecular level due to the steric effect of the polymer chains. The polymers are thus fluorescent in the solution state, which explains why they are not AIE but AEE active.

Park et al. used AIE luminogens to fabricate nanowires, whose emission colors could be blue, green, yellow or red, readily tuneable by varying the luminogen structures [25.27]. It was found that the cyano group on the backbone of 1-cyano-trans-1,2-bis(3',5'-bis-trifluoromethyl-biphenyl)ethylene (CN-TFMBE) serves to increase the polarity of the molecule and to give rise to an anisotropic electronic distribution, leading to stronger intermolecular Coulombic interactions. The π – π interaction between nearest-neighbor molecules seems to be strengthened by coplanarization of the phenyl rings when the molecules are in close proximity. The bulky CF_3 groups attached to the phenyl

Fig. 25.14 AIE-active TPE and AEE-active disubstituted polyacetylenes. (After [25.23], courtesy of R. Society of Chemistry (2011))

rings at each end of **CN-TFMBE** give rise to sliding of the molecules along the molecular axis direction and the formation of hydrogen bonding of the type C–FH–C. The formation of **1-D** nanowires of **CN-TFMBE** molecules was found to result from the relative contributions of these three major interactions to the intermolecular distances, arising intrinsically from the aforementioned structural factors. On the basis of these structural guidelines, they successfully prepared highly fluorescent color-tuned **1-D** nanowires and two-dimensional (**2-D**) nanofabrics. These new nanomaterials exhibited well-defined optical properties and excellent mechanical stability. In addition, the compounds readily formed **1-D** nanowires and **2-D** nanofabrics, irrespective of the processing method and conditions used. *Tang* et al. achieved multicolor emissions from the same microfibers by changing the excitation wavelength but not the luminogen structure (Fig. 25.15) [25.28]. Generally, multicolor emissions are realized with blends of dyes or polymers emitting red, green, and blue light. They synthesized a group of silole derivatives with systematically varying 1,1- and 2,5-substituents. The solid-state emissions of the luminogens were found to be tunable by changing the molecular structure, especially the steric effects, of the substituents. Bulkier substituents help weaken the

intermolecular interactions and restrict the intramolecular rotation **IMR** process, thereby blue-shifting the emission color and dramatically boosting the emission efficiency (Φ_F up to 99.9%). Polarized and multicolor emissions are realized in silole crystals and fibers, respectively. The information gained in this work on the structure–property relationships in the **AIE** system is of great value in terms of guiding future molecular engineering endeavors in designing molecular structures for new luminogenic materials with desired light-emitting properties in the solid state.

Regardless of the **AIE** materials, multicolor emission from the same nanostructures by changing the excitation wavelength was also found by *Zhao* et al. [25.29]. They demonstrated that it is also possible to obtain multicolor emission from crystalline **1-D** nanomaterials and their hierarchical assemblies based on a single low-molecular-weight organic compound [25.29]. The selected model compound, 1,2,3,4,5-pentaphenyl-1,3-cyclopentadiene (**PPCP**, inset of Fig. 25.16), is a well-known blue-light-emitting dye used as the emitting layer material in electroluminescence devices. After being fabricated to crystalline nanoribbon assemblies, **PPCP** displayed a multicolor emission property; that is, blue, green, and red emission was achieved by exciting the same sample with appropriate wavelengths. Figure 25.16 displays the **RGB** emission obtained by exciting the **PPCP** nanoribbon arrays with **UV**, blue, and green light. Spectral measurements in-

Fig. 25.15 (a) Photograph and (b–d) fluorescence images of microfibers of silole taken (b) under normal lighting and upon excitation by (c) **UV**, (d) blue, and (e) green light. (After [25.23], courtesy of R. Society of Chemistry (2011))

Fig. 25.16a–d Fluorescence microscopy images of PPCP nanoribbon assemblies. (a) Bright-field image, (b) excited with UV light (330–380 nm), (c) excited with blue light (460–490 nm), and (d) excited with green light (520–550 nm). The scale bar is 10 μm . (After [25.29], courtesy of Wiley-VCH (2007))

indicated that three kinds of emitting centers (blue, green, and red) coexist in the PPCP nanostructures, in

which the blue-light-emitting centers came from single PPCP molecules in the nanostructures. Comparison of emissions from crystalline nanoribbons with different amounts of defects and the contrast between the emissions from crystalline and amorphous films proved that the green- and red-light-emitting centers in the PPCP nanoribbons were induced by their crystallinity and the structural defect energy levels therein. Meanwhile, the emission from each center can be further enhanced by the 1-D structure of the nanomaterials by self-convergence along specific directions.

25.2.3 Optoelectronic Properties

The optoelectronic properties of organic nanomaterials are fundamentally different from their inorganic counterparts due to the weak intermolecular interactions in organic nanomaterials. Moreover, owing to their unique nanoscale size, the optoelectronic properties of organic nanomaterials are also different from those of their monomer and bulk solid counterparts. Therefore, there is great interest in understanding the optoelectronic properties of organic nanomaterials for their practical application in optoelectronic devices. In this section, we focus on the field-emission, charge-transport, and photovoltaic properties of organic nanomaterials.

Field-Emission Property

The unique electrical and optical properties of organic nanomaterials are the focus of study in this field, for example, the field-emission property of organic nanomaterials. Liu et al. synthesized single-crystalline nanocone arrays of a charge-transfer complex, copper tetracyanoquinodimethane (CuTCNQ) in large area by controlling the reaction velocity of copper and tetracyanoquinodimethane (TCNQ). This was achieved by applying a constant current on the copper source (Cu film) and using a physical and chemical vapor combined deposition technique without catalyst or template [25.30]. It was attractive that, when the used Cu films were brushed with plow grooves but other growth conditions were kept constant, CuTCNQ nanocones grew along the grooves as shown in Fig. 25.17a–c. Regardless of the detailed mechanism, these large-area, homogeneous nanocones indicate their potential appli-

Fig. 25.17 (a–c) SEM images of CuTCNQ nanocone arrays grown at brushed grooves. (d) TEM image of CuTCNQ nanocones; (e) SAED pattern of one CuTCNQ nanocone. (After [25.30], courtesy of Wiley-VCH Verlag (2011)) ◀

cations. A TEM image of an individual nanocone is shown in Fig. 25.17d, and its corresponding selected-area electron diffraction (SAED) pattern is shown in Fig. 25.17e. It is obvious that the nanocones were rather sharp, and the tip diameter could reach down to several nanometers. Moreover, the SAED pattern exhibited no change in different parts of the same nanocone, indicating that the whole nanocone was a single crystal. The nanocones could be very sharp (e.g., with diameter less than several nanometers), and all the nanocones are single crystals, which indicated possibly excellent field-emission property.

The sharp nanocone arrays suggested their potential applications in field-emission devices. As preliminary experiments, the field-emission characteristic of the nanocone arrays were investigated in a vacuum chamber of $\approx 10^{-7}$ Pa at room temperature under a two-parallel-plate configuration. The sample was stuck onto a stainless-steel sample stage using conducting glue as the cathode. Another parallel stainless-steel plate served as the anode. The samples' areas were about 0.064 cm^2 ($0.32\text{ cm} \times 0.20\text{ cm}$). The distance between the anode and cathode was $300\text{ }\mu\text{m}$. A typical plot of the field-emission current density (J) versus the applied field (E) and the corresponding Fowler–Nordheim (F–N) plot are presented in Fig. 25.18a,b. The turn-on field of the sample is about $9.43\text{ V}/\mu\text{m}$, defined as the field giving an emission current density of $10\text{ mA}/\text{cm}^2$. The maximal current density of the sample reaches about $2.7\text{ mA}/\text{cm}^2$ at $17.7\text{ V}/\mu\text{m}$. This was better than the property of CuTCNQ nanowires [25.31], indicating the potential applications of these nanocone arrays in nanoelectronics. Moreover, it was found that the surface of CuTCNQ nanocones (Fig. 25.18c) exhibited superhydrophobicity with contact angles of around 155° (Fig. 25.18d), significantly larger than for other nanostructures of CuTCNQ ($125\text{--}130^\circ$) [25.32], indicating the enhanced hydrophobicity of the nanocones.

Charge-Transport Property

The transport properties of organic nanomaterials are the subject of fundamental investigation of molecular nanoelectronics for the orientation of high-performance molecular nanomaterials and devices. Transport properties of the same materials will be different at different dimensionality or size scale; For example, in organic thin-film field-effect transistors, the two-dimensional (2-D) electron gas transports through the molecular/nanometer-thick film between the gate insulator and organic semiconductor, and depends strongly on the thickness and width of the conducting channel of the

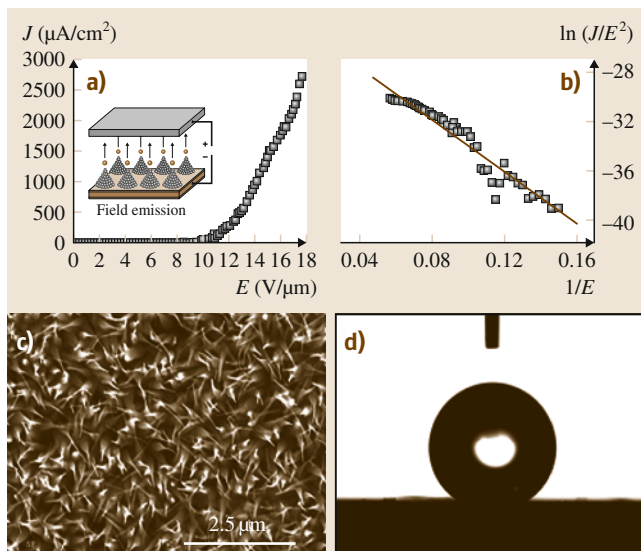

Fig. 25.18 (a) Field-emission J – E curve (inset: field-emission devices), (b) corresponding F–N plot, (c) SEM image, and (d) corresponding water contact angle ($\approx 155^\circ$) of single-crystalline CuTCNQ nanocone layers. (After [25.30], courtesy of Wiley-VCH (2011))

transistor. With reducing channel width, e.g., in organic nanowires or nanoribbons, the transport will be confined in the 1-D structure. The transport changing from 2-D to 1-D will result in some new phenomena due to the confinement effect of the nanomaterials. With further reduction in size, when the organic nanomaterials become zero-dimensional (0-D), many effects of quantum dots will appear. All the low-dimensional organic nanomaterials (1-D, 0-D) have received great scientific and technological interest due to their promising potential applications in electronics and optoelectronics, and are also attractive for fundamental investigation.

Organic field-effect transistors (OFETs), a kind of device with three terminals (drain, source, and gate electrodes), gate insulator, and active semiconductor layer, provide the ability to offer insight into the charge transport of π -conjugated systems, and are acting as a strong tool for exploration of the structure–property relationship of π -conjugated systems, such as field-effect mobility (μ , the drift velocity of carriers under unit electric field), current on/off ratio (the ratio of the maximum on-state current to the minimum off-state current), and threshold voltage (the minimum gate voltage required to turn on the transistor). More importantly, OFETs are essential building blocks for the next generation of cheap and flexible organic cir-

cuits. Therefore, since the discovery of OFETs in 1980s [25.33] they have attracted the world's attention over 20 years, including the discovery, design, and synthesis of π -conjugated systems for OFETs, extending their potential applications to radiofrequency identification (RFID) tags, flexible displays, electronic papers, sensors, etc. [25.34]. Indeed, electrical characterization of OFETs provides a wealth of information on π -conjugated systems [25.35]. The semiconductor layer of OFETs usually consists of organic thin films. Inevitably, the existence of disorder and grain boundaries in thin films masks the intrinsic properties of the organic semiconductors and restricts the mobility of such devices. It is expected that high-quality single crystals of organic semiconductors will reveal intrinsic charge transport in materials and give high mobility in OFETs. The first organic OFET devices based on an individual single-crystalline nanoribbon can be traced back to 2006 [25.36]. Tang et al. fabricated OFETs based on an individual CuPc nanoribbon. The activity of OFETs based on organic nanoribbons was highly sensitive to

electron beam irradiation; For example, OFETs based on organic nanoribbons lost their field-effect activity after being scanned by SEM. Therefore, it was unsuitable to use electron beam deposition or focused ion beam deposition to fabricate devices based on organic nanoribbons. A series of new methods were developed to fabricate OFETs [25.37]. The bottom-contact configuration (Fig. 25.19a) is always adopted when organic crystals are unstable in vacuum (e.g., tetrathiafulvalene, TTF) or the deposition of a top electrode on them is difficult. It is also noticed that the bottom-contact configuration sometimes causes contact problems due to the weak van der Waals force between electrode and crystal. In contrast, top-contact devices could work effectively to avoid this problem, e.g., by using a copper grid or a Au microwire as a mask to deposit electrodes on a small organic crystal (Fig. 25.19b). But during the vacuum deposition of electrodes on organic crystal the thermal irradiation may also do harm to organic crystal. To avoid thermal radiation damage and filling of pinholes in the dielectric layer by metal atoms

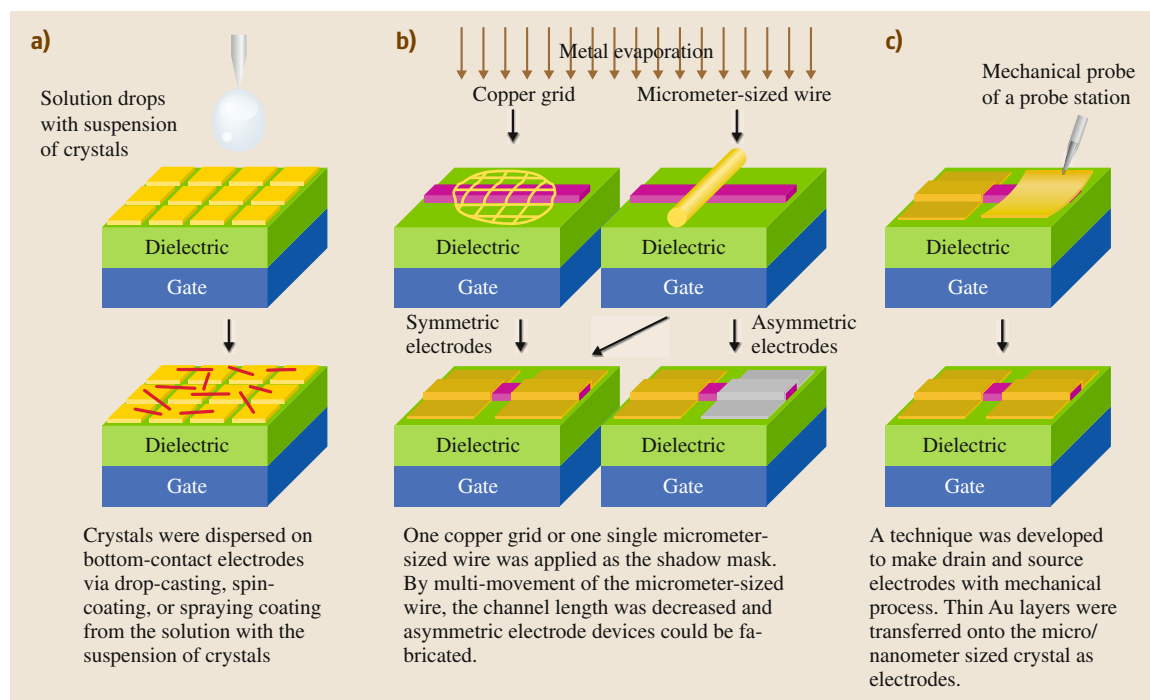

Fig. 25.19a–c Techniques for fabrication of devices based on organic micro- and nanocrystals. **(a)** Bottom-contact configuration with predeposited electrode arrays on substrate, dropping solution on the electrodes for crystallization, **(b)** shadow mask technique employing a copper grid or a Au microwire as the mask for deposition to make symmetrical and asymmetrical electrodes, **(c)** Au-layer stamping technique, thin Au layers are mechanically transferred and pasted on an individual crystal as the electrodes. (After [25.37], courtesy of Wiley-VCH (2008))

during electrode vacuum deposition, a mechanical technique was recently developed to paste electrodes onto crystals directly (Fig. 25.19c). Au thin film deposited on a Si wafer is cut into small pieces (approximately $30\text{ }\mu\text{m} \times 150\text{ }\mu\text{m}$) by a sharp probe, then a piece of the film is peeled off from the substrate by the probe and pasted onto the organic crystal as a source or drain electrodes. This *cold* electrode circumvents the disadvantages of thermal evaporation and thus ensures high device performance.

Based on OFETs with organic and polymer nanostructures, the transport properties of the nanostructures can be analyzed. Structure–property studies are a prerequisite to understand the fundamental properties of organic materials and their corresponding molecular structure and device properties. High mobility is expected when conjugated molecules have strong interactions with neighboring molecules to maximize the overlap between molecular orbitals, e.g., cofacial π – π stacking structure. However, so far, lots of organic semiconductors which exhibit high mobility (e.g., pen-

tacene) adopt the edge-to-face herringbone structure with reduced intermolecular electronic couplings. It is imperative to establish the structure–property relationship of organic semiconductors explicitly. TTF and its derivatives have become one of the most studied heterocyclic systems since its discovery [25.39]. It is well known that TTF crystals have two phases: α -TTF, which belongs to space group $P21/c$ with two molecules at centrosymmetric sites of the unit cell, and β -TTF, which belongs to space group $P1$ with four symmetry-inequivalent molecules at the centrosymmetric sites of the unit cell (Fig. 25.20) [25.38]. Crystals of α -TTF can be grown from *n*-heptane solution, while β -TTF can be obtained by using chlorobenzene as solvent. Single-crystal transistors based on α - and β -TTF (Fig. 25.20) suggest that the maximum field-effect mobility of the α -phase is as high as $1.20\text{ cm}^2/\text{V s}$ while that of the β -phase is only about $0.23\text{ cm}^2/\text{V s}$, which is assigned to the strong π – π stacking and the $\text{S} \cdots \text{S}$ intermolecular interactions of α -TTF. The results provide direct proof of the structure–property relationships of TTF crystals.

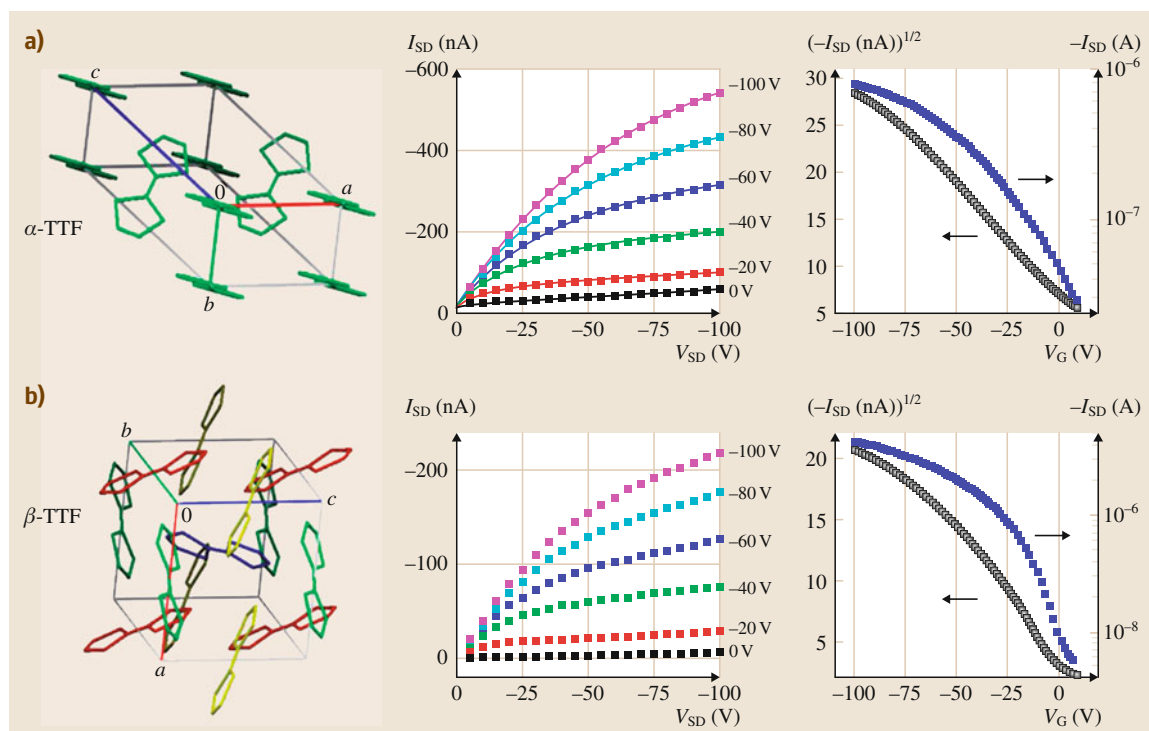

Fig. 25.20a,b Crystal structures of α - and β -TTF, and typical output and transfer characteristics of the transistors based on (a) α - and (b) β -TTF crystals. The maximum field-effect mobility of the α -TTF is as high as $1.20\text{ cm}^2/\text{V s}$, while that of β -TTF is only about $0.23\text{ cm}^2/\text{V s}$. The different charge-transport property indicates the importance of phase control for high-performance devices. (After [25.38], courtesy of American Institute of Physics (2007))

Fig. 25.21a–d Well-defined, highly crystalline nanowires of a derivative of PPE, TA-PPE, are obtained by self-assembly. (a) AFM image, (b) TEM image, (c) SAED pattern, and (d) devices. (After [25.40], courtesy of American Chemical Society (2009))

Certainly, the study of transport properties is not only confined to small molecules, but also extends to conjugated polymers. Well-defined, highly crystalline nanowires of a derivative of PPE, TA-PPE, were obtained by self-assembly [25.40]. Structure analyses demonstrated that the nanowires probably have an orthorhombic crystal unit cell with lattice parameters of $a \approx 13.63 \text{ \AA}$, $b \approx 7.62 \text{ \AA}$, and $c \approx 5.12 \text{ \AA}$. In the nanowires, the backbones of the TA-PPE chains are parallel to the nanowire long axis, with their side-chains standing on the substrate. The transport properties of the nanowires examined using OFETs suggest that the mobility of the polymer crystalline nanowire is $\approx 10^{-2} \text{ cm}^2/\text{Vs}$, with the highest mobility approaching $0.1 \text{ cm}^2/\text{Vs}$, which is 3–4 orders higher than that of thin-film transistors of the same polymer, indicating the high performance and efficient charge transport of the 1-D polymer nanowire crystals (Fig. 25.21).

Photovoltaic Properties

The nanowire geometry provides potential advantages over planar wafer-based or thin-film solar cells in every step of the photoconversion process [25.41]. These advantages include reduced reflection, extreme light trapping, improved bandgap tuning, facile strain relaxation, and increased defect tolerance. These benefits are not expected to increase the maximum efficiency above standard limits; instead, they reduce the quantity and quality of material necessary to approach those limits, allowing for substantial cost reductions. Additionally, nanowires provide opportunities to fabricate complex single-crystalline semiconductor devices directly on low-cost substrates and electrodes such as aluminum foil, stainless steel, and conductive glass, addressing another major cost in current photovoltaic technology [25.42]:

Eindhoven University of Technology (TU) researchers want to develop solar cells with an efficiency of over 65% by means of nanotechnology. In Southern Europe and North Africa these new solar cells can generate a substantial portion of the European demand for electricity. The Dutch government reserves EUR 1.2 million for the research. Stacking nanowires make it possible to stack a number of subcells (junctions). In this process each subcell converts one color of sunlight optimally to electricity. The highest yield reported until now in a nanowire solar cell is 8.4%. Haverkort: We expect that a protective shell around the nanowires is the critical step towards attaining the same efficiency with nanowire solar cells as with thin-film cells. Haverkort thinks that at 5–10 junctions he will arrive at an efficiency of 65%. In addition, the researchers expect considerable savings can be made on production costs, because nanowires grow on a cheap silicon substrate and also grow faster, which results in a lower cost of ownership of the growth equipment. What is more, the combination of the mirror systems with nanotechnology will imply an acceptable use of the scarce and hence expensive metals gallium and indium.

Solar cells and photodetectors operate under the same basic process: converting light into current. Miniature versions of these devices will rely on nanostructured materials with good photoconducting properties. Although the figures of merit for inorganic photoconducting nanowires, such as those made from ZnO or Si, have been measured, relatively little is known about the properties of organic nanowires [25.43]. Given that organic nanowires could be both chemically tunable and relatively inexpensive to integrate into electronic

circuits, *Redmond's* group at the Tyndall National Institute in Cork, Ireland has measured photoconductivity in a single polymer nanowire [25.44]. The authors fabricated the 200 nm-wide, 15 m-long polymer wires using a simple template wetting technique. Metal contacts were made on either end of a single wire to measure the photoinduced current over several on–off cycles of a near-ultraviolet laser. The wire's quantum efficiency – the number of current-carrying electrons produced per photon hitting the wire – is about 0.1%, which is competitive with several inorganic nanowires. As in many polymer-based electronic devices, the limiting factors may be the noncrystalline structure and poor electrical contact with the metal leads.

With the demands for new materials with enhanced properties, such as narrow bandgap and high carrier mobility, control over the interface and morphology of the active layer are key issues for achieving high-efficiency organic photovoltaics (OPVs). In particular, control over the nanoscale phase separation between the donor and acceptor, molecular ordering enhancement of the donor polymers, and an increase in the percolation of acceptor molecules are critical factors that determine bulk heterojunction (BHJ) device properties. Device efficiency is mainly determined by control over the nanostructure of the donor–acceptor blended active layer. A large interface between the donor and acceptor layers is needed for the dissociation of excitons, and efficient charge extraction requires a nanostructure that allows efficient charge transport to the electrodes. Bulk heterojunction solar cells based on blends of poly(3-hexylthiophene) (P3HT) and phenyl-C₆₁-butyric acid methyl ester (PC₆₁BM) were fabricated using self-assembled P3HT nanowires in a marginal solvent without posttreatments by *Cho et al.* [25.45]. The interconnected network structures of self-organized P3HT nanowires create continuous percolation pathways through the active layer and contribute to enhanced carrier mobility (Fig. 25.22). The morphology and photovoltaic properties are studied as a function of aging time of the P3HT precursor solution. Optimal photovoltaic properties are found at 60 h ageing time, which increases both light absorption and charge balance. Multilayered solar cells with a compositionally graded structure are fabricated using preformed P3HT nanowires by inserting a pure P3HT donor phase into the hole-collecting electrode. Applying optimized annealing conditions to the P3HT buffer layer achieves an enhanced hole mobility and a power conversion efficiency of 3.94%. The introduction of a compositionally graded device structure,

which contains a P3HT-only region, reduces charge recombination and electron injection to the indium tin oxide (ITO) electrode and enhances the device properties. These results demonstrate that preformed semiconductor nanowires and compositionally graded structures constitute a promising approach to the control of bulk heterojunction morphology and charge-carrier mobility.

Jenekhe et al. [25.46] prepared P3BT nanowires by solution-phase self-assembly and used them to construct highly efficient P3BT/fullerene nanocomposite solar cells. The fullerene/P3BT nanocomposite films showed an electrically bicontinuous nanoscale morphology with average field-effect hole mobilities as high as $8.0 \times 10^{-3} \text{ cm}^2/\text{Vs}$ due to the interconnected P3BT nanowire network. The power conversion efficiency of fullerene/P3BT nanowire devices was 3.0% (at $100 \text{ mW}/\text{cm}^2$, AM1.5) in air.

p–n junctions are of great importance in optoelectronic devices. Organic/inorganic p–n junction nanowires composed of functional organic molecules and inorganic molecules may be able to realize new or improved chemical and physical properties that were not observed in the individual component on nanosize and their bulk materials. *Li et al.* [25.47] reported fabrication of an organic/inorganic semicon-

Fig. 25.22a–d AFM and TEM images, respectively, of (a,c) homo-P3HT nanowires and (b,d) P3HT nanowires/PCBM blend film. (After [25.45], courtesy of Wiley-VCH (2011))

ductor p-n junction nanowire (Fig. 25.23). They used ordered porous AAO templates and chose the p-type organic semiconductor polypyrrole (PPY) and n-type inorganic semiconductor CdS to prepare heterojunction nanowires, finding remarkable performance of the light-controlled diode within a single hybrid p-n junction nanowire. The CdS-PPY heterojunction nanowire exhibited rectifying property at room temperature. Interestingly, with increasing illumination intensity, the conductivity of the CdS-PPY heterojunction nanowire increased. The rectification ratio of the diode increased from 8.0 to 13 with enhancement of the light intensity from 1.12 to 5.76 mW/cm². Controlling the conductivity of the p-n junction nanowire by the light irradiation simply to achieve diode action indicates a new way to realize photoelectric integration in a single nanowire device.

Hu et al. synthesized organic single-crystalline p-n junction nanoribbons of CuPc and F₁₆CuPc at large scale through crystallization of F₁₆CuPc on CuPc nanoribbon templates [25.48]. The selective crystallization strongly depended on the similar molecular structures, lattice parameters, and similar attachment energies at the interfacial basal planes of the (001) facets of F₁₆CuPc and CuPc. An attractive feature of this system is the ability to generate p-n heterojunction nanoribbons easily over large areas. An individual p-n heterojunction nanoribbon is shown in Fig. 25.24.

The length of the active p-n junction could reach about ≈ 25 μm, as unambiguously identified by optical microscopy and SEM (Fig. 25.24c). The lengths of the p-n junction will depend on the length of the CuPc template and the crystallization time of the F₁₆CuPc on CuPc templates. Such long p-n junctions encouraged us to utilize these structures in nanodevices and circuits. An example SEM image of an individual nanoribbon

of several micrometers length is shown in Fig. 25.24c, and the corresponding composition distribution along the nanoribbon was identified by local elemental mapping by energy-dispersive x-ray spectroscopy as shown

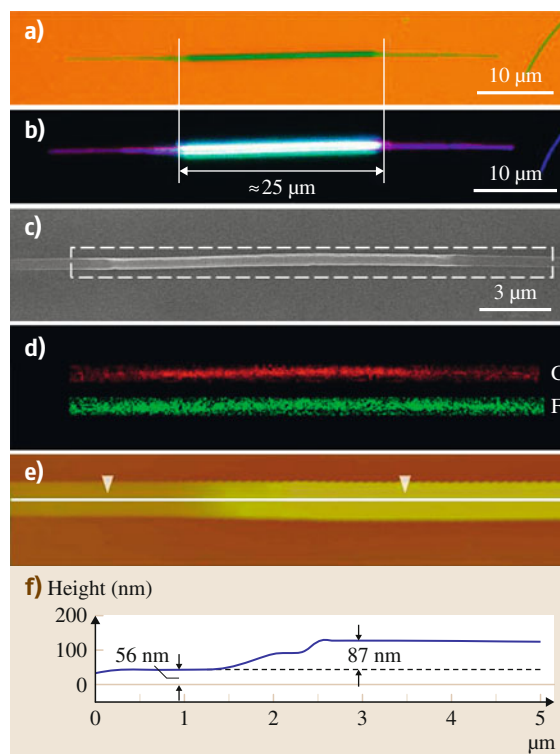

Fig. 25.24 (a,b) Optical images of an individual p-n heterojunction nanoribbon, (c,d) SEM image and corresponding local elemental mapping of an individual nanoribbon, (e,f) AFM image and height curve of the nanoribbon. (After [25.48], courtesy of American Chemical Society (2010))

in Fig. 25.24d. Along the nanoribbon the fluorine (F) was uniformly distributed, while the proportion of carbon (C) was higher at the middle region of the p–n junction than elsewhere because of the integration of C element from both CuPc and F₁₆CuPc. The thickness of the p–n junction was about 1418 nm, consisting of 87 nm of CuPc and 56 nm of F₁₆CuPc as determined by AFM experiments (Fig. 25.24e,f). Well-defined ambipolar transport characteristics were demonstrated on discrete devices. A discrete p–n heterojunction nanoribbon photovoltaic solar cell was fabricated. Figure 25.25a shows a schematic configuration of a p–n device, while Fig. 25.25b shows the current–voltage (*I*–*V*) characteristics for the SEM device shown in Fig. 25.20d. The plot for a CuPc–F₁₆CuPc nanoribbon device yielded a J_{SC} of ≈ 0.054 mA/cm², V_{OC} of ≈ 0.35 V, and fill factor (FF) of ≈ 0.36 under 1 sun (100 mW/cm²). Furthermore, these individual test structures will enable detailed analysis to be carried out in areas that have been difficult to study in bulk heterojunction devices. The p–n nanoribbons will also serve as ideal systems to understand the fundamental charge-transport and photovoltaic behaviors at nanoscale organic–organic interfaces. This work opens the opportunity to explore synthesis of high-quality or-

ganic single-crystalline p–n junction nanoribbons and their application in fundamental science and new device technologies.

25.2.4 Mechanical Properties

Nanomaterials are an attractive group of modern engineering materials with properties superior to those of their coarse-structured counterparts. In particular, this applies to the mechanical properties, such as tensile strength, ductility, fatigue, and wear resistance. The novel mechanical properties of nanomaterials are a subject of nanomechanics research. Nanomechanics is a branch of nanoscience studying fundamental mechanical (elastic, thermal, and kinetic) properties of physical systems at the nanometer scale. It has emerged on the crossroads of classical mechanics, solid-state physics, statistical mechanics, materials science, and quantum chemistry. As an area of nanoscience, nanomechanics provides a scientific foundation for nanotechnology. However, despite the progress made in technology of such materials including nanocrystalline metals and nanocomposites, their application is still restricted by insufficient experimental data and interpretation; For example, organic nanocrystals are usually delicate and

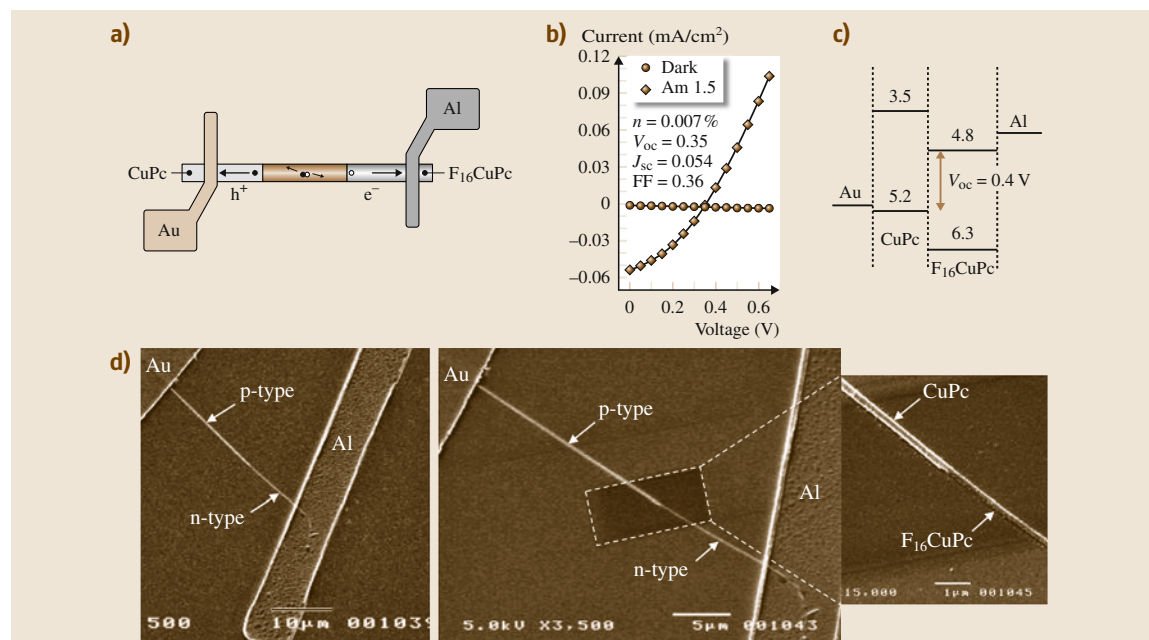

Fig. 25.25 (a) Schematic configuration of a discrete p–n heterojunction solar cell, and (b) the current–voltage characteristics, (c) band diagram, and (d) SEM image of a discrete CuPc–F₁₆CuPc nanoribbon photovoltaic solar cell. The devices were measured under AM 1.5 irradiation (100 mW/cm²) (After [25.48], courtesy of American Chemical Society (2010))

easily broken. However, at micro- and nanometer sizes, some new phenomena are emerging, indicating great promise for organic and polymeric nanomaterials in the study of nanomechanics.

Flexible devices and circuits of organic thin films have been demonstrated successfully [25.50]. A remaining challenge at present is how to integrate flexibility and high carrier mobility together, because flexibility typically originates from microscopically disordered materials, while high mobility originates from highly ordered structures typically with crystalline order; For example, it is well known that organic single crystals exhibit high mobility compared with their amorphous and polycrystalline film counterparts, being some of the best candidates for fabrication of high-performance devices. However, organic bulk crystals are very fragile and delicate, so that they are challenging to use in flexible devices. It has been discovered that organic single crystals of nanometer size exhibit good flexibility [25.51], which provides a chance to obtain high-performance flexible electronic devices based on organic crystals. However, up till now, the mechanical and transport properties of organic nanocrystals at bent status have rarely been studied. One reason is probably due to the difficulty in performing such experiments, e.g., fabricating and investigating flexible devices based on individual organic nanocrystals.

Tang et al. [25.49] found that nanowire crystals with diameter smaller than 150 nm would not break even when bent to very small radius of curvature (Fig. 25.26), and could be twisted (Fig. 25.26a) or bent over 180° without breaking (Fig. 25.26b–d). The nanowire crystals had the unique ability to be bent, forming a perfect

Fig. 25.26a–d SEM images of CuPc nanowire crystals with width smaller than 150 nm, which can be twisted and bent exhibiting excellent flexibility. (After [25.49], courtesy of Wiley-VCH (2011))

circular shape (Fig. 25.26b,c), or a ring adhered to the substrate surface (Fig. 25.26d). The maximum local strain of the wires shown in Fig. 25.26 could be estimated from $\varepsilon = d/2r_c = 3.1\text{--}5.4\%$, where r_c is the bending radius of curvature and d is the width of nanowire in the r_c direction [25.52]. These nanowire crystals could be bent to even smaller radius of curvature than shown in Fig. 25.26 and to endure larger local strains without fracture.

In situ manipulation of individual crystal in a SEM system as shown in Fig. 25.27 provided direct evidence of reversible bending of organic nanowire crystals. In order to reduce the damage of crystals caused by electron beam radiation, the lowest available voltage of 4 kV was used. An individual nanowire with diameter of ≈ 400 nm was transferred and pinned by the van der Waals force to the edge of a silicon wafer. Without ex-

Fig. 25.27a–h SEM images for the typical bending configurations of a CuPc nanowire with width of ≈ 400 nm by a series of transverse manipulations with a mechanical probe. (After [25.49], courtesy of Wiley-VCH (2011))

ternal force, the nanowire was straight (Fig. 25.27a). Subsequently, the nanowire was taken through a series of distinct compression manipulations using the tip of a probe on a three-dimensional probe stage. When a pushing force towards the wafer was applied by the tip of the probe, the wire bent slightly (Fig. 25.27b). Driven by a larger force, the wire was bent further, and the bending radius of curvature decreased gradually (the curvature increased, Fig. 25.27b–d). The radius of curvature reached $\approx 3\text{ }\mu\text{m}$ in Fig. 25.22d, and could be reduced further (Fig. 25.27e,f). The maximum local strain in the wires bent by the probe was estimated at over 10% without breaking. These data of local strain can be used as the reference for the design of flexible devices and circuits. Besides such flexibility, this experiment also showed the elasticity characteristic of the nanowire crystals, which is also important for flex-

ible electronics. When the probe was moved far from the wire, the curvature decreased due to the elasticity of the wire (Fig. 25.27g). Finally, the wire recovered its original straight shape after the mechanical probe was removed (Fig. 25.27h). The bend and recovery could be carried out multiple times reversibly without fracture of the crystal. These results are relevant for the charge-transport theory of organic semiconductors as well as for flexible devices and circuits design. Moreover, our study suggested that small-size nanowire crystals (150–500 nm) showed good flexibility and elasticity. They could be bent over 180° with local strain over 10% without fracture. The Young's modulus of the single-crystalline wires was about 3.8–4.5 GPa, one order of magnitude smaller than that of inorganic nanostructures, indicating that organic nanowire crystals are much more appropriate for use in flexible devices.

25.3 Applications

Since the 1990s, great advancements have been made in the preparation/synthesis of organic nanomaterials and methodologies for characterization of their properties. Simultaneously, applications of organic nanomaterials in various fields have been developed rapidly, such as in sensors and actuators, photodetectors, surface wettability control devices, optical waveguides and lasers, and even organic nanocircuits. It is anticipated that, with the development of organic nanomaterials, many other new applications for these novel materials will be found.

25.3.1 Sensors and/or Detectors

Nanosensors are any biological, chemical, or surgical sensory points used to convey information about nanoparticles to the macroscopic world. Their uses mainly include various medical purposes and gateways to build other nanoproducts, such as computer chips that work at the nanoscale and nanorobots. One of the first working examples of a synthetic nanosensor was built by researchers at the Georgia Institute of Technology in 1999 [25.53]. It involved attaching a single particle onto the end of a carbon nanotube and measuring the vibrational frequency of the nanotube both with and without the particle. The discrepancy between the two frequencies allowed the researchers to measure the mass of the attached particle. Chemical sensors have been built using nanotubes to detect various properties of

gaseous molecules. Carbon nanotubes have been used to sense ionization of gaseous molecules, while nanotubes made out of titanium have been employed to detect atmospheric concentrations of hydrogen at the molecular level [25.54,55].

Organic nanomaterials are widely used as chemical sensors, e.g., to detect different gases, due to the functions of the nanomaterials achieved by molecular design. Certainly, chemical sensors can also detect the speed, wavelength, and level of molecules in strong light; For example, vertical organic nanowire arrays of 1,5-diaminoanthraquinone (DAAQ) on solid substrates were prepared by Huang et al. [25.56] by a facile physical vapor transport method. The color and fluorescence of the DAAQ nanowires could be bleached and quenched by acid vapor and rapidly regenerated by base vapor, making them useful as optical sensor materials (Fig. 25.28). The ease of oriented vertical growth makes them promising nanophotonic elements that may be directly integrated into photonic devices during growth. Similarly, Li et al. [25.57] prepared polyaniline nanofibers through the in situ oxidative polymerization method and used them for detection of aromatic organic compounds (AOCs). The sensor showed an increase in conductivity, and the maximum response measured at 1000 ppm was several tens of percent.

Photodetectors/photoswitches are a major kind of detectors based on organic nanomaterials. It is believed that photodetectors based on organic semiconductors

Fig. 25.28 Vertically aligned DAAQ nanowire arrays and photographs of changes after exposure to HCl for 0, 5, 10, 30, and 60 s, respectively. (After [25.56], courtesy of American Chemical Society (2009))

will afford devices with low cost, light weight, high efficiency, and good environmental benignity, which are important features for organic optoelectronic devices and circuits. Not only low dark current but also high photocurrents are required for fabrication of high-performance photodetectors. Tang et al. [25.58] have fabricated high-quality photoswitches based on F_{16} CuPc single crystals, an air-stable, n-type organic semiconductor. The response and recovery velocities were estimated to be near 100 and 50 Hz, respectively. More significantly, the devices also showed high reproducibility and retention ability. After several tens of cycles and nearly 1 h of continuous work, no degradation in the current was observed. Zhou et al. [25.59] also fabricated excellent photoswitches using organic single-crystal submicrometer ribbons on flexible poly(ethylene terephthalate) (PET) substrates by using low-cost solution methods. The photoswitch exhibited high performance with gain of about 1.3×10^3 , responsivity of about 420 A/W, and highest on/off ratio of more than 1000. More interestingly, the highly reproducible on/off switching property was exhibited either with the planar geometry or in the bending state. No significant current changes under the same illumination level were observed in the bending state. It is worth noting that the

photocurrent even increased a little in the bending state. The Hu group [25.9] also reported a high-performance photoswitch based on ordered single-crystal microwire arrays of anthracene derivatives, prepared via a solution process. Very recently, Wang et al. [25.60] reported that the performance of photoswitches based on 9,10-bis(phenylethynyl)anthracene (BPEA) single crystals showed strong phase dependence, as shown in Fig. 25.29. Devices of β -phase single crystals exhibited higher photoswitching performance than that of α -phase due to the supramolecular assembling motif governing the properties of organic photoswitches.

Phototransistors, a kind of three-terminal device with light as the *fourth terminal*, can reach especially high gains through the transistor action since the applied gate bias of the transistor provides an efficient way for dissociation of photogenerated excitons into free carriers, being beneficial for subsequent carrier transport and collection; i. e., phototransistors provide high efficiency for the mentioned processes and result in effective photodetection [25.61]. Moreover, phototransistors take advantage of the combined light detection and signal magnification properties to realize both functionalities in a single device. Hu et al. [25.62] first self-assembled nanojunction phototransistors based on

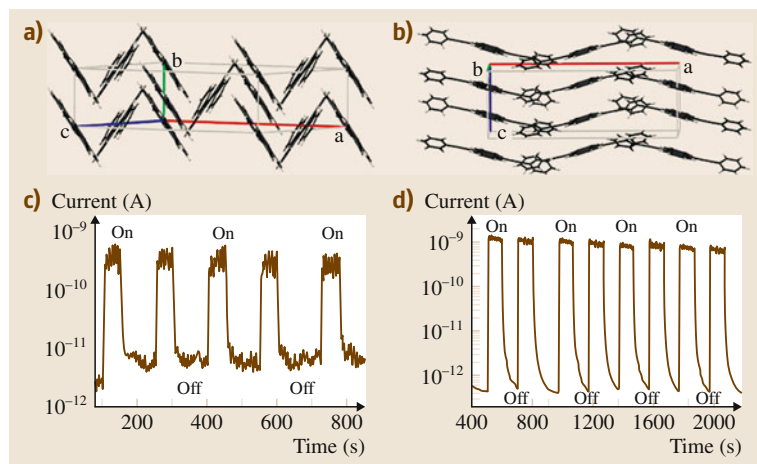

Fig. 25.29a–d The single-crystal structures of (a) α - and (b) β -phase BPEA photoswitching characteristics of (c) α - and (d) β -phase BPEA single crystals. (After [25.60], courtesy of American Institute Physics (2010))

TA-PPE and Au nanogap electrodes (Fig. 25.30), which worked well as nanometer-scale phototransistors. With increasing gate bias, strong conductance oscillation was observed in this self-assembled transistor (at low temperature, 147 K), which was assigned to single-electron charging oscillations arising from electron tunneling through the nanometer-scale transistor.

25.3.2 Surface Wettability Control

Wettability is a fundamental property of a solid surface, playing important roles in daily life, industry, and agriculture. Functional surfaces with special wettability have aroused much interest because of their great advantages in applications [25.64]. The chemical compositions determine the surface free energy and thus have great influence on wettability. However, this has certain limitations; For example, the CF_3 -terminated surface was reported to possess the lowest free energy and the best hydrophobicity, while on flat surfaces, the maximum contact angle (CA) could only reach about 120° . The surface topographic structure is also an important factor that influences the wettability. Lotus is well known for the self-cleaning effect observed on its leaves, which show a water CA as large as $161.0 \pm 2.7^\circ$ and a sliding angle (SA) as small as only about 2° . Such superhydrophobicity and the excellent anti-adhesion capability are the origin of the self-cleaning effect.

Jiang et al. [25.65] revealed the novel finding of micro- and nanoscale hierarchical structures on the leaf. The randomly distributed papillae with diameters ranging from 5 to $9 \mu\text{m}$ were found to consist of further branch-like nanostructures with average diameter of $124.3 \pm 3.2 \text{ nm}$, which could also be observed on the lower part of the leaf. Theoretical simulation [25.65] indicates that the CA may increase to about 160° af-

Fig. 25.31a–f SEM images of cast products (a) layer-like structures, (b) ordered microwires, (c) networks composed of micro- and nanowires, (d) enlarged SEM image of Fig. 25.25c microwires and nanowires networks, (e) self-assembled fireworks structures of the micro- and nanowires, the self-assembly was performed by heating the substrates under 100°C for 30 min, (f) enlarged SEM image of Fig. 25.25e micro- and nanowires. (After [25.63], courtesy of Wiley-VCH (2010))

ter considering the contribution of the nanostructures, which is well consistent with the experimental result, i. e., the role of the hierarchical micro- and nanostructures giving this property. To confirm this, a comparison between aligned carbon nanotube (ACNT) films with and without hierarchical structures was made. The results indicate that the hierarchical structures would not only further improve the hydrophobicity of the films but also result in small sliding angles. This opens the way to tune surface wettability by using organic nanomaterials; For example, by using molecular interactions such as hydrogen bonds and $\pi-\pi$ interactions, micro- and nanometer sized, single-crystalline nanowires of an anthracene derivative (Fig. 25.31a) could be cast efficiently into different morphologies by controlled the experimental conditions [25.63]. Attractively, large-area ($4 \times 4 \text{ cm}^2$) film consisting of assembled micro- and nanowires was obtained, which showed contact angles over 150° independent of whether composed of network or firework micro- and nanowires; i. e., the films exhibited excellent superhydrophobicity. For example,

Fig. 25.32 The superhydrophobicity of a film consisting of self-assembled micro- and nanometer-sized wires; the water drops floated on the film with contact angle around 151° . (After [25.63], courtesy of Wiley-VCH (2010))

films with network structure exhibited contact angles of around 151° , as shown in Fig. 25.32.

25.3.3 Optical Waveguides and Lasers

In the last couple of years, nanowires have also gradually been adopted as optically driven lasers [25.67] because the significant difference in refractive index between the nanostructure and its surroundings defines a subwavelength-sized optical cavity. Moreover, semiconducting nanowires and nanoribbons have also been used as optical waveguides [25.68], which propagate and manipulate light on the subwavelength scale. However, most of the research in this field is focused on inorganic materials, while fewer attempts are made to construct 1-D structured low-molecular-weight compounds [25.69] even though it is well known that the optical and optoelectronic properties of organic nanomaterials are fundamentally different from those of their inorganic counterparts [25.70]. Due to their optical tunability, high luminescence efficiency, and self-assembly property, organic compounds can serve as effective building blocks in future miniaturized optoelectronics that generate and propagate light [25.71]. Therefore, the fabrication of 1-D organic nanomaterials is of great scientific interest and technological significance. This is particularly the case for single-crystalline organic nanomaterials, because their high crystallinity effectively enhances the performance of corresponding devices [25.72].

Zhao et al. [25.73] prepared single-crystalline nanowires from a small organic functional compound, 2,4,5-triphenylimidazole (TPI), via adsorbent-assisted PVD. As-prepared TPI nanowires can serve as single-wire active optical waveguides and ultraviolet lasers, which may be used as building blocks for nanoscale

Fig. 25.33 PL microscopy images of isolated BPEA tubes excited with light between 460 and 490 nm. Scale bars: 20 μm . (After [25.66], courtesy of Wiley-VCH (2008))

photonic devices. The microcavity behavior of as-prepared wires is influenced significantly by their dimensions. The results presented in [25.73] provide useful information for the construction of nanoscaled photonic devices from molecular materials. After that, they further examined 9,10-bis(phenylethynyl)anthracene (BPEA) [25.66]. Two kinds of 1-D microstructures, tubes and rods, were prepared from BPEA. While both types of 1-D microstructures can absorb excitation light and propagate the photoluminescence (PL) emission towards the tips, the air inside the hollow tubes changes the waveguide behavior and helps to reduce the optical loss (Fig. 25.33).

25.3.4 Nanocircuits

Nanocircuits are electrical circuits operating on the nanometer scale. A variety of proposals have been made to implement nanocircuitry in different forms. These include single-electron transistors, quantum dot cellular automata, and nanoscale crossbar latches. In producing these nanocircuits, there are many aspects involved. Transistors are an integral part of circuits, as they control the flow of electricity and transform weak electrical signals into strong ones. They also control electric current as they can turn it on/off, or even amplify signals. Circuits currently use silicon as a transistor because it can easily be switched between conducting and nonconducting states. However, in nanoelectronics, transistors might be organic

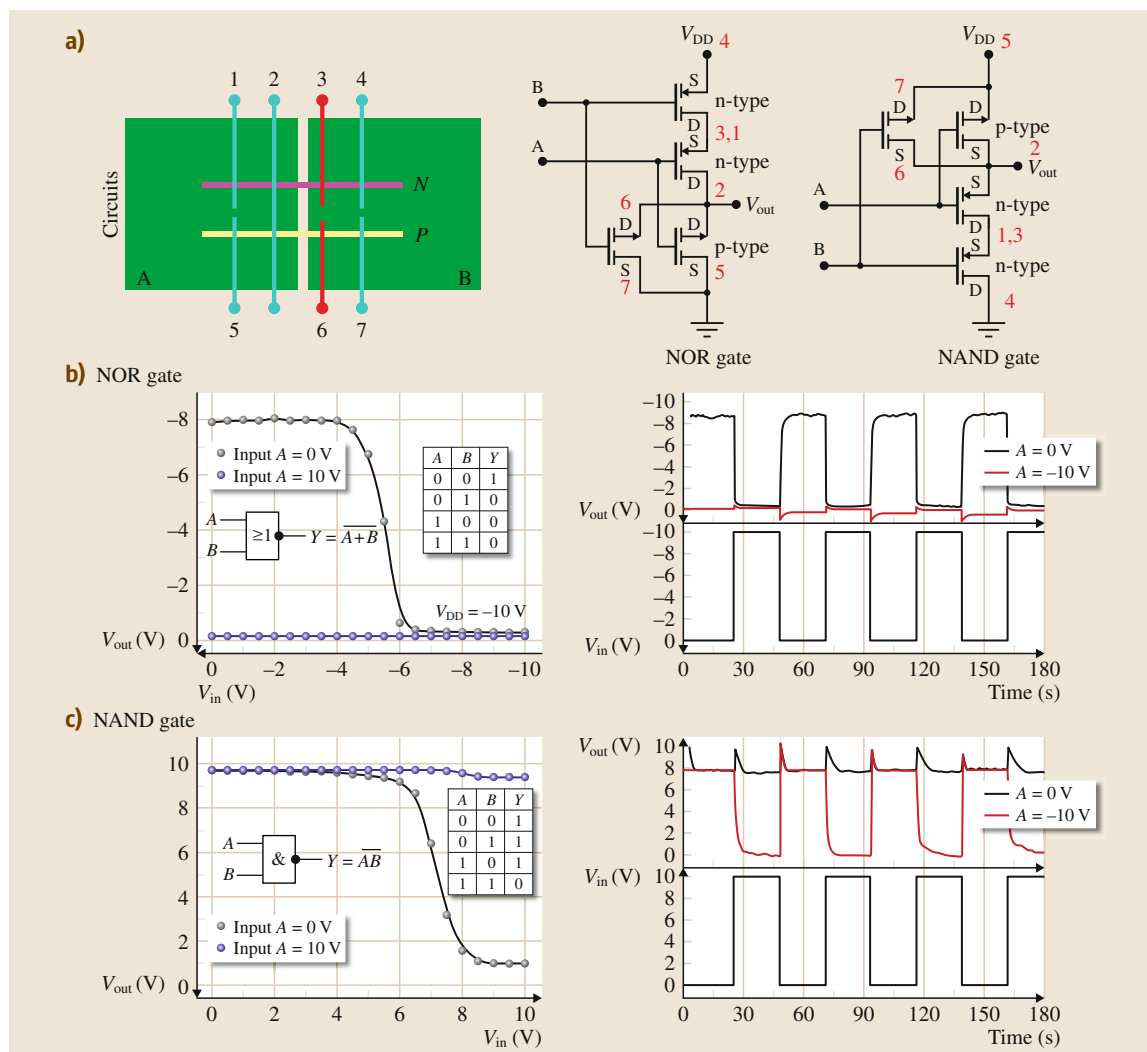

Fig. 25.34a–c Organic single-crystal NOR and NAND logic circuits using nanowires of CuPc, F₁₆CuPc, and SnO₂:Sb as building blocks. **(a)** Circuit and schematic of logic circuits of NOR and NAND, **(b)** transfer and dynamic switching characteristics of a NOR gate at $V_{DD} = -10$ V, **(c)** transfer and dynamic switching characteristics of a NAND gate at $V_{DD} = 10$ V. (After [25.74], courtesy of Wiley-VCH (2009))

molecules or organic and polymeric nanostructures. The second aspect of nanocircuit organization is interconnection. This involves logical and mathematical operations and the wires linking the transistors together that make this possible. The last part of nanocircuit organization is architecture. This has been explained as the overall way the transistors are interconnected, so that the circuit can plug into a computer or other system and operate, independently of the lower-level details.

Tang et al. [25.74] fabricated organic single-crystal transistors and circuits (Fig. 25.34) by mechanically assembling nanowires of CuPc, F₁₆CuPc, and SnO₂:Sb. The devices exhibited low operational voltage, high mobility, and excellent air stability. The complementary circuits of the nanowires demonstrate versatile functions such as inverters, NOR and NAND gates, wherein the inverters exhibit sharp switching and high gain, and the logic circuits of NOR and NAND demonstrate ultralow power consumption (< 40 pW). In combination

with generic *bottom-up* assembly methods developed for nanowires, this opens up important new opportunities based on tailor-made organic nanowires. The power consumption of the single-crystal logic circuits is even one order of magnitude lower than that of organic thin-film circuits (1 nW), of great interest for possible applications [25.75]. Logic circuits, such as NOR and

NAND, are basic elements of large and superlarge integrated circuits, offering the advantages of low power consumption, high stability, and anti-interference ability. Several pioneering studies have addressed logic NOR and NAND gates based on carbon nanotubes, inorganic nanowires, polymer fibers, and organic thin films.

25.4 Concluding Remarks

Nanostructured materials represent a fascinating class of materials whose structural elements such as atomic clusters, crystallites or molecules have dimensions in the nanometer scale range, where intriguing phenomena are observed. Unique electrical, optical, and sensing properties that are readily tunable through controlling their size enable novel applications that are impossible to realize using their bulk counterparts. Organic nanomaterials play an important role in this field.

Because organic nanomaterials are composed of molecular units with weaker intermolecular interactions, they allow for higher structural tunability, reactivity, and processability. Synthesis and processing of organic nanomaterials have come a long way. Methods have now been established to obtain organic nanomaterials with desired morphologies and properties, in particular advances in synthetic chemistry and in methods for the investigation and manipulation of individual

molecules and small ensembles of molecules. Novel organic nanomaterials based on small molecules and polymers are being actively developed (beyond the examples in the text, some other examples are given in Tables 25.1–25.3). One key step towards novel applications of organic nanomaterials concerns their surface functionalization, assembly, patterning, orientation, and alignment into functional networks without mutual aggregation. Among the bottom-up strategies, self-assembly provides a promising route to build up complex systems with immense flexibility in terms of nanoscale building blocks and resulting functionalities and properties. As the name suggests, self-assembly is a process in which organization of organic molecules into the desired system occurs through naturally occurring phenomena, either mediated by physicochemical pathways or assisted by biomolecules to promote molecular selectivity and specificity. Methods have also been sought to exploit the properties of these materials in optoelectronic devices, and prototypes for new nanoscale devices have been demonstrated.

Though great progress has been made in research of organic nanomaterials, development of this area is

still in its infancy. At present, the development of organic low-dimensional materials still lags far behind that of their inorganic counterparts. In the near future, further work on the molecular design of organic nanomaterials will continue to be crucial. On the one hand, developing multiple kinds of materials with various nanostructures is a primary task; in particular, considering the needs of practical applications, we should put emphasis on those materials with optimum optoelectronic properties and low-dimensional nanostructures, to further improve their optoelectronic properties. For those targets, none of the following elements is dispensable: design and synthesis of novel optofunctional molecules, successful construction of nanomaterials with desired structures from the synthesized molecules, and then powerful characterization of the constructed materials. More importantly, to realize the full potential of applications, the 1-D building blocks should be more efficiently integrated into devices with various optoelectronic functions; For example, one of the major challenge to maximize the competitiveness of organic solar/photovoltaic (PV) cells in terms of efficiency/cost ratio is to develop new

functional complex nanoarchitectures made of semiconductive organic electron-acceptor and electron-donor materials, in particular, to combine two molecular materials, one electron acceptor with one electron donor, and to try to achieve nanoscale control of the materials morphology, since whether an exciton can reach the interface and dissociate or not is critical, considering the exciton diffusion length (about 20 nm).

Finally, it should be mentioned that the development of hybrid nanomaterials is also a key point of this field [25.168]. Hybrid materials with organic–inorganic or bio–inorganic character represent not only a new field of basic research but also, via their remarkable new properties and multifunctional nature, offer prospects for many new applications in extremely diverse fields.

Nanocomposites

26. Nanocomposites as Bone Implant Material

Vinod Kumar, Bipul Tripathi, Anchal Srivastava, Preeti S. Saxena

The increasing demand for a suitable bone implant material has been forcing researchers to work on various man-made materials that may be used as a suitable replacement for natural bone and are affordable and easy to fabricate. In the past years, although significant efforts have been made in tissue engineering and regenerative medicine to put forward an ideal bone implant, they are far from meeting the real objective. Recent advances in nanobiotechnology in the field of therapeutics hold great promise to achieve the objective of an ideal implant in proper synchronization with tissue engineering. Nanocomposites, a product of synergistic efforts in nanobiotechnology and tissue engineering towards an ideal orthopedic implant, possess enormous potential for use as suitable bone implant material. Along with discussing the existing/conventional bone implant materials and their shortcomings, the main focus of this chapter is to elucidate nanocomposite as a potential next generation bone implant material. In this review, attempts have been made to deliver concise and relevant information about various nanofabrication technologies, characterization of nanocomposites, and their in vitro and in vivo biocompatibility study. Primary investigations support that nanocomposites are an ideal implant material for orthopedic applications; however, substantial developments are still highly needed to put nanocomposites into real practice, where current leanings in nanobiotechnology foreshadow a bright future through the use of nanocomposites in orthopedics. After defining the quest for bone implants, Sect. 26.2 gives a brief introduction to bone, and its structure and composition will be discussed. Section 26.3 gives a description and

highlights shortcomings of conventional implant materials, followed by Sect. 26.4 describing the challenges posed by conventional and existing implants. In Sect. 26.5 a detailed study of the possible role of nanotechnology for suitable orthopedic implants are presented. Future perspectives in Sect. 26.6 close the chapter.

26.1 The Quest for a Suitable Bone Implant

The human body is always prone to several kinds of diseases, injuries, and trauma, which leads to damage and degeneration of cells and tissues. To overcome this unavoidable problem, treatment should be personalized in such way that facilitates the repair, replacement, or regeneration at an early stage. Bone is a vital and versatile part of the human body, which provides the framework of the whole body. A healthy skeletal system keeps us active and working throughout life, but with the passing of time several kinds of bone disease development take place; the most common being osteoarthritis, osteoporosis, and bone cancer which affects billions of peoples worldwide. Apart from bone diseases, accidents are the leading cause of bone fracture. In fact, annually an estimated 1.5 million individuals in the United States suffer from bone fractures. Progression of bone diseases takes some time to completely inactivate the bone function but accidents or trauma immediately have an impact on the functioning of bone. Bone diseases like osteoarthritis and osteoporosis need continuous and long-term medications, but bone fracture due to accidents necessitate an accelerated treatment. Bone scaffolds or bone implants are the class of materials that have the potential to meet the early need for accelerated treatment during bone accidents or trauma along with possible therapeutic contribution to other bone diseases. A suitable bone

scaffold has enormous potential for recruiting bone cells (osteoblast) at the site of trauma and helps in their proliferation and growth to mature bone cells (osteocytes), thus healing the site of trauma in a short period of time and relieving the patient from physical and mental stress.

Although the journey of finding and developing suitable bone implants started several decades ago under the brand name of bone tissue engineering, the development of an ideal bone scaffold that can support the growth and proliferation of osteoblast and thereby increment the replacement the bone tissues still remains a major challenge for biomedical engineers. The incredible pace and advancement of nanobiotechnology has created tremendous enthusiasm and opportunity in academia and industries to assimilate nanotechnology for tissue engineering applications. It is strongly believed that the new discoveries in nanotechnology and the new abilities of engineering will enable material scientists and engineers to design and fabricate novel scaffolds by incorporating nanoscale features, thus imitating the characteristics of the natural extracellular matrix.

By considering the potential of nanotechnology to improve the bone scaffold, this review is aimed at providing the best possible facts related to the application of nanotechnology in tissue engineering.

26.2 Bone

Bone is the dynamic and main vascularized component of the human skeletal system and plays a vital role in physiology, protection, and in mechanical functions in daily life. Hematopoiesis (formation of red blood cells) and homeostasis (storage of Ca and P ions and regulation of the concentration of key electrolytes in the blood) are the chief physiological functions of bone. The rigidity and hardness of bone enable the skeleton to maintain the shape of the body, to protect vital delicate organs, such as lungs, heart, etc., and bone marrow filled with nutrients. It is the primary site of muscle attachment for movement and provides mechanical support for soft tissue during adequate load-bearing capacity. Structure and properties of bone differ significantly on the basis of anatomical location, even though there are some common features among all bones.

26.2.1 Structure and Composition of Bone

Bone is a natural nanostructured composite and a perfect example of hierarchical structure [26.1]. Non-stoichiometric nanocrystalline hydroxyapatite HAP, $(\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2)$ with 20–40 nm in length are the main inorganic components of bone, and type-I collagen molecules approximately 300 nm in length are the main organic counterpart.

Deep microscopic structural investigation into bone revealed that collagen molecules are covered with HAP nanocrystals and they form nanocomposites fibers, in which HAP C-axes are approximately aligned along with collagen molecules [26.2, 3]. From a mechanical point of view, bone is a non-homogeneous and anisotropic material.

Fig. 26.1 Schematic diagram showing the hierarchical organization of bone

As mentioned before, bone consists of different hierarchical levels. At the macrostructure level, bone is distinguished into the cortical (or compact) and cancellous (spongy or trabecular) types. From its cross-section, it is revealed that the end of a long bone such as the femur has a dense cortical shell with a porous, cancellous interior [26.4]. Cancellous bone is primarily found at epiphysis and metaphysis of both long and cuboidal bones, while cortical bone is present at the diaphysis of long bones. Cancellous bone is characterized by a three-dimensional sponge-like structure with 50–90% porosity with a pore size up to several mm, while cortical bone porosity is less than 30% and the pore size is up to 1 mm.

Cancellous bone is a lattice of narrow rods and plates (70–200 μm in thickness) of calcified bone tissue called trabeculae, with an average thickness of 100–150 μm.

Osteon is the main structural unit of cortical bone, which is a hollow cylinder with 200 and 50 nm of outer and inner diameter, respectively. An osteon is composed up of 20–30 concentric lamellae and the outer border

is lined by a 1–2 μm thick layer of mineralized matrix deficient in collagen fibers which act as crack stoppers [26.5]. There are no blood vessels in the cancellous bone but it is surrounded by bone marrow which is vascular and provides nutrients and waste disposal for bone cells. Cancellous bone is less mineralized than cortical bone and it is more active in bone remodeling than the cortical bone [26.6]. The main role of the cancellous bone is to receive compression under physiological loading conditions.

At the microstructure level, cancellous bone is composed of woven bone and lamellar bone. Woven bone is sometimes referred as primary bone or immature bone. Woven bone is isotropic, composed of relatively disoriented coarse collagen. Woven bone is normally present in the metaphysical region of growing bone, as well as in fracture callus and diseased bone such as pagetic bone. In contrast, lamellae bone is mature bone which is formed by the remodeling of woven bone or previous existing bone. Lemellae bone shows anisotropic characteristics and it is due to parallel orientation of collagen fibers to the lamellae; this imparts great strength

parallel to the longitudinal axis of collagen fibers. The thickness of lamellae bone is 3–7 μm and it is formed into concentric rings of (4–20 rings) as osteons. Each osteon has a central blood supply called a haversian system.

The nanolevel of bone is characterized by the presence of hydroxyapatite crystals and collagen fibers. In composition, 90% is type-I collagen protein while 10% is non-collagenous protein and other ground substances. The molecular weight of collagen protein is 139 kDa and it is composed of two identical $\alpha 1$ chains and one unique $\alpha 2$ chain. This configuration imparts collagen, a fairly rigid molecule that is 300 nm long [26.7]. Type-I collagen molecules in bone are self-assembled to form a triple helix bundle having a periodicity of 67 nm with 40 nm of gap (hole zones) between the end of the collagen molecules and pores between the sides of parallel molecules. The chief role of collagen fibers is to provide the framework and architecture of bone. Inter-molecular and intra-molecular cross-links between collagen fibrils stabilize the network and provide high levels of tensile strength and stiffness that are advantageous for tensile loading. Non-collagenous proteins are growth factors for, e.g., insulin-like growth factors, osteogenic proteins, and bone inductive protein like osteonectin, osteopontin, and osteocalcin are present. In extracellular matrix bone sialoprotein, bone proteoglycans, phosphoproteins, as well as proteolipids are found. The major role of these proteins is to regulate the size and orientations of the minerals and serve as reservoir for Ca^{2+} and PO_4^{2-} .

The hydroxyapatite or mineral component of bone is plate-like nanocrystals and is located in the hole zones with in collagen fibers. The dimension of HAP crystals are length \times width \times thickness and are $50 \times 20 \times 2\text{--}3 \text{ nm}^3$ [26.8]. The growth of HAP crystals is in a specific orientation, that is the C-axis of the HAP crystals is parallel to the long axis of the collagen fibrils [26.9].

HAP crystals improve the properties of bone by offering high strength and stiffness to resist compressive stresses.

Regeneration and remodeling is a peculiar property of bone Fig. 26.1. Bone can regenerate when damaged or remodeled during the change of loading conditions for, e.g., the mass of bone increases with exercise and thus prevents the bone from fracturing [26.10]. The remodeling and regeneration process of bone is governed by the cellular components of bone in a coordinated way. The major cellular components of bone are, osteoclasts, which are also known as bone resorbing cells, osteoblasts, known as bone making cells, osteocytes, known as mechano-sensors [26.10], and bone lining cells (inactive cells on the resting surfaces of bone) perform the coordinated process of bone regeneration and remodeling. The fate of bone implant material is determined by the remodeling process.

26.2.2 Limitations of Natural Bone

Bone plays an important role as the structural material maintaining the structure of the body of vertebrates and guarding the delicate internal organs. In fact, all material experiences fatigue by long use. To keep a material in working condition, periodic renewal of bone material is necessary to maintain sufficient toughness to work a whole life. In fact, annually, an estimated 1.5 million individuals in the United States suffer from bone fractures [26.11].

Although bone has its own capability to regenerate and remodel, during disease, its efficiency is greatly reduced. With the onset of bone disease like osteoarthritis and osteoporosis, bone gradually becomes weak and spongy and this time its own regeneration and remodeling machinery do are not efficiency enough to help cope with these diseases.

Therefore, bone implant is the one and only alternative that can help to improve the quality of bone.

26.3 Existing/Conventional Bone Implant Materials and Their Shortcomings

Implantation is the only possible way to treat bone fracture. Traditionally, autograft, allograft, and xenograft implants have been used to repair fractures and other bone defects. However, these substitutes are far from being ideal implants, as each has its own specific problems and limitations [26.12]. Autografts have been

considered as the gold standards for bone replacement for many years, but they have some severe concerns like donor shortage and donor site morbidity with infection, pain, and hematoma, which further limit their suitability, thus their applications [26.13–19]. Allografts and xenografts always have the risk of disease transmis-

sion and immune response, and may cause loosening or complete loss of bone inductive factors [26.17, 20, 21].

As an alternative to autografts, allografts, and xenografts several materials like metal, ceramics, and polymers have been introduced as artificial bone implants. Out of these metallic implants have gained maximum popularity and have been able to reach real practice.

26.3.1 Metallic Implants

The most used artificial implant materials are metallic in nature, such as stainless steel, titanium alloys, and cobalt-chromium alloys [26.22–24]. Metallic implants provide the necessary strength and toughness that are required in load-bearing parts of the body, and due to these advantageous metals continue to play an important role as orthopedic biomaterials in the current era.

Metallic implants are strong enough to meet the requirements for the desired mechanical strength for an ideal implant; however, these traditional implant materials exhibit several problems, such as a short average lifetime 10–15 years, failure of implants due to implant loosening, inflammation, infection, osteolysis, and the release of certain ions and corrosion products (debris) at the site of implantation. Metallic implants may lead to mechanical mismatch problems (stress shielding) between the implant and the adjacent bone tissue where the integrity of bone/implant interface may be compromised due to the resorption of bone tissue. The short average lifetime (10–15 years) of traditional implants leads to much painful and expensive surgery to replace such failed implants.

26.3.2 Polymeric Implants

In addition to metal as an implant, polymers are a class of material that has shown enormous potential for use as a bone implant. There are number of biocompatible polymers that have been found suitable for different biomedical applications including orthopedics. Polyanhydride has been found to be useful as bone augmentation or replacement due to its photopolymerization property [26.25–27].

Polylactides are a suitable candidate for skeletal tissue regeneration [26.27], while polycarbonate-modified tyrosine derived amino acids have been the choice as suitable materials as scaffolds for bone replacement [26.25]. Polymethylmethacrylate (PMMA) is widely used in orthopedics as a bone cement for implant fixation, as well as to repair certain fractures

and bone defects [26.28]. PMMA is not biodegradable and does not bind covalently to bones and is immunogenic [26.26, 29]. Polyethylene (PE) has been used as an implant for hip replacement [26.30, 31], while polyethylene terephthalate, polypropylene, and polytetrafluoroethylene (PTFE) have been used for knee ligaments [26.32].

Nonetheless, the most popular synthetic polymers used in medicine are the linear aliphatic poly(α -hydroxyesters), such as polylactic acid (PLA), polyglycolic acid (PGA) and their copolymers poly(lactic-co-glycolic) acid (PLGA), these are biodegradable polymers and have been approved by the FDA [26.27, 33–38]. Wide application of these polymers for orthopedic purposes is due to their good biocompatibility, non-immunogenicity, and biodegradability [26.17, 25, 27, 36, 39–43].

Poly(α -hydroxyesters) have been investigated as scaffolds for replacement and regeneration of a variety of tissues, cell carriers, controlled delivery devices for drugs or proteins (e.g., growth factors), membranes or films, screws, pins, and plates for orthopedic applications [26.25, 27, 36, 44–46]. The degradation rate of PLGA can be adjusted by varying the amount of the two component monomers, which can be exploited to create an orthopedic material that degrades in concert with bone ingrowth [26.17, 47]. The suitability of PLGA as a scaffold material in tissue engineering is due to its unique physicochemical properties that support osteoblast migration and proliferation [26.27, 40, 48, 49]. Unfortunately, despite the potential as a scaffold material for orthopedic purposes, the poor mechanical strength of these polymers, further limits their applications and they are only recommended for certain clinical applications such as ankle and elbow fractures [26.36, 43]. Another major issue with these polymers is their bulk degradation when used as implants. This leads to a lowering of pH, and at this reduced pH further degradation of polymers occurs autocatalytically. This results in an increased number of monomer units in the body, which might lead to an inflammatory response [26.27].

26.3.3 Ceramic Implant

Next to the metal and polymeric implant materials, ceramic materials have been used extensively in orthopedics due to their well-known biocompatible properties with bone cells and tissues [26.50–53].

Metal oxides (e.g., alumina, zirconia, titania), calcium phosphates e.g., HAP, tricalcium phosphate (TCP), calcium tetrakisphosphate ($\text{Ca}_4\text{P}_2\text{O}_9$) [26.54], and

glass ceramics (e.g., Bioglass and Ceravital) [26.55] are commonly used as orthopedic implants. Ceramic materials are considered bioactive materials because they can bind with bone without intervening fibrous tissue. The surface property of bioactive ceramics support bone cell adhesion, proliferation, and differentiation. Ceramics such as HAP and TCP have similar chemical composition to the mineral phase of natural bone. Consequently, their reaction with physiological fluids creates strong bonds to hard and soft tissues, thereby increasing osseointegration between implant and bone. Moreover, these ceramics are degradable, and their dissolution rate depends on crystallinity. By virtue of this, degradation of many ceramic materials can be controlled to match the rate of new bone growth. Amorphous calcium degrades much faster than crystalline HAP [26.56]. Conventional ceramic materials, like alumina, titania, and HAP (grain size > 100 nm) possess good biocompatibility [26.50–53, 57–64].

However, similar to metallic implants, the clinical application of ceramic materials is still limited due to insufficient prolonged bonding of these materials to the just exposed bone and brittleness (this restrict its application to large bone defects).

26.3.4 Ceramic Polymer Composites as Implants

Although both ceramic and polymeric materials have shown much potential as bone implant material, their clinical application is still a challenging issue. Ceramic scaffolds alone can be suitable as an implant material because it is easy to engineer the macro and microporosity within the structure, but their poor degradability and poor mechanical properties like tensile strength and brittleness limit their further application. It is believed that the incorporation of biodegradable polymers to ceramic materials will help to improve their degradability and will also improve their mechanical (physical) properties.

Poly(lactic/Polyglycolic Acid)-Based Polymer-Ceramic Composites

Poly(lactic/polyglycolic acid derived polymers are poly(lactic acid (PLA, PLLA), polyglycolic acid (PGA), poly-(D/L-lactic-co-glycolic) acid (PLGA), and polycaprolactone (PCL) have been investigated as bone material, due their good properties. Due to the good biocompatibility and ideal degradation properties of these polymers, they have been employed to make a composite bone implant material with ceramics. Most

poly(lactic/ceramic composite materials, therefore, exploit these degradation properties by using the polymer as the scaffold material. Ceramic particles are added to the polymer to make it (more) osteoconductive and/or to increase mechanical properties. These scaffolds can be of either porous or dense structure using bioactive glass, HAP, amorphous calcium phosphate (ACP), and biphasic calcium phosphate (BCP) as ceramic component in a PLLA, PLGA or PCL matrix. Navarro et al. reported the fabrication of a glass-ceramic particle/PLA scaffold by homogeneous mixing of the glass ceramic into a PLA solution, and its macroporosity was controlled by the addition of H₂O solvable NaCl particles [26.65]. Furthermore, they found that the mechanical strength of PLA increased after the addition of 40% glass ceramic, which is far away from the desired compressive strength.

On the contrary, Niemelä et al. observed the decrease in bending strength/modulus as well as in compression and shear strength on the addition of glass ceramic to poly-L, DL-lactide by twin-screw extrusion [26.66]. Yao et al. observed that despite the unfavorable mechanical properties bioactivity of the polymer was increased by addition of bioactive glass [26.67].

Synthesis of a highly porous composite of HAP and PLLA/PLGA was reported by Zhang and Ma [26.68]. Shikunami and Okuno have shown that HAP and PLLA/PLGA composite show reinforcement of PLLA [26.69]. However, the degradation of these composite materials is very slow [26.70]. Mondrinos et al. synthesized a 3-D porous composite of PCL with 10–20% CaP and found that the compressive strength of the composite is increased dramatically with increased cell proliferation at 20% of CaP [26.71]. Ambrosio et al. prepared a macroporous scaffold by sintering composite CaP/PLGA microspheres, where the CaP-phase was trapped inside the microspheres [26.72]. It was found that the composites of slowly degrading polymers like PCL and PLLA do not show any toxicity and promote cell growth, while faster degrading polymers show signs of toxicity due to the presence of a vast number of acid degradation products both in in vitro and in vivo studies. Ignatius et al. observed a strong inflammatory response of composites of PLA and α -TCP or a glass ceramic in sheep, 24 months after implantation [26.73].

Poly(lactic/glycolic acid and CaP cement composites can be formulated by the introduction of PLA/PGA microspheres. Simon Jr. et al. were the first to introduce the PLGA microspheres inside the calcium phosphate [26.74]. In a further study, they introduced

180–360 μm of microspheres to tetracalcium phosphate cement and evaluated their cell response. As a result they found that this scaffold material promotes cell proliferation with improved biocompatibility.

Ruhe et al. [26.75] and *Habraken et al.* [26.76] synthesized the macroporous scaffold by placing 20–40 μm of PLGA microsphere and reported that the incorporation of 20% PLGA microsphere in the CaP scaffold decreased the compression strength, injectability, and increased cement setting time, but within manageable ranges. Bulk erosion of the microspheres in the scaffolds was also observed, corresponding to a sudden decrease in mechanical strength.

In comparison to microporous cement PLGA degradation causes a decrease in pH; in turn, resorption of cement is increased around the microsphere. This decreased pH does not cause considerable harm in vivo applications because it has been found that subcutaneous implantation of these scaffolds showed no adverse tissue reaction during microsphere degradation [26.77]; in cranial defects even bone ingrowth was observed [26.78, 79].

Protein-Based Polymer–Ceramic Composites

Biocomposites of CaP ceramics and cements with protein-based polymers are being extensively investigated. It is believed that organic-inorganic biocomposites will be similar to bone composites with improved mechanical/physical and biological characteristics. Well-known examples of such biopolymers are collagen and gelatin.

Collagen is one of the most abundant protein components inside the human body and has been employed in numerous research as a tissue-engineered construct. Gelatin is a cheap and commercially available biomaterial. Gelatin is either a processed form of collagen that is usually derived from pig-skin with an acidic process (type A) or of bovine origin with a basic (lime cured) process (type B). Gelatin and collagen are biodegradable polymers which are solely degraded by proteolysis (collagenase, gelatinase). The tailored degradation rate of these biopolymers provides a better opportunity to make a biocomposite with ceramics, with a better control over degradation along with improved biological and physical properties of both materials.

Synthesis of biocomposites of a porous gelatin/collagen scaffold with CaP ceramic material has been reported in several works [26.80–82]. As a material of high interest, unfortunately some studies revealed that these biocomposites suffer from poor mechanical strength and biocompatibility (due to glutaldehyde as

a cross-linker) [26.83]. To overcome the problem of the cross-linker, fabrication of a B-TCP/collagen biocomposite without use of any extra material was reported by *Shibata et al.* [26.82]. *Duo et al.* synthesized the collagen-CaP biocomposite with high tensile strength by using collagen-I as matrix for mineralization of CaP, exploiting the biomimetic property of collagen (with 60–70% of CaP) [26.84].

Tampieri et al. prepared a ceramic/gelatin scaffold by soaking macroporous HAP in a gelatin solution by using a cross-linker to slow down the diffusion rate of gelatin [26.85]. They further reported that at low concentration of the cross-linker, the scaffold shows good biocompatibility.

For the evaluation of the release characteristics of growth factors through these CaP-biopolymer composites, *Takahashi et al.* investigated gelatin sponges containing β -TCP particles that were loaded with BMP-2 [26.80]. A biocomposite of CaP cement (α -TCP) with 18% gelatin was synthesized by *Bigi et al.* in a further study, which showed improved osteoblast activity along with increased mechanical strength [26.86–88]. The synthesis of porous (20–100 μm) biocomposites of gelatin and α -TCP, at varying concentrations of gelatin 5–20% was reported by *Fujishiro et al.*, and results showed an increase in mechanical properties with 5% gelatin content (with time), although with 20% gelatin the compressive strength was lowered [26.89]. The improved biological response and increased mechanical strength is mostly attributed by the biomimetic abilities of gelatin that function as a nucleation point of CaP-crystal growth [26.90].

Biocomposites of collagen with CaP cement were also investigated. *Rammelt et al.* added 3% of collagen-I to a nanocrystalline hydroxyapatite cements, which led to an increased bone remodeling in rat tibia defects [26.91]. *Knepper-Nicolai et al.* added 1–2.5% collagen-I to a commercial apatite cement and observed mechanical and physical changes of the cement especially when osteocalcin was added [26.92]. Extending the work of *Knepper-Nicolai et al.*, *Hempel et al.* studied the behavior of osteoblast on the same 2.5% collagen containing cement and found that proliferation and differentiation of cells was greatly influenced by a local microenvironment like pH [26.93].

Apart from gelatin and collagen, some other proteins like fibrin were used in biocomposite formation with CaP ceramics [26.94, 95] and cement [26.96], soybean and casein protein were used with Al_2O_3 and TCP [26.97], and polypeptide with CaP [26.98].

Carbohydrate-Based Polymer–Ceramic Composites

In addition to the protein-based polymer–ceramic composites, carbohydrate-based biopolymers are of great interest for biocomposites with ceramics. Chitin, chitosan, alginate hyaluronic acid, and cellulose are well-known carbohydrate polymers. Among these polymers, chitosan is often applied together with CaP–cement or CaP–particles because it is biodegradable by lytic enzymes and gives a good match to natural bone with respect to mechanical properties. Chitosan can improve the mechanical/physical properties of CaP cement in biocomposites, as well as influence the cement setting, although the compression strength of the ceramic is superior to chitosan.

Leroux et al. reported that chitosan can be added as adjuvant to CaP cement to make it more injectable without considerable modification in the setting reaction [26.99]. *Takagi* et al. also reported that the CPC–chitosan composite exhibits a better cohesion in water than **TTCP** [26.100]. Reinforcement of tetracalcium phosphate (**TTCP**) cement by chitosan lactate was investigated by *Xu* et al. [26.101]. Mannitol crystal introduces macroporosity to these biocomposites, which in turn reduces the flexural strength and elastic modulus [26.102]. *Lee* et al. introduced TCP particles to chitosan sponges, by freeze-drying and cross-linking a mixture of a chitosan solution and TCP [26.103]. *Zhang* and *Zhang* added HAP and calcium phosphate invert glass to a chitosan sponge using a similar procedure and reported that the osteogenicity of the scaffold is increased manifold [26.104]. An improved elastic modulus and yield strength have been obtained in biocomposites of chitosan with invert glass and β -tricalcium phosphate (**BTCP**) [26.105].

Hydroxypropylmethyl cellulose (**HPMC**, a cellulose derivative) is another carbohydrate which has been used in combination with ceramic particles or as an addition to calcium phosphate cement for fabrication of biocomposites. By combining **BCP** and **HMPC**, *Daculsi* et al. developed an injectable bone substitute and reported its poor mechanical strength [26.106]. Cross-linking the **HPMC** by silanol groups (si-**HPMC**) renders a more stable scaffold with a comparable in vivo performance [26.107]. On addition of **HMPC** to the **DCPD**, a dramatic increase in the injectability of dicalcium phosphate dehydrate (**DCPD**) was observed by *Burguera* et al. [26.108]. Injectable paste of amylopectin with **BTCP** was prepared by *Ongpipattanakul* et al. and a better release profile (about 80%) of growth factor rhTGF- β was reported as a result of in vitro stud-

ies after 24 h [26.109]. Further, a positive sign towards the bone growth was reported when it was implanted in rabbit unilateral segmental defect model, after 56 days.

Biocomposites of bioactive glass and starch/cellulose acetate and a mixture of methylmethacrylate/acrylic acid have been reported by *Boesel* et al. [26.110]. Different amounts of bioactive glass were added (up to 30%), which resulted in a significant improvement in the elastic modulus and yield strength of the material. In general, no bioactivity was observed due to the inhibiting effect of the acrylic acid because only with the highly reactive bioglass, calcium phosphate precipitation occurred.

Hyaluronan is another attractive carbohydrate-based polymer for tissue engineering that is present in the human body and proteolytically degradable by hyaluronidases. *Liljensten* et al. investigated the biocomposite of HAP granules in a hyaluronan carrier and found better bone growth [26.111]. Application of alginate in inorganic–organic scaffolds is limited due to its poor biodegradability; recently attempts have been made to improve the biodegradation of alginates [26.112]. Alginates have been used as cohesion promoters in biocomposites with calcium phosphate which in turn decreases the rate of disintegration in biological fluids like blood/serum. Chitosan also possesses a cohesion property similar to alginates.

A thorough investigation of the cohesion property of commercially available carbohydrates after the addition of a wide range of these polymers, i.e. hydroxyethyl starch, starch, sodium dextran sulphate, $\alpha/\beta/\lambda$ -cyclodextrine, alginic acid, hyaluronic acid, and chondroitin sulfate, has been done by *Khairoun* et al. [26.113].

Other Polymer–Ceramic Composites

Composites of ceramics with different types of polymers have also shown potential as bone implants. Especially synthetic polyesters, other than polylactic/glycolic acid discussed previously, can be suitable carrier materials for ceramic particles. In this paragraph the characteristics of these and other polymer composites, as well as their use for tissue engineering have been discussed briefly. *Peter* et al. formulated a biocomposite of 25% **BTCP** in a propylene fumarate (**PPF**) carrier, with increased mechanical strength, along with good osteoinductive properties [26.114]. *Charvet* et al. synthesized and reported a composite of a poly(desaminotyrosyl-tyrosine ethyl ester carbonate) (poly(**DTE** carbonate)) and CaP–glass fibers ($\text{CaO-P}_2\text{O}_5\text{-Fe}_2\text{O}_3$) with improved mechanical

strength [26.115]. Ceramic particles of β -TCP, HA and bioglass were added to polymers of poly (3HB) and poly(3HB-co-3HV) [26.116], which led to an increase in mechanical properties and bioactivity.

Qiu et al. reported the synthesis of poly(diols citrate)-HAP microparticles with better mechanical properties, a slower rate of degradation, along with improved mineralization in vitro [26.117]. Mickiewicz et al. added a range of water-soluble polymers comprising different polyelectrolytes, poly(ethylene-oxide), and bovine serum albumin (BSA) during cement setting of

a brushite and reported an improvement in mechanical strength [26.118]. Dos Santos et al. reported the synthesis of a composite of a α -TCP-based apatite cement, reinforced with polypropylene nylon and carbon fibers, which showed a decrease in compressive strength and an increase in toughness and tensile strength [26.119].

Biocomposites consisting of fibers of aramide, carbon, epoxy-glass, or polyglactin with calcium phosphate cement was investigated by Xu et al., and an increase in tensile strength, work-of-fracture, and elastic modulus were found [26.120].

26.4 Major Challenges with Existing/Conventional Implant Materials

26.4.1 Mechanical Integrity

The mechanical properties of artificial scaffolds made up of porous bioactive ceramics and biodegradable polymers foams are insufficient to meet the real mechanical strength of bone [26.121–123]. The stiffness achieved by fabricated bioactive ceramics is less than the stiffness of the porous biodegradable polymer scaffolds. A slight increase in the stiffness and in the mechanical strength was found in polymer scaffolds but it was certainly below expectations.

26.4.2 Incorporation of Biomolecules

Surface modification of implants by protein adsorption or by plasma treatment generates significant scope and provides more clues to cells' attachment and response [26.124, 125]. The possibility of incorporating growth factors into composites formed by biodegradable polymers and bioactive glasses or HAP inclusions has started to be explored [26.126–136]. However, the immobilization of these proteins and growth factors on the

scaffold surface results in the shortening of bone healing and reduction of patient recovery time. The incorporation of biomolecules does not allow extreme temperature ranges ($> 70^\circ\text{C}$) or extremely aggressive chemical conditions during processing, this being a challenge to the scaffold fabrication process. The other challenge is the elucidation of the local impact of growth factors on the cell and tissue systems, including long-term effects.

26.4.3 Long-Term Characterization of Porous Composite Scaffolds

There is no sufficient proof in the literature which provides the long-term behavior of the existing scaffold material (in vivo and in vitro studies).

26.4.4 Biocompatibility Study

There are adequate reports about the biocompatibility of biodegradable polymers and bioactive ceramics [26.14, 19, 83, 131, 133, 134, 137–139] while for composite materials only a few are available.

26.5 Nanotechnology and Tissue Engineering

During the last several decades, a huge amount of research has been made in the field of tissue engineering and regenerative medicine to improve the design and performance of existing orthopedic implants. Tissue engineering proved its significant role in orthopedics in the form of various scaffolds of polymers, ceramics, and their composites, as discussed in the paragraphs above. Even though a positive sign towards the suitable implant

materials is visualized, some considerable challenges still remain.

With the advent of nanotechnology and its accelerated progress in recent years, better opportunities have been created to tune material as needed. During the last few years, nanomaterials were developed with basic structural units, grains, particles, fibers, or other constituent components smaller than 100 nm in

at least one dimension [26.140]. They have received much attention for improving disease prevention, diagnosis, and treatment. Nanomaterials can be of different in sizes and different morphologies such as nanoparticles, nanoclusters, nanotubes, nanofibers, nanowires, nanorods, and nanofilms. The enormous therapeutic potential of nanomaterials has drawn the attention of tissue engineers towards nanomaterials to meet their requirements. To exploit the unique physicochemical properties which arise in nano dimensions, conventional micrometer-size implant materials like metal, ceramics, polymers, and composites can be tailored to materials with nano dimension. There are numerous nanofabrication technologies like electrospinning, phase separation, self-assembly, thin films deposition, chemical vapor deposition, chemical etching, nanoimprinting, photolithography, electron-beam lithography, and nanosphere lithographies [26.141] for the synthesis of ordered or random nanotopographies [26.142–145].

The biomimetic features and excellent physicochemical properties of nanomaterial play a key role in stimulating cell growth as well as in guiding tissue regeneration. Natural tissue or organs, which are themselves of nanometer size, can directly interact with nanostructure extracellular matrices (ECM) without any hindrance.

Of relevance to the merging of nanotechnology and tissue engineering is the realization that bone is a natural nanostructured composite material composed of intertwined inorganic (bone apatite) and organic compounds (mainly collagen) [26.146]. Natural bone formation, is

itself a kind of nanofabrication that occurs inside the body and we have become familiar with this fact very recently. The material of natural choice in nanotechnology will be those occurring at the nano hierarchy level of bone.

Bone is a natural nanocomposite (as discussed in the preceding paragraphs) and its constituents contribute unique properties to create a structure optimized not only for high loading and bending moments, but also for fracture and fatigue resistance [26.8, 137]. The mechanical property of bone is highly dependent on the percentage of both mineral and protein matrix and their interaction, porosity, and degree of cross-linking [26.147, 148]. The viscoelastic property of bone is contributed by collagen molecules, comparable to rope, where it offers mechanical advantage for tensile loading but has poor compression or shear properties. While the role of apatite crystals in bone is to improve the compression or shear properties.

It is firmly believed that nanotechnology will help to overcome the challenges of tissue engineering in a synergistic way. *Nanocomposites*, the implant material created after the fusion of two novel technologies, i. e., tissue engineering and nanotechnology, will definitely solve the most awaited problem of an ideal implant. The principle of nanocomposite design is based on the creation of nanocomposite materials with superior properties by the fusion of two materials which individually possess inadequate properties.

26.5.1 Unique Properties of Nanomaterials

Features like pores, ridges, grooves, nodes, and their combination in scaffold material is known as nanotopographical features which improve the cellular function.

Nanotopography

Nanotopography created in Ti, Ti₆Al₄V and CoCrMo alloys resulted in increased osteoblast adhesion due to the presence of more particle boundaries in comparison to conventional metals [26.57]. Strong alignment and orientation of osteoblasts in the direction of patterned grooves was found in nanopatterned polystyrene grooves (with two different depths of 50 and 150 nm, with a periodicity of 500 ± 100 nm) [26.149]. Migration of primary human osteoblasts, away from the Ti oxide surface patterned with 110 nm hemispherical protrusion with varying topography has been reported [26.150].

Cell behavior on nanotopographic surfaces is dependent on the cell type [26.151]. At this stage, it

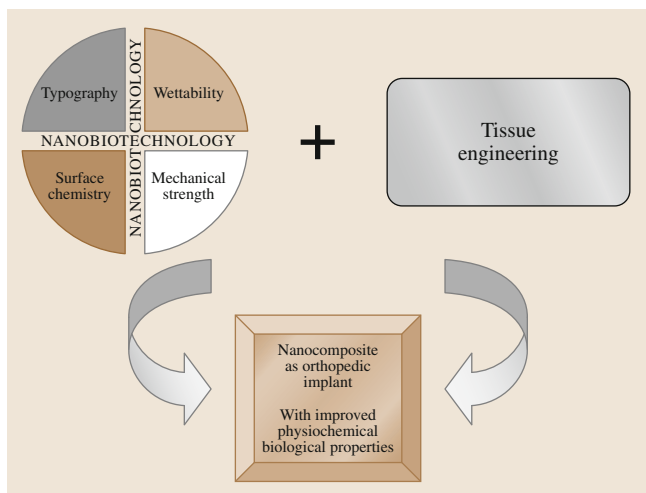

Fig. 26.2 Schematic diagram showing synergistic effect of nanotechnology and tissue engineering for orthopedic implants

is not fully understood how cells detect and respond to nanostructured surfaces. Thus, it is important to understand cell-nanotopography interactions and that variability in results may exist among varying cell types.

Surface Chemistry

Besides the nanotopography, the property of nanomaterials that plays an important role in deciding the fate of success and performance of implant is the surface chemistry. Protein and other biomolecules adsorbed over the implant surface can trigger the non-specific inflammatory response characterized by foreign body reaction and fiber capsule formation, which in turn limit the integration of the scaffold and its in vivo performance. The self-assembled monolayer with different terminal functionalities like $-\text{CH}_3$, $-\text{OH}$, $-\text{COOH}$, and $-\text{NH}_2$ possesses a different affinity for fibronectin adsorption, thus differentially influences the integration, binding, and cell adhesion [26.152, 153]. Differences in integrin binding differentially regulate local adhesion assembly and signaling, which, in turn, modulate cellular functions in biomaterial and implant surfaces.

Wettability

Apart from surface functionalization the hydrophilicity and hydrophobicity of the implant surface significantly influence the cell behavior for a particular implant. The wettability of a material allows the characterization of nanomaterials with regards to their, hydrophobic/hydrophilic categories. The surface wettability that affects the cell behavior depends on the surface composition, surface treatment, surface roughness, surface functionalization, and the presence of nanostructures on the surface. Surface wettability of Al_2O_3 can be improved by reducing the size of grain from 167 to 24 nm [26.154]. An enhanced adhesion rate of pre-osteoblasts was observed on a titanium surface with a high degree of wettability created by high pressure torsion [26.155]. Enhancement of the adsorption of vitronectin and fibronectin due to improved surface wettability stimulated the adhesion of osteoblasts over the surface of the implant.

26.5.2 Nanoscaffold Fabrication Techniques

An ideal scaffold should have the property to augment or completely replace damaged, missing, or compromised tissue, or organs without creating any further complexities. The scaffold should be bioresorbable or

Fig. 26.3 Schematic diagram showing the comparison of conventional and nanophase scaffolds for bone cell function

should be permanently attached to the applied part and must be capable of mimicking the condition and characteristics of the local micro-environments.

Nanofabrication technology has shown great promise for the development of clinically relevant scaffolds specifically in the field of nanofiber fabrication. Nanofibers composed of natural or synthetic material, can be fabricated by self-assembly, phase separation, or by electrospinning methods.

Self-Assembly

This is a technique where the organization of disordered molecules into a structured pattern without external intervention takes place. It is a very good approach for the fabrication of supra-molecular structures [26.156].

Self-assembly takes place by non-covalent bonds such as hydrogen bonds, van der Waals bonds, and electrostatic and hydrophobic interactions. Self-assembly is ubiquitous in nature; biomolecules like proteins and peptides achieve a special configuration by self-

Fig. 26.4a–e SEM images of MC3T3-E1 pre-osteoblastic cells cultured for 7 days on 15% RGDS PA-Ti hybrids in a rotating bioreactor. (a) Cell stretched across a gap and adhering to the PA matrix (indicated by arrows). (b) Cell migrating into the PA matrix-filled porosity of the PA-Ti hybrid (arrow). (c–e) Confocal fluorescent images of cross-sectioned 15% RGDS PA-Ti hybrids at days 1, 7, and 28, showing GFP-transfected MC3T3-E1 pre-osteoblastic cellular ingrowths and proliferation. (After [26.159])

assembly, which is very important for their functional aspect. Nanostructured fibers can be formed by self-assembly [26.157, 158] under certain conditions.

The most commonly self-assembled nanofibers, peptide amphiphiles (PA), were initially developed by Berndt et al. for their application in investigating the interaction between peptide structures and ligands [26.160]. PA systems are ligand–receptor pairs that are integrated into separate lipid molecules and fixed by means of self-assembly onto a surface [26.160]. PA systems are made up of a head, N-alpha amino group which is hydrophilic in nature and is attached to dialkyl moiety of tail; both these moieties were developed from the peptide sequences from collagen fragments [26.161, 162]. Self-assembly takes place in both mono-alkyl and dialkyl PA to form a stable triple helix conformation [26.161]. Self-assembled PA nanofibers can have fiber diameters as small as 10 nm and pore sizes of 5–200 nm (well within the range of the native ECM and significantly smaller than those produced through electrospinning) [26.158, 162].

PA nanofiber scaffolds have been found to be good material for use as bioactive implant surfaces. PA fibers have been used to generate the bioactivity into inert Ti foam by filling foam with PA nanofibers. Bioactive Ti foam was used as a bone plug model in rat femurs to help implant fixation; bone formation was found inside and outside of the implant [26.159] after 4 weeks (Fig. 26.4a,b). Development of self-assembled bioactive hydrogels has also been reported [26.163–165]. PEG hydrogels have been synthesized containing arginine,

glycine and aspartate peptides, and matrix metalloprotein as a substrate [26.163, 164].

The cells are shown in green, with the top surface of the metal reflecting white, and the PA matrix not visible. At day 1, cells adhere to the exterior of the implant and proceed to migrate and proliferate into the core of the PA-Ti hybrid up to 28 days (Fig. 26.4c–e). At 28 days cells are observed both adjacent to the pore wall and in the PA matrix in the center of the pores [26.159].

Although the self-assembly technique produces fibers that are very close to the approximate size-scale of the native ECM, issues regarding mechanical properties of the scaffold and high complexity limits the use of this technique.

Phase Separation

To produce highly porous scaffolds, a phase separation technique is used. With this technique porous polymer membranes can also be fabricated for purification and separation purposes [26.166].

The process of phase separation can be achieved either by thermal induction or by using a non-solvent technique. The result of non-solvent induced phase separation is heterogeneous pore formation, which is not suitable for scaffold fabrication where uniform pores are desired. A thermally induced phase separation (TIPS) technique can be employed to fabricate nanofibers to mimic natural collagen fibers [26.167]. The TIPS process for nanofiber formation follows the five steps: polymer dissolution, phase separation and gelation, solvent extraction, and freezing and freeze

Fig. 26.5a,b SEM micrograph of PLLA nanofibrous matrix prepared from a 7.5 wt/v % PLLA/dioxane/pyridine (dioxane/pyridine = 1/1) solution and paraffin spheres showing increasing interconnectivity with increasing time of heat treatment up to 40 min. Sphere size range was $d = 250\text{--}420\text{ }\mu\text{m}$: (a) original magnification \times so; and (b) original magnification $\times 8000$

drying under vacuum. The fiber network formation depends on the solvent of the polymer solution and the gelation temperature. During the process of TIPS, a homogenous polymer solution becomes thermodynamically unstable under certain temperature conditions and tends to separate into a multiphase system for, e.g., a polymer-rich phase and a polymer-lean phase, and thus lower the free energy. The polymer-rich phase is solidified to form the structure of the scaffold and the polymer-lean phase forms the pores. Numerous 3-D polymeric scaffolds have been fabricated by the phase separation technique [26.12, 68]. Fibers of PLA, PLLA, and PLGA with a size range of 50–500 nm and with 95% porosity (which is close to natural collagen fiber size) were fabricated using TIPS [26.161, 167, 168] (Fig. 26.5).

During the scaffold fabrication, the polymer gelation time and its temperature are the critical parameters that control the porosity and size of fibers [26.161]. The major loop hole in the nanofiber scaffolds, generated by TIPS, is the lack of interconnected pores, which is very critical for cell seeding and recruiting, mass transfer, vascularization, and tissue organization. To overcome this problem, the phase separation technique was combined with a progen leaching technique and a solid freedom fabrication (SFF) technique which results in better control over the porous architecture from macro, micro to nano [26.142, 169, 170]. A number of progens such as sugar, inorganic salt, and paraffin spheres [26.142, 168, 171] have been incorporated into the phase separation technique to provide better control over the size of the scaffold and have the potential to work well in bone tissue engineering [26.172, 173].

Layered phase separation scaffolds have been reported with various biomolecule coatings (such as matrigel, collagen type I and III, and elastin) for small diameter tube scaffolds or with multiple polymers (such as polyurethane (PU) and collagen) for nerve conduits [26.174, 175]. Although the phase separation technique is simple and consistent, the practical use

of this method for scaffold production [26.161, 168] is limited due some issues, like progen extraction, the restricted number of usable polymers, and its amenability to large-scale production.

Electrospinning

Electrospinning is an established non-mechanical process that has been used for the fabrication of ultrafine fibers including microfibers ($> 1\text{ }\mu\text{m}$) or nanofibers ($< 1000\text{ nm}$) from a variety of synthetic polymers and natural proteins [26.176, 177]. In this technique, a high voltage is applied to a polymer solution or melt, which overcomes the surface tension to form a charged jet. Ejection of the charged polymer solution or melt takes place on a grounded substrate, which is subsequently dried, and solidified. Repulsion occurs among the ejected polymer solutions during their travel to the grounded collector, and formation of thin fibers after evaporation of the solvent takes place. Fibers ranging from 0.02 to 20 μm can be produced by controlling the spinning conditions. The orientation of fibers is random when a stationary collector is used, but preferential orientation can be obtained by using an electrically grounded rotating drum as the collector [26.176]. Electrospinning techniques have been applied for the fabrication of numbers of biomaterial scaffolds [26.178, 179]. Biodegradable polymers PGA, PLGA, PLLA, PCL, and several natural macromolecules like collagen and silk fibroin have been used in the electrospinning technique for scaffold fabrication (Fig. 26.6a,b) [26.138, 139, 176, 180–182]. Proteins, the growth factor, and HAP can be incorporated into nanofibrous material during electrospinning [26.139, 183].

The diameter of fiber and porosity can be regulated by controlling the composition of the electrospinning solvent and the identity, the concentration, and the degree of chain entanglements (viscosity) present in the starting polymer(s) [26.176, 177, 184].

The main advantage of the electrospinning process is the relative quick and simple way to fabricate a va-

Fig. 26.6 (a) SEM of electrospun type-III collagen (human placenta). The isotype (type-I versus type-III) collagen used in electrospinning also determines the structural properties of the deposited filaments. Under conditions optimized for calfskin type-I collagen an electrospun matrix of type-III collagen is composed of fibers that average 250 ± 150 nm in diameter (magnification 4300 \times). (b) SEM of collagen type-I calfskin electrospun onto a rotating mandrel (magnification 4300 \times). (After [26.176])

riety of materials into nanofibrous structures but the fabrication of a 3-D scaffold is still a challenge for this technique. Thus although it is an easy fabrication technology, its inability to fabricate 3-D scaffolds or to generate the designed internal pore structure, limits its potential for many tissue engineering applications.

26.5.3 Nanomaterial Scaffold for Orthopedic Purposes

Metallic Nanoparticle Scaffold

Numerous studies have reported the increased adhesion of osteoblasts to the surface of metallic nanoscale implants [26.57, 185–187] and this gives a clear picture that there is strong potential for long-standing osseointegration of nanostructured metals to replace bone.

Osteoblast functions like adhesion, proliferation, and deposition of calcium containing minerals have increased in the nanophase compared to conventional metals like Ti, $\text{Ti}_6\text{Al}_4\text{V}$, and CoCrMo [26.185]. In a comparative study of nano and micro-powder of Ti, $\text{Ti}_6\text{Al}_4\text{V}$, and CoCrMo for osteoblast adhesion, a significantly higher osteoblast adhesion of nano-powder was found than of micro-powder of the same elements (Fig. 26.7) [26.7]. The osteoblast adhesion occurred primarily at metal particle boundaries. Increased osteoblast adhesion might be due to the greater number of defect boundaries at the surface of nanophase materials, creating unique surface energy, attracting the adsorption of certain proteins.

Anodization is another possible way to create nanostructure of metals. Yao et al. reported that performance of the metallic implant could be increased by anodiza-

tion process [26.62]. In his study, Yao et al. created the nanotubes like pores over the surface of the Ti implant by an anodization process and increased osteoblast function was found over nanoscale Ti implants (Fig. 26.8) [26.62]. Sirivisoot et al. grew carbon nanotubes on the surface of anodized Ti and tried to create in situ orthopedic biosensors to detect the control of bone growth (Fig. 26.9) [26.64]. Carbon nanotubes (CNT) grown out of anodized nanotubular Ti show significantly higher alkaline phosphatase activity and calcium deposition by osteoblasts in comparison to micro Ti implants. Many other recent studies have reported an improvement of bone cell functions by nanophase materials [26.185, 186]. Ambiguities concerning the contribution of nanostructure surfaces have been found in some of the results, since the nanophase materials simultaneously changed surface roughness and chemistry [26.58–60, 188].

Khang et al. studied the role of nanosurface alone without changing the chemistry of the surface for tissue growth enhancement, by taking three types of Ti implant which differ in their surface structure (flat, nanometer, and submicrometer) [26.61]. They found that the cell densities were higher on the nanometer and sub-micron surfaces compared to flat Ti surfaces. This study further provides a support that nanometer roughness had the highest efficiency for increasing both surface energy and osteoblast adhesion compared to the altered pattern width of surface features, and therefore suggested an important role of nanometer and submicrometer surface features on the future design of improved Ti-based implants.

Ceramic Nanomaterial Scaffolds

Nanostructured metal has presented great potential for osteoblast function. Next to the metal nanostructure, nanostructured ceramics promote the bone cell functions compared to traditional, nano-smooth ceramics [26.185, 186]. The influence of nanometer-size ceramics was first studied in the year 1999 [26.185] and it was found that osteoblast adhesion was significantly higher on nanophase alumina and titania substrates when compared to micrometer-size conventional substrates. The study further adds that the increased osteoblast growth is due to surface topography of the nanophase implant only and independently to the surface chemistry in the same way as the nanostructured metal. An increase in osteoblast function like proliferation, alkaline phosphate activity, and calcium deposition on nanoceramics was further evidenced in [26.186]. Nanophase titania, alumina, and HAP show

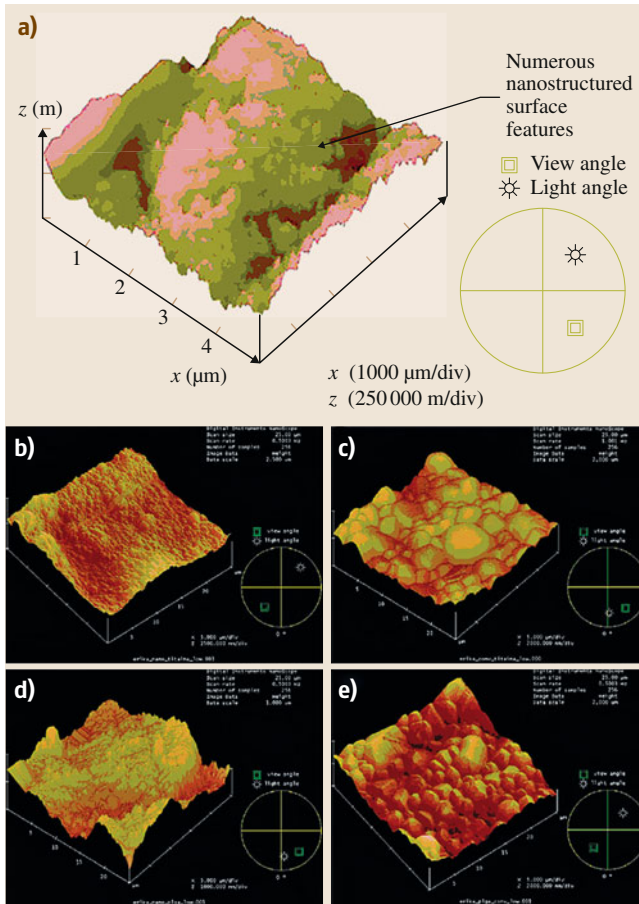

Fig. 26.7 (a) Representative AFM image of cortical bovine bone. Numerous nanostructured features on the surface are visible. Root-mean-square values from AFM for $5\mu\text{m} \times 5\mu\text{m}$ and $25\mu\text{m} \times 25\mu\text{m}$ scans were 32 and 25 nm, respectively (Digital Instruments NanoScope, scan size $5000\mu\text{m}$, scan rate 1.001 Hz, number of samples 256, data scale 250.0 m). (b–e) AFM images of nanophase titania and the PLGA mold of nanophase titania, conventional titania and the PLGA mold of conventional titania. Images provide evidence of the successful transfer of the surface roughness of nanophase titania to PLGA molds of nanophase titania, and conventional titania to PLGA molds of conventional titania. Root-mean-square values from AFM for nanophase titania at $5\mu\text{m} \times 5\mu\text{m}$ and $25\mu\text{m} \times 25\mu\text{m}$ scans were 29 and 22 nm, respectively. Root-mean-square values from AFM for the PLGA mold of nanophase titania at $5\mu\text{m} \times 5\mu\text{m}$ and $25\mu\text{m} \times 25\mu\text{m}$ scans were 35 and 27 nm, respectively. Root-mean-square values from AFM for conventional titania at $5\mu\text{m} \times 5\mu\text{m}$ and $25\mu\text{m} \times 25\mu\text{m}$ scans were 12 and 11 nm, respectively. Root-mean-square values from AFM for the PLGA mold of conventional titania at $5\mu\text{m} \times 5\mu\text{m}$ and $25\mu\text{m} \times 25\mu\text{m}$ scans were 13 and 12 nm, respectively. (b) Nanophase titania; (c) PLGA mold of nanophase titania; (d) conventional titania; (e) PLGA mold of conventional titania. (After [26.7])

Fig. 26.8 Scanning electron microscopy images of Ti, CoCrMo, and $\text{Ti}_6\text{Al}_4\text{V}$ compacts. Increased nanostructured surface roughness was observed in the nanophase compared to conventional Ti, CoCrMo, and $\text{Ti}_6\text{Al}_4\text{V}$ (bar = $1\mu\text{m}$ for nanophase, $10\mu\text{m}$ for conventional ones). (After [26.62])

Fig. 26.9a–f SEM micrographs of (a) unanodized Ti, (b) anodized Ti without CNTs, (c) lower and (d) higher magnification of CNTs grown from the nanotubes of anodized Ti without a Co catalyst, and (e) lower and (f) higher magnification of CNTs grown from the nanotubes of anodized Ti surface with a Co catalyst. (After [26.64])

higher cell densities (after 5 days) as a result of osteoblast proliferation in comparison to conventional micron-sized ceramics of these materials. The calcium content in the extracellular matrix of osteoblasts cultured on nanophase alumina, titania, and HAP was 4, 6, and 2 times greater than, on the respective conventional ceramics. This study provides important information regarding the unique properties of nanophase ceramics which enhance the bonding of orthopedic/dental implants to juxtaposed bone and therefore, possibly improve bone implant efficacy. The increased osteoblast function on nanophase ceramics is due to the increased adsorption of vitronectin over the surface of nanophase ceramics [26.189]. The increased wettability of nanostructured ceramics enhances the adsorption of vitronectin in comparison to their conventional micro implant. Increased adsorption of vitronectin on nanophase ceramics induces increased osteoblast adhesion and proliferation. Decreased adsorption of apolipoprotein A-I and/or increased adsorption of calcium on nanophase alumina were additional possible

causes of the observed enhanced adsorption of vitronectin on nanophase alumina [26.189]. Moreover, this study provides evidences related to different conformations of vitronectin adsorbed on nanophase materials compared to conventional alumina, which in turn result into an increased unfolding of the cell-adhesive macromolecule to exposed epitopes (such as arginine-glycine-aspartic acid or RGD) recognized by specific cell membrane receptors.

Polymeric Nanomaterials Scaffold

Among other bone implant materials, polymers have also shown great promise as implant material. Synthetic polymers have presented enormous potential in tissue engineering applications [26.25]. Synthetic polymers can be fabricated and tailored to give a wide range of properties and are often free from concerns of immunogenicity [26.190]. Recently, it was reported that the nanophase polymer enhances the adsorption and conformation of proteins (such as fibronectin and vitronectin), which regulate osteoblast adhesion and other functions, in comparison to conventional polymers [26.7, 154, 189]. Selective adsorption of proteins, including fibronectin and vitronectin, on 3-D nanofibrous polymer scaffolds was reported by *Wei* and *Ma* (Fig. 26.10) [26.12]. Synthesis of nanoparticulate hydroxyapatite/poly(L-lactic acid) (NHAP/PLLA) composite scaffolds was achieved by the phase separation technique and the protein adsorption study was compared to micron particulate hydroxyapatite/poly(L-lactic acid) (MHAP/PLLA) scaffolds. Higher protein adsorption was found on NHAP/PLLA for higher HAP content and this further enhances osteoblast functions like adhesion, proliferation, and Ca deposition. In another study, the nano-rough surface of PLGA was prepared by treating nano-smooth PLGA with 0.1 N NaOH for several periods to transform it, into a nano-rough surface. The nano-rough surface improves the osteoblast function [26.191]. Bone cell promotion by polymers can be obtained by combining the features of nanophase ceramics and metals to the polymers (Fig. 26.11) [26.192–194]. *Price* et al. conducted an experimental study of osteoblast cell function over polymer PLGA cast over carbon nanofiber-based material and noticed an improved osteoblast function in comparison to conventional carbon fiber materials [26.192]. In the same manner, polymer casts on composites of polycarbonate urethane-CNTs also promoted osteoblast functions compared to casts of polycarbonate urethane/conventional carbon tubes [26.194]. The mechanism behind the increased bone cell function

(After [26.12]) ►

over nanophase polymers in comparison to conventional polymers is same as presented by nanophase metals and ceramics and is mediated by fibronectin and vitronectin [26.154, 189].

Nanostructured polymers have been used for vascular, cartilage, and bladder applications where unique nanometer surface features are needed for each type of tissue engineering application [26.190].

Nanocomposites as Smart Orthopedic Implants

The independent promising results shown by nanophase ceramic and polymeric material, led to the foundation of thinking about even better bone scaffold material by combining the advantages of both types of materials [26.39, 195, 196]. The composite material created by the combination of nanophase of both constituents is termed nanocomposite scaffold. An important feature of the nanocomposite is that it can mimic the constituents of natural bone to some extent better than individual counterparts [26.197]. Nanocomposite material can improve the osteoconductivity several folds in comparison to their individual counterparts [26.198, 199]. For, example, the nanoscaffold of nanohydroxyapatite (NHAP) and calcium phosphate can give greater strength to the scaffold as well as improved cell function than conventional material can. However, both calcium phosphate and NHAP suffers a slow rate of biodegradation, which limits their further usefulness.

Nanocomposites with biodegradable polymer can remove such drawbacks and will provide a more favorable material for orthopedic purposes. Nanocomposites of nanophase ceramics and nanostructured polymers offer improved bone cell function over their individual constituents [26.17, 200–203]. NHAP, a most promis-

ing nanoceramic, is a popular bone substitute due to its documented ability to promote mineralization, has also been used as filler and coating material in several applications. Due to the presence of the high surface fraction of grain boundaries in nanoceramics, osteoblast functions such as adhesion, proliferation, and Ca deposition is greatly enhanced. In some in vitro studies it was found that nanophase HAP with 79 nm grain

size, significantly enhances the fibroblast adhesion and strikingly inhibiting competitive fibroblast adhesion compared to the conventional 179 nm grain size of HAP, just within 4 h [26.154].

Nukavarapu et al. fabricated a biodegradable NHAP/polyphosphazene microsphere 3-D scaffold with suitable mechanical properties (compressive moduli of 46–81 MPa) and cytocompatible properties for bone tissue engineering applications [26.205]. It should not be surprising that nanostructured composites have similar mechanical properties to bone since bone itself is a nanostructured composite. Importantly, such results have not been limited to in vitro studies. In in vivo studies it was demonstrated that nanocrystalline HAP accelerates new bone formation on tantalum scaffolds, when used as an osteoinductive coating in comparison to uncoated or conventional micron-sized HAP coated tantalum (Fig. 26.12) [26.204].

Nanophase ceramics like alumina, zinc oxide, and titania have shown increased bone cell functions, which are highly dependent on their surface features and independent of the surface chemistry. For example, osteoblast adhesion increased by 146 and 200% on nanophase zinc oxide (23 nm) and titania (32 nm) compared to microphase zinc oxide (4.9 μm) and titania (4.1 μm), respectively [26.206]. Furthermore, nanophase zinc oxide, nanophase titania and nanofiber alumina enhanced collagen synthesis, alkaline phosphatase activity and calcium mineral deposition compared to conventional equivalents [26.206, 207].

In bone and cartilage, collagen is present in triple helical structure self-assembled into nanofibers 300 nm in length and 1.5 nm diameter. Numerous of efforts have been made to understand the inductive effect of novel biomimetic nanofibrous or nanotubular scaffolds on regenerative medicine by following a bottom-up self-assembly approach. Hartgerink et al. reported a peptide-amphiphile (PA) with the cell-adhesive ligand RGD (Arg-Gly-Asp) self-assembled into supramolecular nanofibers [26.208]. A new nanofiber composite was designed by directly nucleating and aligning HAP on the long axis of a nanofiber with the same self-assembly pattern as collagen and HAP crystals in bone. Promise has also been validated for other novel nanostructured self-assembled chemistries. For example, bone tissue engineering applications of osteogenic helical rosette nanotubes obtained through the self-assembly of DNA base pairs (guanine, cytosine) in aqueous solutions have been reported (Fig. 26.13c). The presence of tailorable amino acid and peptide side chains such as lysine, RGD, and KRSR (Lys-Arg-Ser-Arg) over rosette nanotubes help in osteoblast adhesion and inhibits fibroblast adhesion and further works as excellent mineralization templates to assemble a biomimetic nanotube/HAP structure (Fig. 26.13d). Improved osteoblast adhesion has been noticed over helical rosette nanotubes irrespective of their incorporation into hydrogels or their coating over titanium in comparison to untreated control (Fig. 26.13) [26.208, 209]. A fibrous nanocomposite of PCL/HAP/gelatin at a ratio

of 1 : 1 : 2 was synthesized (by electrospinning) by Venugopal et al., and increased osteoblast proliferation, alkaline phosphatase activity and Ca deposition was reported in comparison to other PCL nanofibrous scaffolds [26.143]. In a recent study, Osathanon et al. reported the synthesis of polymer/calcium phosphate nanocomposites, which further promotes the osteoblast alkaline phosphatase activity and osteoblast marker gene (mRNA) expression thus supports the bone maturation in vitro and in vivo (mouse calvarial defect model) [26.210]. Nanocomposites of Ti/PLGA were also prepared with different ultrasonic power to ensure dispersion of nanoceramic particles into the polymer because agglomeration of ceramic nanoparticles in polymers is a major problem [26.197,

211]. In a further study, improved osteoblast adhesion and long-term functions were reported in comparison to the scaffold made of pure PLGA. Adherence of osteoblasts was found to be increased threefold on nanophase titania/PLGA over the conventional titania/PLGA composite with same weight ratio and porosity (Fig. 26.14a,b) [26.211].

Nanocomposites offer great advantages in mechanical properties in comparison with conventional materials. McManus et al. reported superior mechanical properties of polymer-ceramics with nanometer grain size over micron sized ones [26.212].

Nanocomposites of PLA with 40 and 50 wt% nanophase (< 100 nm) alumina, titania, and HAP showed significant increase in bending moduli that is

very close to bone, than composite of coarse grained ceramics. The bending modulus of nanophase titania/PLA composites with a weight ratio 50 : 50 was 1960 ± 250 MPa (close to the magnitude of the trabecular bone), which is much higher than the bending moduli

of plain PLA, i. e., 60 ± 3 MPa and conventional titania/PLA composites, i. e., 870 ± 30 MPa, respectively.

Apart from the metallic, polymeric, ceramic nanoscaffolds along with their nanocomposites as scaffold materials, nanotechnology has introduced a class of carbon-based nanomaterial for orthopedic applications. Nanocomposites of carbon nanomaterials possess enormous potential for orthopedic application due to their outstanding physiochemical properties.

Since their discovery by Ijima, 1993, carbon nanotubes have gained tremendous popularity among all other allotropes of carbon. Carbon nanotubes are of tubular structure which is formed by a single cylindrical graphene sheet (single-walled carbon nanotubes) or several graphene sheets arranged concentrically (multi-walled carbon nanotubes (MWNT) or MWCNT). Due to the presence of sp² bonding, carbon nanotubes have excellent mechanical and electrical properties. Single-walled carbon nanotubes possess a tensile strength about one hundred times higher than that of steel at a specific weight which is six times lower than steel [26.213,214].

The excellent mechanical properties of carbon nanotubes made them a suitable candidate for hard tissue engineering purposes to reinforce artificial implants that have poor mechanical strength.

Among the carbon-based nanomaterials, carbon nanotubes and carbon nanofibers (CNT/CNF) are the ideal scaffold candidates for bone tissue engineering applications [26.215]. Recently, Price et al. reported that 60 nm CNFs increases the osteoblast adhesion significantly and concurrently decreases competitive cell adhesion in order to stimulate sufficient osseointegration [26.216]. CNTs are suitable for osteoblast functions [26.217]. In a recent study, Sitharaman et al. demonstrated that SWCNT polymer nanocomposites exhibit favorable hard and soft tissue response after 4 and 12 weeks of implantation (femoral condyle and subcutaneously) in rabbits [26.218]. Further, they also reported that the SWCNT-polymer induces 300% greater bone volume after 4 weeks and 200% larger bone growth at defect sites than control polymers without CNT after 12 weeks. Excellent electrical conductivity has been demonstrated by the CNT/CNF polymer nanocomposite for tissue regeneration. PLA is an electrical insulator and not suitable for electrical stimulation for bone growth but PLA/CNTs nanocomposites (at 80/20 wt %) exhibit ideal electrical conductivity for bone growth. A 46% increase in osteoblast proliferation and 307% increase in Ca content was reported after electrical stimulation for 2 and 21 days

by the PLA/CNT composite, respectively, in comparison to PLA alone [26.219]. These studies indicate that CNT/CNF and their composites can serve as osteogenic scaffolds with good cytocompatibility properties, reinforced mechanical properties, and improved electrical conductivity to effectively enhance bone tissue growth. Carbon nanotubes have been widely used in combination with a variety of polymers [26.220, 221]. *Khang* et al. synthesized and reported a nanocomposite of carbon nanotubes with poly(carbonate)urethane [26.220, 221]. *Supronowicz* et al. demonstrated the synthesis of a nanocomposite of CNTs with PLA a biodegradable polymer. *Shi* et al. [26.222] synthesized the nanocomposite of carbon nanotubes and propylene fumarate. *Misra* et al. [26.223] reported a nanocomposite with poly(3-hydroxybutyrate). *Lahiri* et al. [26.224] and *Pelto* et al. [26.225] reported a nanocomposite with polylactide-caprolactone and polypyrrole-hyaluronic acid, respectively. *Balani* et al. [26.226], *Hahn* et al. [26.227], and *Yadav* et al. reported the reinforcement of HAP by carbon nanotubes [26.228]. They also reported the reinforcement of HAP-gel nanocomposites by different weight % of MWCNTs and found that the flexural strength of the composites without any reinforcement is 5.05 ± 1.18 MPa, which gradually improved with the increment in MWCNT concentration up to 3.5–4%. Further, they thoroughly investigated the biocompatibility of nanocomposites in a mouse model through the histopathological investigation of tissues from skin, kidney, and liver, and reported that there is mild reversible change in the liver and tubular damage in the kidney for higher concentrations of MWCNTs (4 wt% of MWCNTs) (Fig. 26.15).

The usefulness of carbon nanotubes is not only limited as a reinforcement material that improves the mechanical properties like tensile strength, compressive and flexural moduli in polymeric material, and fracture toughness, hardness, elastic modulus and adhesion to the HAP, which was described before, but also increased the attractiveness of these materials in nanocomposites with improved bone cell functions (osteoblast adhesion, proliferation, and Ca-deposition). The mechanism of improved cell function by these composites is due to the increased adsorption of fibronectin, i.e., an important cell-adhesion mediating ECM protein which is a prerequisite for bone cell function [26.220, 221]. *Khang* et al. explained that the increased adsorption of fibronectin on this nanocomposite is due to surface properties such as the nanoscale surface roughness of the material by the addition of carbon nanotubes

and an increased material surface hydrophilicity due to the presence of the polymeric component [26.217]. *Supronowicz* et al. [26.219], *Zanello* et al. [26.220], *Khang* et al. [26.220], and *Pelto* et al. have demonstrated that the excellent electrochemical property of carbon nanotubes can favor the electrical stimulation of cells [26.219]. *Supronowicz* et al. reported increased proliferation activity, concentration of extracellular Ca and mRNA expression for collagen type I by osteoblast cells cultured with a nanocomposite of PLA and carbon nanotubes and exposed to electrical stimulation (current 10 μ A, frequency 10 Hz) [26.219]. *Khang* et al. reported that a similar response is presented by the human chondrocytes cell, when they are cultured with a nanocomposite of MWCNT/poly(carbonate) urethane (weight ratio 1 : 2) [26.220]. *Bacakova* et al. [26.229, 230] reported the synthesis of nanocomposites of carbon nanotubes with polymers like terpolymer of polytetrafluoroethylene, polyvinylidene fluoride, and polypropylene (PTFE/PVDF/PP) or polysulfone (PSU) (the most promising material for the construction of bone implants). *Zhang* et al. [26.231] and *Orefice* et al. [26.232] synthesized the composite of PSU with bioactive glass and reported its potential bone and cartilage tissue engineering. *Jan* and *Grzegorz* [26.233] reported the application of the same composite for the fabrication of bone joint screws. Carbon nanotubes have also been used for the formation of prominences in nanoscale on the material surface, which could promote the colonization with bone cells. *Bacakova* et al. [26.229] reported the synthesis of nanocomposites of carbon nanotubes and carbon nanohorns with PTFE/PVDF/PP. Further they reported that the addition of SWCNT or MWCNT to the PTFE/PVDF/PP terpolymer markedly improved several parameters like adhesion and growth of human osteoblast-like MG 63 cells. They further performed an ELISA study and found that the cells on the material with 4 wt% of SWCNT contained a higher concentration of vinculin, i.e., by 64 and 69%, a component of focal adhesion plaques, in comparison with the values in cells on pure terpolymer and tissue culture polystyrene, respectively. The higher concentration of talin (an important integrin-associated focal adhesion protein) was also found in cells grown on terpolymer samples with 4 and 8 wt% of SWCNT (by 35 and 28%, respectively). MWCNT-terpolymer nanocomposites have shown a dramatically increased cell proliferation and it was most apparent on samples with 4 wt% of MWCNT. On the 7th day, cell density, i.e., $228\,000 \pm 1050$ cell/cm² on the nanocomposite was found to be 4.5 times

(e–h) TEM microphotographs of the composite (e) 0% MWCNT showing the rod-like HAP crystals distributed in the gel mesh work; the inset shows the indexed diffraction pattern; (f) 4% MWCNT showing the former is well entangled in the HAP-gel composite; (g) 1% MWCNT showing the nucleation of the HAP on MWCNT preferentially at the sites of defects; (h) 4% MWCNT showing the latter well coated with HAP crystals. (i–p) Histological photomicrographs of control tissues from (i) liver, (j) kidney, and (k) skin showing normal cytomorphology. Tissues from (l) liver, (m) kidney exposed to composites having 1% reinforcements showing no significant change due to toxicity. The tissues exposed to composites with 4% MWCNT (n) liver showing hydropic changes and ballooning of hepatocytes; (o) kidney exhibiting glomerular ablation and tubules showing cloudy swelling (p) skin exhibiting no significant alteration. (After [26.228])

higher than unmodified PTFE/PVDF/PP, i.e., $50\,300 \pm 5400$ cells/cm².

The addition of SWCNT or MWCNTs also lowers the wettability of the composite material (sessile water drop contact angle from $99 \pm 7^\circ$ to $105 \pm 2^\circ$) compared to the non-modified terpolymer (contact angle $100 \pm 4^\circ$). The surface roughness of the composite material is also increased significantly on addition of MWCNTs and SWCNT. An increase in the microscale surface roughness in polymer-CNT composites has been considered as a factor decreasing the colonization of the composites with cells. Misra et al. [26.223] reported the synthesis of poly(3-hydroxybutyrate)/bioactive glass composites with MWCNTs and in a further study they found that the cell population density and growth rate of MG 63 cells decreased proportionally to the increasing concentrations of MWCNT (2, 4, 7 wt%) and

increasing microscale surface roughness (RMS from 6 ± 2 to $10 \pm 2 \mu\text{m}$) of the material. On the contrary, Bacakova et al. reported that the cell adhesion and growth of MG 63 cells (evaluated by the concentration of integrin-associated proteins talin and vinculin and the cell population density) was, in most cases, the highest on composites with 4 wt% of SWCNT or MWCNT and then decreased [26.230].

Bacakova et al. also reported the synthesis of polysulfone-nanotube composites (Fig. 26.16) [26.230]. In a further study they found that the addition of carbon nanotubes to polysulfonate (PSU) did not significantly influence the adhesion, spreading, morphology, and growth of MG 63 cells in cultures on these materials from 5 days after seeding, the cell numbers on these composites were usually similar to the values found on the pure PSU. The cell adhesion area measured after

3 days was found to be significantly higher in the case of **PSU** with 2 wt% of **MWCNT** ($1770 \pm 90 \mu\text{m}^2$) in comparison to pristine **PSU** ($1330 \pm 70 \mu\text{m}^2$) and cell culture polystyrene dishes ($1400 \pm 110 \mu\text{m}^2$). The possible explanation of such a finding is that a relatively higher surface hydrophilicity of the pure **PSU** (water drop contact angle $85 \pm 5^\circ$) compared to the terpolymer **PTFE/PVDF/PP** (contact angle $100 \pm 4^\circ$), which might mask the supportive effects of the surface nanoroughness (created by the addition of carbon nanotubes) (R_a from $11 \pm 4 \text{ nm}$ to $27 \pm 8 \text{ nm}$ versus $4 \pm 2 \text{ nm}$ on the pure **PSU**) as well as cell colonization. The addition of carbon nanotubes causes a slight decrease in the surface hydrophilicity of the materials (i.e., the water drop contact angle increased from $85.0 \pm 5^\circ$ to $93 \pm 4^\circ$), but these differences were not statistically significant [26.230].

In addition to nanocomposites, carbon nanotubes, in the form of film deposited on various substrates such as polycarbonate membranes [26.234] glass coverslips [26.235], titanium [26.236], silicone rubber [26.237], or pressed in compacts [26.238] have shown significant improvement in bone cell functions in comparison to non-coated substrates. *Hirata et al.* reported that films of carbon nanotubes on 3-D matrices like on the walls of pores inside sponge-like collagenous scaffolds improved the ingrowth of mouse osteoblast MC3T3-E1 cells and human osteosarcoma SaOs-2 cells inside the scaffolds, increased the strength of the cell adhesion and cell number (measured by **DNA** content), when compared to the scaffolds without nanotubes [26.239]. *Aoki et al.* [26.234], *Li et al.* [26.238], and *Zanella et al.* [26.217] synthesized composites of carbon nanotubes with polymers and ceramics, reports that composites promote the growth of bone cells in similar way as reported above, in brief, an increased adsorption of specific proteins (such as cell adhesion-mediating proteins from the serum of the culture medium and bone morphogenetic protein-2) promotes cell adhesion, growth and differentiation.

Among carbon materials, carbon nanofibers have also been shown to exhibit excellent conductivity and exceptional mechanical and cytocompatible properties, thereby giving a strong rationale to investigating them for application in orthopedic or dental tissue engineering [26.240]. Carbon nanofiber-based nanocomposite implants can be a better alternative to conventional metal alloys [26.193, 216]. *Price et al.* showed that carbon nanofibers show greater osteoblast adhesion than conventional carbon fibers [26.216]. They further reported that **PLGA** coated carbon nanofibers enhanced

Fig. 26.15 (continued)

the osteoblast function in comparison to conventional carbon fibers. Enhanced osteoblast function on carbon nanofiber composites is due to surface area of the nanofibers, nanometer topography, and surface chemistry of fibers.

Graphite has been used in three-dimensional systems as a component of various composite materials used for construction of bone implants. *Ekstrand and Hirsch* [26.241] reported the reinforcement of poly(methylacrylate) implant by carbon/graphite designed for reconstruction of the maxilla damaged by malignant tumors. *Yildiz et al.* [26.242] reported the synthesis of graphite fiber reinforced composites of polyetheretherketone (**PEEK**) for hip joint prostheses [26.243].

Fig. 26.16a–d Immunofluorescence staining of β -actin in osteoblast-like MG 63 cells on day 3 after seeding on a terpolymer of polytetrafluoroethylene, polyvinylidene fluoride, and polypropylene (a), terpolymer mixed with 4% of single-walled carbon nanohorns (b) or high crystalline electric arc multi-walled nanotubes (c) and tissue culture polystyrene dish (d). Microscope Olympus IX 50, digital camera DP 70, obj. 20. Bar = 100 μ m. (After [26.229]) ◀

Graphene is the mother of all forms of carbon-based nanomaterial and a material of wonder, due to novel properties such as the quantum Hall effect at room temperature [26.244], tunable bandgap [26.245], and high elasticity [26.246–249], etc. After its discovery and realization in the year 2004, graphene has become the center of attraction in scientific community. The

excellent mechanical strength and good biocompatibility of graphene and graphene oxide [26.250–253] make them ideal candidates for tissue engineering purposes. Polymer composites containing graphene possess good electric and thermal conductivity along with improved mechanical stiffness [26.254–256]. Recently, Rao et al. [26.247] reported a significant increase in mechanical properties of polyvinyl alcohol (PVA) by the addition of functionalized few-layer graphene [26.257]. Rafiee et al. compared the mechanical properties of graphene/epoxy and carbon nanotube/epoxy nanocomposites at a low filler content of 0.1 wt% and found that graphene platelets significantly out-performed carbon nanotubes as a reinforced additive [26.258]. Fan et al. reported first a study on the reinforcement of biomacro-

Fig. 26.17 (a) Cell phase contrast micrographs at 12 h. The scale bar represents 50 μ m. (b) Cell phase contrast micrographs at 24 h. As time increases, cells extend gradually. Cells with the lower concentration graphene/chitosan composite materials performed better. (After [26.259])

molecules like chitosan by graphene [26.259]. In their study, they found that the addition of graphene significantly increased the modulus of chitosan at a very

low content (between 0.1 and 0.3 wt%) and in addition these composites showed good biocompatibility for L929 cells (Fig. 26.17).

26.6 Future Perspectives

Nanotechnology has shown great potential to solve the ever challenging issues in tissue engineering, i.e., the search for suitable artificial implants. Advancement and integration of nanotechnology to tissue engineering has made it possible to fabricate advanced materials, i.e., nanocomposites with more favorable properties for orthopedic purposes.

Nanocomposites have shown a better response as artificial scaffold material than conventional scaffold materials. The commercialization of nanomaterials in the form of nanoproducts has already begun. Nanoceramic products such as nano-HA-paste-ostim from Obernburg, Germany, nano-beta-tricalcium phosphate-Vitoss from Orthovita, USA, are commercially available and have started their impact on society [26.260]. The inclination of nanotechnology towards bone tissue engineering is in its early age and at this stage commercialization of nanoproducts raises some serious concerns.

Before pledging the complete reliability of the technology and products there are still some challenges that need to be addressed. The first concern related to the fabrication processes of nanocomposites is the need to develop facile and inexpensive techniques for the fabrication of nanomaterials with the desired size, shape, and topography. The currently used fabrication techniques are very costly and complicated, and often a lot of time and attention is needed to complete the fabrication (for instance e-beam lithography).

The second and most important concern is the biocompatibility of nanocomposite materials. Although

some reports indicate that nanocomposite materials are safe, others tell about the toxic responses to nanoparticles generated from the degradation of implanted nanomaterials; the conflict about the toxicity of nanomaterials is a debatable issue. Accurate assessment of nanoparticle toxicity is very difficult because it depends on several factors like dose, chemical composition, method of administration, size, biodegradability, solubility, pharmacokinetics, bio distribution, surface chemistry, shape, and structure, etc. [26.261, 262] Most biocompatibility reports on nanocomposites are a result of in vitro evaluation and there are only few reports which are based on in vivo investigations. In vitro studies are enough for primary screening, but to obtain complete knowledge about the biological behavior of nanocomposites, sound in vivo studies are highly needed. In vivo research will help to establish the safety of nanocomposites and their applications in the near future. Therefore, to exploit the full potential of nanotechnology for tissue engineering purposes, safety evaluation is the first and utmost requirement at the time of synthesis and the time implantation.

Apart from carbon nanotubes, graphene, a class of material having superior mechanical and electrical properties, has a great potential to be used in nanocomposites for orthopedic implants. Good biocompatibility and the absence of metallic impurities on graphene sheets makes them potential candidates for tissue engineering applications.

Nanofiber Bi

27. Nanofiber Biomaterials

Rachelle N. Palchesko, Yan Sun, Ling Zhang, John M. Szymanski, Quentin Jallerat, Adam W. Feinberg

Since its inception, the field of tissue engineering has sought to rebuild the complexity of normal tissues by seeding cells onto scaffolds to support the formation of new tissue. Recently, nanofibers have gained increasing attention because these biomaterials have unique properties and are able to interface with cells at the same scale as native extracellular matrix fibrils. New fabrication technologies provide novel ways to control the nanoscale structure and properties of biomaterials, which is advantageous in the engineering of tissues for in vitro study and in vivo applications in regenerative medicine. This chapter explores the properties of nanofiber biomaterials (diameters < 500 nm) and examines the specific advantages relative to other scaffold materials. This includes nanofibers from biopolymers as well as synthetic polymers, with consideration of relative advantages and disadvantages. A range of fabrication strategies is discussed that span from fiber spinning techniques, to phase separation in bulk, to directed and self-assembly. Insight is provided as to how synthetic polymers and biopolymers are used to make these nanofibers and the specific molecular structures that impart the unique mechanical, electrical, chemical, and biological properties. Analysis of these nanofiber biomaterials requires characterization techniques that are able to probe at the nanometer, micrometer, and macroscales. Examples are provided using optical microscopy, electron microscopy, scanning probe microscopy, mechanical characterization, and as-

27.1 Methods of Production	980
27.1.1 Fiber Spinning	980
27.1.2 Phase Separation	982
27.1.3 Directed and Self-Assembly	983
27.2 Properties of Nanofiber Biomaterials	986
27.2.1 Structure and Physical Properties .	986
27.2.2 Mechanical Properties.....	988
27.2.3 Electrical Properties	988
27.2.4 Chemical Properties	989
27.2.5 Biological Properties and Cell Response	990
27.3 Characterization of Nanofiber Biomaterials	993
27.3.1 Optical Characterization	993
27.3.2 Electron Microscopy	995
27.3.3 Atomic Force Microscopy (AFM)	995
27.3.4 Mechanical Characterization	996
27.4 Applications	999
27.4.1 Cardiac Tissue Engineering	999
27.4.2 Skeletal Muscle Tissue Engineering.....	1001

essment of biocompatibility and biodegradation. Finally, nanofiber biomaterials have wide applications in tissue engineering; here we focus on representative examples in cardiac, musculoskeletal, ophthalmic, and neural tissue engineering.

Nanofiber biomaterials provide a number of advantages over existing micro- and macroscale biomaterials. The small size (diameter < 500 nm) results in very high surface area such that surface properties often dominate over bulk material properties. When formed into tissue

engineering scaffolds, nanofiber biomaterials possess low density and high porosity, which can facilitate cell attachment and infiltration. To leverage these and other unique properties, it is necessary to understand how cells and tissues are constructed and how nanoscale ma-

terials interact with biological systems. Every tissue in the body is composed of an extracellular matrix (ECM) consisting of biopolymer fibrils and fibers that structurally hold cells together and serve as an insoluble signaling network for biochemical and biomechanical communication. These biopolymers include ECM proteins, proteoglycans (PGs), and glycosaminoglycans (GAGs), each of which serves multiple roles in normal ECM structure and function. In fact, any tissue can be thought of as a complex network of different types of ECM nanofibers interconnected with each other and with the constituent cells (Fig. 27.1). Understanding the basic role of the ECM is necessary in order to design and utilize nanofiber biomaterials in tissue engineering and medical device applications. The focus here is on the basic structure and properties of the ECM as it relates to cell interactions with nanofibers; in-depth review articles are available on ECM proteins [27.1–6], PGs [27.7,8], and GAGs [27.9,10] as

further reading. Collagens are ECM proteins that make up $\approx 25\%$ of the protein mass in mammals, have at least 25 known isoforms, and are found in nearly all tissues. Collagen type I, with an elastic modulus of ≈ 1 GPa, is the most prevalent and is organized into fibers that are hierarchically assembled from a basic unit of three coiled polypeptide α -chains into larger and larger fibrils, fibers, and bundles with diameters from nanometers to micrometers [27.4]. Elastin is another ECM protein that is responsible for much of the elasticity of tissues such as arteries, lung, and skin [27.11, 12]. It is thought to be assembled in a random, cross-linked network and mechanically behave like an entropic spring, providing an elastic modulus of ≈ 0.1 MPa. Collagens and elastins are primarily considered structural ECM proteins, however they do have some role in biochemical interactions, and may be important in the mechanobiology of the ECM [27.13]. Adhesive ECM proteins include fibronectin and laminin, which contain binding

Fig. 27.1 The importance of the 3-D environment for engineering cell function. The composition, architecture, and degree of cross-linking dictate the mechanical properties of the extracellular matrix (ECM) and control how mechanical forces are transmitted to cells. Whereas collagen fibers resist tensional forces and compaction by cells, proteoglycans (PGs) control hydration, which, in turn, determines the resistance to compressive forces, and hinders protein transport by their high, fixed charge density. Basement membrane, which is secreted basally by epithelial and endothelial cells, further hinders protein transport and increases mechanical stiffness. The matrix composition also controls cell adhesion and migration, and its sensitivity to proteolytic enzymes will determine the ability of the cell to remodel the matrix and migrate through it. Other nonstructural ECM proteins are important for cell function in vivo, such as matrix proteins that support various intermediate states of cell adhesion and de-adhesion to help regulate cell migration, proliferation, apoptosis, and differentiation. Because many growth factors, chemokines, and other morphogenetic and signaling proteins are secreted in matrix-binding forms, particularly sulfated PGs, the presence of heparin sulfate in the matrix will allow better cellular control of local gradients of such molecules, which can be stored in the matrix and later released proteolytically. Perfusion of the tissue culture will promote nutrient transport and can also impart mechanical stresses on the cells, as well as alter local biochemical gradients (after [27.17])

domains for cells, other **ECM** proteins, growth factors, and signaling molecules as well as self-binding domains in order to form fibrils. Laminins are found in basement membranes in combination with collagen type IV to form **ECM** mats that underlie epithelial cells, fat, and muscle [27.14, 15]. Fibronectin is the first **ECM** protein assembled during embryogenesis and wound healing [27.16], and among many roles it forms a template upon which collagen fibrils are assembled [27.4]. There are also a number of other **ECM** proteins in various tissues, including fibrinogen, fibrin, and fibrillin. GAGs are nonprotein biopolymers consisting of unbranched polysaccharide chains, such as hyaluronan, that adsorb large amounts of water and occupy space in the **ECM**. PGs consist of GAGs attached to a protein core, such as decorin and aggrecan, and regulate the movement of water, cells, and molecules through the **ECM**. This is a very brief description of **ECM** proteins, PGs, and GAGs and is still only a subset of the biopolymers that make up the natural nanofibers in the **ECM** of tissues. It is important to realize that the chemical composition, two-dimensional (**2-D**) and three-dimensional (**3-D**) architecture, and synthesis/repair are all tightly regulated by the constituent cells and that as cells interact with nanofibers they secrete and assemble a new **ECM**.

Nanofiber biomaterials are engineered to mimic one, or multiple, structural and functional roles of the **ECM**. A large variety of synthetic and biologically derived polymers are processed into nanofibers using fiber spinning, phase separation, and directed or self-assembly techniques. Typical synthetic polymers include poly(lactic acid) (**PLLA**), poly(glycolic acid) (**PGA**), copolymers of **PGA** and **PLLA** (**PGLA**), poly(acrylic acid) (**PAA**), and poly(ϵ -caprolactone) (**PCL**). Typical biopolymers include collagen type I, fibrin, gelatin, and fibronectin. The fabrication method used depends on the specific polymers and the processing conditions necessary to achieve the final nanofiber structure. Also, the organization of the nanofibers in the context of the macroscale scaffolds varies greatly with fabrication methods; For example, electrospinning is commonly used to create biodegradable nanofibers from medical-grade polymers such as **PLLA** or natural polymers such as collagen type I. However, control over the architecture of the scaffold is limited, with minimal influence over the individual placement of nanofibers. Alternative techniques such as surface-initiated assembly provide submicrometer control of nanofiber placement, but are limited to a small set of **ECM** proteins such as fibronectin and are difficult to build into macroscale scaffolds. Thus, the choice of fabrication

strategy and polymer type depends on the desired nanofiber properties for the specific application.

Biological systems that interface with nanofiber biomaterials are sensitive to a wide range of properties that must be controlled. Thus, characterizing the nano-, micro-, and macroscale properties is necessary in order to understand how molecules, cells, and tissues interact with these materials across spatial scales and dynamically over time. This requires analytical techniques that can probe at these dimensions, with nanoscale characterization being one of the more challenging aspects. The structure of nanofiber biomaterials is typically assessed using scanning electron microscopy (**SEM**), transmission electron microscopy (**TEM**), and/or atomic force microscopy (**AFM**), which are capable of resolving features from < 10 to > 100 nm. However, these techniques are typically not sensitive to chemical differences, requiring complementary techniques that can detect specific chemical bonds, such as Raman and infrared spectroscopy, or that can detect specific biological ligands such as fluorescently conjugated antibodies. At the micro- to macroscales, optical microscopy is an integral analytical technique, able to probe basic structure in bright field and specific biological structure/function using antibodies, transgenic fluorescent proteins, and voltage/ion-sensitive dyes. A number of advanced optical techniques such as confocal and multiphoton microscopy enable true **3-D** imaging of cells and nanofibers, and a number of new superresolution techniques are able to image below the diffraction limit of light with true nanometer spatial resolution. Cells respond to the mechanical properties of their environment, making mechanical characterization an important part of determining how nanofibers will interact with biological systems. A number of techniques are used to probe the nano- and micromechanics of individual nanofibers as well as the macroscale mechanics of scaffolds, where the **3-D** organization of the nanofibers is an important factor. Similarly, electrical properties are important for conductive nanofibers, which need to be analyzed at both the nanofiber and scaffold scales. These structural, chemical, mechanical, and electrical properties are all important in terms of biological interaction and determine the biocompatibility, bioactivity, and biostability/biodegradation of nanofiber biomaterials. These properties are tuned for the specific tissue engineering application, which can vary greatly depending on the tissue or organ system of interest.

Nanofiber biomaterials for tissue engineering have applications in nearly every tissue type in the body.

Presented here are representative examples where the organization of cells at the nano- and microscales relates directly to tissue function. This includes cardiac, muscle, ophthalmic, and neural tissue engineering. In each case, there are tissue-scale readouts of function that relate back to nanoscale interactions between cells and nanofibers: specifically, force generation in skele-

tal muscle, action potential propagation in nerve, force generation and action potential propagation in cardiac muscle, and optical transparency in cornea. Nanofiber biomaterials offer unique advantages in each of these areas, but achieving good results requires a detailed understanding of how the nanofibers interface with the biology.

27.1 Methods of Production

Nanofiber biomaterials require specialized methods that are able to fabricate structures that are truly at the nanometer scale. There are a limited number of techniques that can do this, which can be organized into three main categories:

1. Fiber spinning
2. Phase separation
3. Directed or self-assembly of polypeptides and amphiphiles.

Spinning is a standard approach to fiber production; however there are only a few techniques that can achieve nanometer dimensions. Electrospinning is the most common nanofiber fabrication method, and has been used with a wide variety of synthetic polymers and biopolymers. Not all polymers are compatible with the large electric field required for electrospinning, which has spurred the development of centrifugal force-based spinning techniques such as rotary jet spinning (RJS) and related methods. Phase separation involves the mixing of components that under the proper conditions separate into relatively pure fractions. This can be used to generate a bulk material composed of interconnected nanofibers, although it cannot be used to generate individual nanofibers as done with spinning techniques. Directed and self-assembly are done with biopolymers that naturally undergo assembly into fibrils and fibers or with engineered molecules that assemble due to their amphiphilic structure. These techniques can be used to create individual fibers and complex networks, and are the most recent development in nanofiber fabrication.

27.1.1 Fiber Spinning

Electrospinning

Electrospinning is a technique that is able to produce nanofibers out of a wide range of polymers. In this process, a polymer solution is loaded into a reservoir,

where surface tension prevents it from flowing out of the tip (Fig. 27.2). A high-voltage source is connected between the tip and a metal collector, commonly a plate, but other setups are used including rotating drums. The electric potential overcomes the surface tension, and a jet of liquid is pulled toward the collector. In its most common form, a mat of randomly aligned fibers are collected, which can be used for many applications including tissue engineering.

A wide variety of polymers and copolymers have been successfully electrospun to produce fibers ranging in diameter from 3 nm up to 10 μm [27.18]; For example, *Li et al.* electrospun copolymers of gelatin and polyaniline (PANI) to form mats of 200 nm-diameter fibers [27.19], while *Riboldi et al.* electrospun much larger, 10 μm -diameter fibers of DegraPol (for skeletal muscle engineering) [27.20]. This versatility, as well as the straightforward setup and low cost, make electrospinning a popular technology to produce nanofibers. Properties can be optimized by controlling parameters such as flow rate, polymer viscosity, voltage, distance to the collector, tip and collector shape, and collector movement.

Fig. 27.2 Typical electrospinning setup: a polymer solution is spun from the syringe by high voltage and forms a mat of nanofibers on the collector. Important parameters include: V voltage, Q flow rate, and d distance between tip and collector (after [27.18])

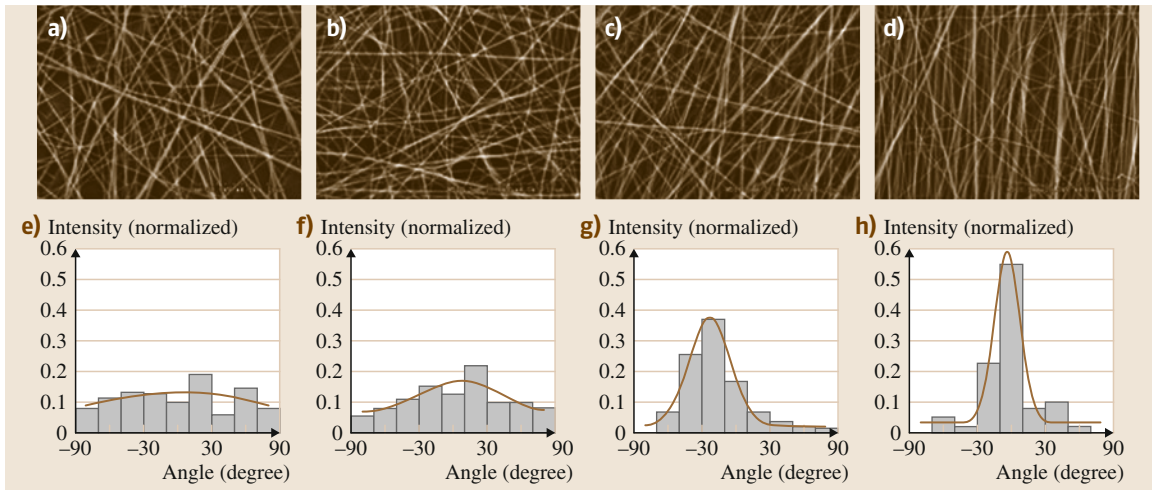

Fig. 27.3 Fiber angles for different rates of rotation: (a–d) SEM images of electrospun PCL/collagen nanofibers (4000× magnification) and (e–h) normalized histograms of fiber angle, (a,e) static, (b,f) 800 rpm, (c,g) 1500 rpm, and (d,h) 2350 rpm (after [27.21])

Scaffolds are often fabricated with a degree of anisotropy in order to align cells, for example, in nerve and muscle tissue engineering. Electrospinning using a static collector (Fig. 27.2) creates a random, isotropic architecture with nanofibers oriented in all directions (Fig. 27.3a,e). To align nanofibers, a rotating collector is used to create a degree of anisotropy; For example, *Li et al.* collected nanofibers on a rotating cylinder where a PCL solution was drawn on a 2.54 cm-diameter aluminum rod placed in the path of the polymer jet (Fig. 27.4) [27.21]. Increasing the speed of the rotating cylinder onto which the fibers are deposited increases alignment. *Choi et al.* produced PCL-collagen nanofiber meshes with progressive increases in fiber alignment by increasing the rotation rate of the cylindrical collector (Fig. 27.3) [27.22]. Their results also demonstrated that the rotation speed did not affect the nanofiber diameter. Other collectors, such as rotating drums, can also be used to align nanofibers [27.23]. Anisotropy can also be achieved by modifying electrospun scaffolds after spinning [27.24, 25]; For example, *Huang et al.* uniaxially stretched electrospun PLLA scaffolds 200% at 60 °C to obtain alignment of nanofibers [27.24].

Thermal, electrical, and mechanical properties of the fibers can also be modified by changing the parameters of the electrospinning process. Some examples are discussed in Sect. 27.4 for different applications in tissue engineering.

While electrospinning is widely used to produce nanofibers, there are two main drawbacks: (i) the high-

voltage electric field to create the polymer jet, and (ii) the need for the polymers to be dissolved in a dielectric solution [27.26, 27]. The high electric fields can degrade certain polymers and cause interference between the nozzles in multinozzle systems. It is also difficult to

maintain a constant jet of polymer due to the need for frequent nozzle cleaning, the lack of uniformity in the feed rate, and the lack of consistent solution viscosity due to evaporation of the often toxic solvents [27.27]. Table 27.1 presents a few of the advantages and disadvantages of electrospinning versus the other nanofiber fabrication methods discussed below.

Rotary Jet Spinning

Two recently developed nanofiber fabrication techniques that are very closely related are rotary jet spinning (RJS) and ForceSpinning. RJS was developed in the Parker laboratory at Harvard University, and ForceSpinning was developed in the Lozano and Sarker laboratories at the University of Texas-Pan American. In these techniques, a high-speed rotating nozzle and centrifugal force are used to form a stream of polymer that is deposited onto a stationary col-

lector [27.26, 28]. A schematic diagram of the RJS system is shown in Fig. 27.5. Briefly, a reservoir with two orifices is attached to a high-speed motor, and polymer in the reservoir is propelled by the rotation onto a stationary collector. Once the solvent evaporates the polymer solidifies into a fiber, with nanometer to micrometer diameters readily achievable. The morphology, diameter, and porosity of the resulting nanofibers and scaffold can be controlled through nozzle geometry, motor rotation speed, temperature, and the type of polymer solution; For example, using more volatile solvents and/or a slower rotational speed will result in fibers with larger diameter. RJS has been successfully used to form nanofibers with natural and synthetic polymers including PAA and gelatin [27.26]. The resulting fibrous scaffolds are three-dimensional, and the nanofibers are well aligned. ForceSpinning is commercially available from FibeRio Technology Corporation and has been used to form nanofibers of poly-ethylene oxide, PLA, polypropylene, acrylonitrile butadiene styrene, polyvinyl pyrrolidone, and polystyrene [27.28]. ForceSpinning and RJS have advantages over electrospinning in that a high electric field and dielectric solution are not needed, expanding the types of materials from which nanofibers can be produced.

27.1.2 Phase Separation

Phase separation is a well-established method for creating porous polymer membranes or scaffolds by separating a polymer solution into two phases, typically a polymer-poor phase and a polymer-rich phase [27.29]; For example, Ma and Zhang first utilized phase separation to create a nanofibrous scaffold from

Fig. 27.5 (a) A diagram of the rotary jet spinner. (b) The resulting spun nanofibers. (c) The nanofibers viewed at 10 μm scale (after [27.26])

PLLA [27.30]. PLLA was dissolved in tetrahydrofuran (THF) and quenched to a lower temperature to allow gelation (phase separation) for a few hours. The THF was exchanged by water, and the scaffold was freeze-dried. This process led to a nanofibrous scaffold with porosity of 98.5% and fiber diameter ranging from 50 to 500 nm, which is similar to the range of natural collagen fibers. Fiber diameter was controlled by the gelling temperature, with high temperature resulting in only macroscale fibers. Below the nanofiber forming temperature, fiber diameter will not be affected by gelling temperature, while the scaffold architecture will be affected (i.e., the interfiber spacing becomes more uniform) (Fig. 27.6). Similarly, polymer concentration does not change the fiber diameter but affects the architecture of the scaffold, with higher concentration resulting in a more uniform fibrous structure. The type of solvent used determines the gelling temperature of the polymer solution. The *Ma* group has produced a scaffold with 3-D macrostructure by building a structured porogen (sugar or salt) into the scaffold solution before phase separation to further facilitate cell migration into the scaffold, mass transport of nutrient in and out of the scaffold, and tissue organization [27.31]. More recently, this phase separation has been applied to other polymers such as poly-hydroxyalkanoate, PCL, PLGA, chitosan, and gelatin [27.32–35].

27.1.3 Directed and Self-Assembly

Directed Assembly – Surface-Initiated Assembly

Surface-initiated assembly is a directed assembly technique that mimics the way cells build ECM proteins into fibers. In vivo, the assembly of ECM protein fibers relies on the use of cell-derived mechanical forces to unfold protein subunits and expose their cryptic self-binding domains [27.36]. Mimicking this process in vitro has proven to be difficult, typically requiring denaturants or reducing agents to chemically denature proteins and expose their cryptic self-binding domains [27.37]. This results in a matrix of protein fibers that has no structural organization. Improved organizational control has been demonstrated by drawing fibrils out of a concentrated protein droplet, but this method is limited to creating planar geometries of fibers permanently bound to the substrate [27.38]. It is also necessary to point out that these fibers have diameters of the order of micrometers, well above the diameters of cell-derived fibers, which are of the order of nanometers.

Fig. 27.6a–f SEM micrographs of PLLA matrices prepared from 5.0% (wt/v) PLLA/THF solution at different gelation temperatures: (a) 23 °C, 2000× magnification; (b) 19 °C, 2000× magnification; (c) 17 °C, 2000×; (d) 15 °C, 2000× magnification; (e) –18 °C, 2000× magnification; (f) liquid nitrogen, 2000× (after [27.30])

Surface-initiated assembly is able to overcome the deficiencies of the prior methods to create free-standing protein fibers that are < 10 nm thick. This process utilizes protein–surface interactions instead of denaturants or force to form nanofibers (Fig. 27.7a). Briefly, ECM proteins are first adsorbed onto a patterned, hydrophobic poly(dimethylsiloxane) (PDMS) surface, causing them to partially unfold into an extended conformation. The unfolded proteins are then transferred to a thermally responsive poly(*N*-isopropylacrylamide) (PIPAAm) surface through microcontact printing. Subsequent hydration and reduction of temperature triggers the expansion followed by the dissolution of PIPAAm, resulting in the formation and nondestructive release of the protein nanofibers [27.39]. This technique has been demonstrated for a number of fiber-forming ECM proteins including fibronectin, laminin, collagen type I, collagen type IV, and fibrinogen (Fig. 27.7b–p). Microcontact printing is a soft lithography technique that enables the microscale patterning and formation of protein matrices in a variety

of geometries and compositions. However, surface-initiated assembly is limited to ECM proteins that have self-binding domains in order to undergo fibrillogenesis.

Self-Assembly

Self-assembling nanofibers are molecular systems engineered to spontaneously undergo organization into nanofibers under specific conditions. The first self-assembling peptide (sa peptide), EAK16, was discovered in the Rich laboratory at MIT while researchers were investigating yeast genetics and Z-DNA [27.40, 42]. It was found to spontaneously assemble in an aqueous environment, first into nanofibers and then further into a hydrogel-like scaffold [27.40, 43]. The three main factors that drive self-assembly for these peptides are the hydrophobic interaction, ionic interactions, and peptide backbone hydrogen bonds [27.40]. These peptides are ionic and self-complementary because both the positive and negative side-chains are located on one side of the β -sheet and the hydrophobic side-chains are on the other, resulting in one hydrophobic and one hydrophilic side [27.40, 41]. The hydrophobic sides interact with one another and form double sheets inside the nanofiber, while the outside ionic/hydrophilic side interacts with the water to form a high-water-content hydrogel with around 99.5–99.9% water content [27.40] (Fig. 27.8).

The properties of all self-assembled peptide nanofibers are dependent upon the amino acid sequence chosen, the stereochemistry of the peptide, the molecular size, and the environmental conditions during and after formation of the nanofibers.

There are three different types of peptides that self-assemble into β -sheet nanofibers (Fig. 27.9). Type I, e.g., EAK16, are peptides with alternating hydrophobic and polar amino acids that self-assemble in the presence of Li^+ and Na^+ ions [27.41]. Type II are peptide amphiphiles, which have a hydrophobic alkyl tail coupled to a peptide block with β -sheet-forming segments and charged residues [27.41, 44–50]. The driving force behind peptide amphiphile nanofiber self-assembly is the tendency of the alkyl chains to aggregate together in water, with the main stabilizing forces being hydrogen bonding and hydrophobic and electrostatic interactions [27.41, 51]. Peptide amphiphile self-assembly can be triggered by changing the pH or ion concentration in solution and results in well-defined fibers that are micrometers in length and usually about 5–10 nm in diameter [27.41]. The final type is type III, the peptidomimetics, which are amphiphilic oligopeptides combined with synthetic compounds, such as the dibenzofuran peptidomimetic [27.41, 52]. Peptidomimetics first self-assemble into quaternal structures, which (mediated by hydrophobic interactions) dimerize face to face [27.41]. These dimers then further elongate to

Fig. 27.9 Chemical structures of various types of artificial peptides and peptidomimetics (type I–III) that assemble into β -sheet-based nanofibers (after [27.41])

form filaments that then interact to form ribbons or fibrils [27.41].

Self-assembly is usually spontaneous, but it can be tuned with *switches* that respond to light or enzymatic reactions; For example, a polyethylene glycol (PEG) sequence can be added to the end of the peptide sequence so that, as the polymer is digested using thrombin, the peptides are released and can interact with one another and begin to self-assemble [27.41]. The formation of self-assembled nanofibers and scaffolds can be dynamic, such that when the structure is disrupted, the fibers can spontaneously reassemble. This was shown by sonication of self-assembled nanofibers and analysis of the reformation of the nanofibers by AFM [27.40].

Although β -sheet-forming self-assembling nanofibers are the most common, there are a few reports on α -helix-forming self-assembling peptides. These structures are modeled after the collagens and keratins. One example is the switch from α -helix to β -sheet and

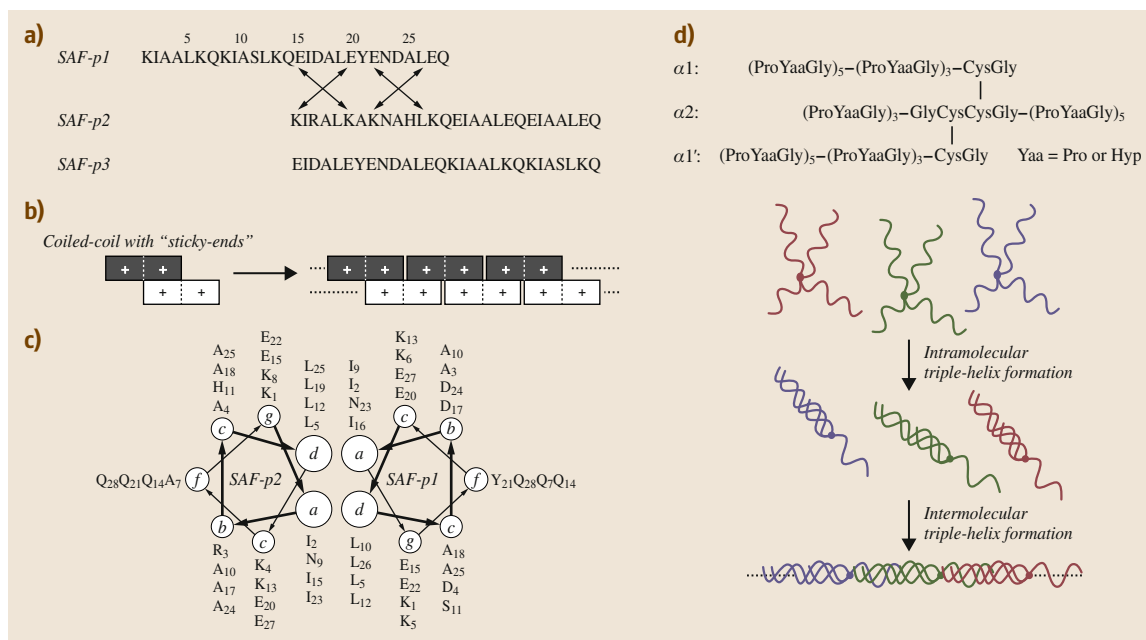

Fig. 27.10a–d Coiled-coil-based self-assembling peptide system designed by Woolfsen's group. **(a)** Amino acid sequences of self-assembling fiber peptides. **(b)** Concept for sticky-end assembly process. **(c)** Helical wheel representation of coiled-coil conformation. **(d)** Molecular structures of multibranching self-assembling collagen models and representation of the self-assembly process of the collagen models through triple helix formation (after [27.41])

vice versa of the LKL16 peptides, which can be controlled with pH [27.41]. Most commonly they feature the sequence *abcdefg* repeated, with *a* and *d* being hydrophobic residues and the rest being polar. The hydrophobic interaction between *a* and *d*, as with the β -sheet-forming peptides, stabilizes a core, but in this case the rest of the residues create a side-by-side packing of two α -helices, which the *e* and *g* residues stabilize (Fig. 27.10) [27.41]. These types of nanofibers can also be formed using collagen mimetics with *sticky ends*.

The properties of nanofibers made by self-assembly are determined by the environmental conditions, which is a limitation of this approach. The nanofibers are sensitive to changes in environment including pH, electrolyte addition, and electrostatic interactions [27.51]. The formation of self-assembled peptide nanofibers requires careful design of the starting peptide or peptide amphiphile, which is also important to tune properties for a given tissue engineering application.

27.2 Properties of Nanofiber Biomaterials

27.2.1 Structure and Physical Properties

Understanding the structural and physical properties of nanofibers is critically important because these factors influence how biomolecules and cells interact with the nanofibers. For tissue engineering, either single nanofibers or multiple nanofibers integrated into a scaffold should mimic some aspect of the natural ECM environment of the tissue. From a structural standpoint,

the important properties include fiber diameter, spacing, orientation, entanglement, and interconnectedness.

Common Properties of Nanofiber Biomaterials

Regardless of the manufacturing technique applied, nanofiber biomaterials share a range of structural and physical properties due to the small size of the materials. The nanofibers considered here have diameters < 500 nm, making them distinct in size from microscale

and larger fibers. Relative to the diameter, nanofibers are typically quite long, from tens of micrometers up to centimeters or even meters in length. This high surface area means that surface properties can dominate over bulk properties, which become quite important in terms of chemical and biological properties. The small size also results in mechanically weak fibers that fail under very low stresses. However, when integrated into scaffolds the mechanical properties can be on par with solid bulk materials.

Fabrication-Dependent Properties of Nanofiber Biomaterials

While these nanofibers share many similar characteristics, there are structural differences that depend on the fabrication conditions and polymers used; For example, self-assembled peptide nanofibers are unique in that the hydrophobic interactions, electrostatic interactions, and hydrogen bonding drive the assembly of the amphiphilic peptides. The overarching structure of self-assembled peptide nanofibers is predominantly β -sheet, with similar structure to silk fibroin from silkworms or spiders with similar nanostructures to Matrigel [27.42]; however, there are some cases in which self-assembled peptide nanofibers are used to model collagen or keratin. In this case, the nanofibers have mostly α -helix structural character [27.41]. When formed into scaffolds, self-assembled peptide nanofibers have extremely high water content, above 99.5%, which is favorable for some tissue engineering applications. Ultimately, the most important determinants of the final structure of self-assembled peptide nanofibers are their specific amino acid sequence and the environmental conditions.

Directed self-assembly, in the form of surface-initiated assembly, is capable of producing protein nanofiber matrices in a variety of planar geometries. The scope of the geometries possible is limited by the soft lithography techniques used to pattern the PDMS substrates involved in the fabrication of the nanofibers [27.39].

Electrospinning enables the formation of nanofibers using either synthetic materials such as PLGA [27.55] and PCL [27.56] or natural ones such as collagen [27.57] and chitosan [27.58]. Altering the structure of scaffolds to include multiple types of nanofibers enables one to capitalize on the favorable qualities of each type of nanofiber. This is illustrated in the case of using electrospun scaffolds consisting of PANI and gelatin nanofibers [27.19]. PANI nanofibers are electrically conducting, whereas gelatin nanofibers provide biocompatibility and promote cell adhesion. Together,

Fig. 27.11a,b Using electrospinning methods to create matrices of randomly oriented (a) or highly aligned nanofibers (b). Scale bar is 10 μm (after [27.53])

they create a tissue-engineered scaffold capable of providing electrical stimulation to promote the desired cell response. In addition to forming random, porous networks of nanofibers, it is also possible to control the orientation of these fibrous matrices to promote a favorable cell response (Fig. 27.11). Although there is limited control over the exact size of the nanofibers and the uniformity of the pores, in both size and shape, electrospinning allows users to finely tune the composition and the general orientation of the nanofiber scaffolds.

Phase separation techniques have been used to create nanofibrous scaffolds that are extremely porous, in excess of 98%. From a physical standpoint, scaffolds containing such high percent porosity resemble more a nanofibrous foam than a scaffold [27.30]. This is evidenced by comparing the structure of scaffolds using phase separation (Fig. 27.12) with scaffolds fabricated from electrospinning (Figs. 27.10, 27.11). Similar to the previous methods, the structure and morphology of these scaffolds are dependent on the fabrication conditions such as the solvent used, type of polymer, and the polymer concentration. Phase separation methods easily enable the formation of complex three-dimensional scaffolds. Phase separation is a mold-based process; therefore, fabrication of the appropriate mold is the only

Fig. 27.12 Scanning electron micrographs of a PLLA fibrous matrix formed through phase separation methods (after [27.54])

limitation to the architecture of scaffolds formed using this method [27.54].

All of these methods are used to create nanofibers or nanofibrous networks/scaffolds that try to mimic the structural properties of the natural extracellular environment to promote cell adhesion, proliferation, and differentiation into desired tissues. However, obtaining the appropriate cell response is more complicated than simply recapitulating the diameter of fibers in the native ECM. There needs to be a distinct balance between the structural, mechanical, and biological properties of nanofiber matrices.

27.2.2 Mechanical Properties

Cells can sense and respond to their mechanical environment, affecting tissue form and function, which makes the mechanical properties of an engineered scaffold extremely important. The mechanical properties of nanofibers vary greatly depending on the starting polymers and the fabrication method used. Further, the mechanical properties of nanofiber scaffolds at the macroscale depend on the diameter, porosity, and physical arrangement of the fibers. The strength of a nanofiber scaffolds needs to be sufficient to withstand handling of the scaffold for transplantation purposes as well as to support the ingrowth of cells and tissue. It is also important to match the mechanical properties of the surrounding tissue to minimize mechanical mismatch and maximize host integration.

The mechanical properties of self-assembled peptide nanofibers are dependent on the hydrophobic interactions that occur between the peptide residues present at the core of the nanofiber. This makes the specific peptide sequence a primary factor in determining the resulting mechanical properties [27.40]. More efficient nanofiber formation and better mechanical properties result when more hydrophobic residues are present in the peptide sequence [27.40]. The mechanical properties of the macroscale scaffolds are determined by the interfiber interactions and the mechanical properties of the individual self-assembled nanofibers [27.51]. Although the peptide sequence can be controlled, it is difficult to control the pore size and shape inside of the macroscale scaffolds formed through self-assembly. This results in poor direct control of mechanical properties [27.43]. It is also difficult to predict the mechanical properties of the resulting scaffolds, because there is not a direct correlation between the starting concentration of peptide and the resulting mechanical properties, as there usually is with polymeric materials [27.51]. Due

to the aqueous formation of the nanofibers and high water content of the scaffolds, both have an inherent lack of mechanical strength and cannot be used in structural tissues [27.43].

Electrospinning is a method capable of producing nanofiber scaffolds with a wide range of mechanical properties. This makes it an attractive fabrication method for a wide variety of tissue engineering applications. One way of controlling the mechanical properties, specifically the tensile strength, is use of appropriate starting materials; For example, electrospun nanofiber poly(3-hydroxybutyrate-co-3-hydroxyvalerate) matrices were found to have a Young's modulus of about 350 MPa [27.59], whereas PLGA and chitosan nanofibrous matrices were observed to have a Young's modulus of 2.5 and 40 MPa, respectively [27.60]. Controlling the alignment of the nanofibers within the scaffold is another method to optimize the mechanical properties. In the case of composite nanofiber scaffolds consisting of chitosan and PCL nanofibers, the tensile strength in scaffolds with randomly oriented fibers was 3.53 MPa whereas it was 13.21 MPa when the fibers were uniaxially aligned [27.61].

There are similar variables controlling the mechanical properties of nanofibers formed by phase separation. Like electrospinning, the orientation of the fibers is critical to the overall mechanical properties of the scaffold; For example, it was found that the compressive modulus is about 3 times higher if the load is parallel to the fibers (≈ 9.5 MPa) than if the load is acting on randomly oriented fibers (≈ 3 MPa) [27.43]. The polymers used and also the starting concentrations of the polymers have large effects on the mechanical properties; For example, for nanofiber PLLA scaffolds, if the starting polymer concentration is less than 1%, the Young's modulus is ≈ 1 kPa, whereas when the PLLA concentration is around 10%, the Young's modulus is ≈ 20 MPa. A similar trend was observed for the tensile strength, which is likely due to the increase in the fiber network density [27.30]. Phase separation techniques can therefore allow the creation of nanofibrous constructs with tunable mechanical properties.

27.2.3 Electrical Properties

The electrical properties of scaffolds are important in nerve and muscle tissue engineering, where propagation of an action potential is integral to the function of the tissue or organ. For nanofiber biomaterials, the materials used must be conductive and the processing of the material must preserve this conductivity or enhance

it. Nanofibers may be composed of either a conducting polymer with a conjugated backbone and/or doped with conductive nanoparticles such as gold or carbon nanotubes. The diameter of nanofibers means that the resistance of a single fiber may be high, but scaffolds can contain large numbers of fibers, which can mitigate this problem. In typical biological applications, the range of voltages will span from > 10 mV to < 10 V.

Electroactive polymers such as polyacetylene, polypyrrole (PPY), polythiophene, and PANI, first developed for applications in applied physics and chemistry, are now widely investigated for tissue engineering. These polymers are often used in conjunction with another more biocompatible polymer to ensure good cell viability and function. Additionally, conductive nanostructured materials such as carbon nanotubes are used as additives to enhance the conductivity of both electroactive and nonconductive polymers; For example, Stout et al. added carbon nanofibers to electrospun PLGA meshes which showed good compatibility and raised the conductivity from 0 S/m for 100% PLGA to ≈ 0.001 S/m after adding 50% carbon nanofibers [27.63]. Conductive and nonconductive polymers can also be combined, as shown by Lee et al. in their study on PPY-coated PLGA nanofibers. It was found that the surface resistance was dependent on the fiber orientation, decreasing from $1.7 \pm 0.6 \times 10^4 \Omega/\square$ for randomly aligned nanofibers to $17.4 \pm 3.2 \times 10^3 \Omega/\square$ along the length of uniaxially aligned nanofibers [27.64].

27.2.4 Chemical Properties

The chemical and biochemical properties of nanofiber biomaterials are dependent on the natural and synthetic polymers and the fiber fabrication method used. Because of the high surface area to volume ratio, the surface chemistry of the nanofiber dominates the chemical properties. To work in a biological environment, the material chemistry must not be cytotoxic or mutagenic or otherwise damage cells. All the polymeric biomaterials discussed in this article fall into this category.

Nanofiber biomaterials interact with cells, but it is actually the surface interaction with biomolecules that are of utmost importance. Proteins and other biomolecules attach to the surface via nonspecific interactions (e.g., hydrophobic, hydrophilic, ionic, hydrogen bonding) or specific interactions (e.g., receptor-ligand bonding, covalent bonding). Controlling the first biomolecules that attach to a nanofiber surface is a key factor in controlling the subsequent attachment of other

biomolecules and cells. There are a number of ways to do this by controlling the chemistry of the polymers used, applying surface treatments to the nanofibers, and/or incorporating biomolecules into the nanofibers.

Biomolecules such as proteins, DNA, viruses, and small molecules (such as pharmaceuticals) have been incorporated into or used to modify the surface of nanofibers by a number of techniques (Fig. 27.13). Direct incorporation has been achieved by solution blending during electrospinning and core-shell electrospinning techniques. Surface modification has been achieved through adsorption or covalent attachment using solu-

Fig. 27.13a–d Fabrication techniques for bioactive electrospun scaffolds. (a) Physical adsorption, (b) blend electrospinning, (c) coaxial electrospinning, (d) covalent immobilization (after [27.62])

tion deposition methods and plasma treatment [27.23, 62]. A common approach is the attachment of ECM proteins such as collagen, fibronectin or laminin to the surface of synthetic polymer nanofibers to enhance cell attachment. However, nanofibers composed of biopolymers, such as collagen, have intrinsic bioactivity and can bind cells directly or can be further modified. The chemical properties of the polymers used and the desired, final surface biochemistry will dictate the processing and any chemical modifications that need to be made.

The biochemical properties of self-assembling peptide nanofibers are dependent on the molecular structure of the polypeptides. This includes the amino acid sequence, the stereochemistry of the amino acids, and the molecular size of the polypeptide [27.41]. Further, the environmental conditions to which the nanofibers are exposed are important because they influence how the polypeptides interact with each other. Because of the protein content, these nanofibers are typically hydrophilic with specific hydrophobic amino acid residues that can associate in aqueous environments. Thus, self-assembled peptide nanofibers are extremely stable in water and typically remain stable at high temperatures, across a wide pH range and in high concentrations of urea and guanidine hydrochloride [27.40].

Many synthetic polymer nanofibers are hydrophobic and need to be modified in order to control protein attachment and/or increase hydrophilicity; For exam-

ple, PCL nanofibers electrospun into a mat are very hydrophobic. Li et al. developed PCL–silk fibroin (SF) core–sheath nanofibers and found that increasing the ratio of silk fibroin to PCL increased hydrophilicity (as seen in Fig. 27.14) [27.65]. Pure PCL nanofibers have a very high water contact angle, whereas the PCL/SF 5:5 nanofibers have a much lower contact angle, yet the nanofibers are still hydrophobic relative to most materials. For comparison, the water contact angle of electrospun chitosan-graft-PCL/PCL nanofibers (CS-PCL/PCL) with as little as 20% CS-PCL decreases to $\approx 0^\circ$, completely wetting the material [27.66]. Other polymers such as pure PLLA have contact angles ($\approx 73^\circ$) in between that of PCL and self-assembling peptide nanofibers [27.67]. Blending PLLA with poly(aniline-*co*-3-aminobenzoic acid), increases the water contact angle as the ratio of PLLA decreases [27.67]. These experiments demonstrate that the surface chemistry of the nanofibers can be modified by combining synthetic polymers with natural biopolymers.

The chemical properties of nanofiber biomaterials are also dependent on the environment in which they are used; For example, *p*-carboxyphenoxy propane/sebacic acid nanofibers incubated at 37°C in phosphate-buffered saline caused a drop in the pH of the solution from ≈ 7.4 to ≈ 6.7 [27.68]. This indicates that degradation of the nanofibers resulted in increased acid concentration of the solution, but also a possible decrease in the acid concentration at the nanofiber surface. Thus, the chemical composition and surface properties of nanofiber biomaterials may be environment dependent and change dynamically over time.

27.2.5 Biological Properties and Cell Response

The biological properties and cell response to nanofibers and nanofiber scaffolds is a primary issue for tissue engineering applications. The biological properties are closely related to the chemical properties, as many of the proteins and other biomolecules on the surface of nanofibers have specific biological functionality. An optimal scaffold should promote cell migration into the scaffold, cell adhesion to the nanofibers, and cell proliferation. Both synthetic and natural polymer nanofibers are considered biocompatible and used for tissue engineering applications. In this context, biocompatible means that the materials are not cytotoxic or mutagenic, nor are there any other abnormal metabolic responses; For example, synthetic nanofibers fabricated

from PLLA [27.69], PGA [27.70], PLGA [27.71], and PCL [27.56] and natural nanofibers fabricated from gelatin [27.72], silk [27.73], and collagen [27.57] have been widely used. Researchers have also coated synthetic nanofibers with ECM proteins such as fibronectin, laminin, and collagens, which contain many cell binding sites [27.74]. Also common is attaching short polypeptide fragments that contain the RGD amino acid sequence or other cell binding moieties.

Cell Response

The cell response to nanofiber scaffolds depends on multiple factors, including the mechanics, physical dimensions, and chemistry. A desirable response is typified by cell adhesion, proliferation, and the formation of a functional tissue. A representative example is shown in Fig. 27.15, where mesenchymal stem cells (MSCs) were seeded onto PCL electrospun scaffolds in vitro [27.56]. In this case, the PCL nanofiber scaffold is isotropic with a pore size that limits cell infiltration. Upon seeding, cells adhere to the nanofibers and begin to spread and proliferate (Fig. 27.15b). As the cells grow they modify their environment, which in the case

of MSCs is secretion and assembly of collagen fibrils on top of the nanofibers (Fig. 27.15c). After extended culture, the cells have formed a continuous monolayer and continued to modify their environment with collagen fibrils and mineral calcifications (Fig. 27.15d,e). This illustrates a couple of points: (i) cells will remain on the surface of nanofiber scaffolds unless the pore size is large enough to enable cell infiltration, and (ii) cells modify their environment when seeded onto scaffolds by secreting and assembling ECM of their own. The choice of nanofiber materials and scaffold architecture are always tailored to the cell type involved and the desired cellular response.

Changing the properties of the nanofibers can change the cell response. In contrast to PCL and many similar hydrophobic synthetic polymers, scaffolds formed from self-assembled peptide nanofibers have an extremely high water content (usually above 99.5%) which allows cells to migrate easily throughout the scaffold [27.40]; For example, chondrocytes cultured on these nanofibers retain their shape and produce collagen type II, which does not usually occur in vitro as chondrocytes dedifferentiate into fibroblasts [27.40].

Fig. 27.15a–e SEM micrographs of MSCs seeded on electrospun PCL scaffolds. **(a)** Scaffold prior to seeding. The scaffold has a three-dimensional, interconnected pore structure and consists of randomly oriented fibers. The average fiber diameter is 400 nm (± 200 nm). The standard deviation is denoted in parentheses. Occasional outliers with diameters of up to 5 μ m are sometimes observed. The fibers have irregular surfaces. **(b)** Low-magnification view of the cell–polymer constructs after 1 week of culture. The surface is partially covered with multilayers of cells. **(c)** High-magnification view of the cell–polymer constructs after 1 week of culture. Osteoblast-like cells are present, and globular accretions together with collagen bundles are also observed. **(d)** Low-magnification view of the cell–polymer constructs after 4 weeks of culture. The surface is completely covered with cell multilayers. **(e)** High-magnification view of the cell–polymer constructs after 4 weeks of culture. The globular accretions have increased in size. Abundant calcification and collagen bundles are also seen (after [27.56])

The integration of bioactive motifs can further enhance cell attachment and migration [27.40].

Immune Response

The biological response occurs at the cell/material level, but this is important beyond just the cells seeded on the scaffold. For scaffolds implanted *in vivo*, the immune response is critically important and will dictate in part overall success/failure. Traditionally, implanted materials have undergone a foreign-body response where the body seeks to wall off the implant. This is characterized by inflammation and fibrosis, and needs to be avoided because it impedes tissue growth and regeneration. This has resulted in materials designed to prevent a foreign-body response and to be *invisible* to the body. One problem with nanofiber and nanostructured materials is that their interaction with cells is still being studied; it remains unclear how the many types of

nanoscale materials enter cells and what their effect is once inside. Recently, it has become clear that there are different types of immune response, and that materials can modulate the immune response and actually improve regeneration, as illustrated in Fig. 27.16 [27.75]; For example, materials can be functionalized with or designed to release growth factors or cytokines to reduce or enhance inflammation and the behavior of dendritic cells. Using this process, it is possible to switch macrophages from an M1 phenotype, which is associated with phagocytic behavior and destruction of tissue-engineered scaffolds, to an M2 phenotype, which is associated with normal wound healing and tissue repair. The full complexity of the immune response to nanofiber biomaterials and scaffolds is beyond the scope of this chapter, and readers are encouraged to search the current literature for the latest developments. However, at a basic level, it should be understood that

Fig. 27.16a,b Potential of materials to control the immune response. **(a)** Materials can promote tolerance to specific antigens and cells by directly signaling antigen-presenting cells (APCs), such as dendritic cells (DCs), or by releasing growth factors or cytokines that promote tolerance. After antigen internalization, DCs can activate effector cells, such as T and B cells, to promote tolerant responses to the associated antigen. This approach could potentially be used to promote the survival of transplanted cells. *Abbreviation: PRR*, pattern recognition receptor. **(b)** Alternatively, materials might promote a destructive immune response by directly providing immunity-promoting signals or by releasing soluble factors. Activated APCs can then induce destructive immune responses, for example, through B cells secreting antibodies specific for the antigen, which subsequently lead to the antigen's targeting and removal. This approach could be used to combat infectious diseases and cancer (TGF- β : transforming growth factor; IL: interleukin; TNF- α : tumor necrosis factor) (after [27.75])

in vitro assays that evaluate the biological response to nanofiber biomaterials may not be predictive of the biological response in vivo in the presence of the immune system.

Biodegradation

The biodegradative properties of a scaffold are extremely important in tissue engineering. Typically, the nanofiber scaffold is meant to be a temporary construct, with the goal for the tissue to regenerate and the scaffold to disappear. For this to occur, the scaffold needs to biodegrade into nonharmful products that can be metabolized or cleared by the body. Additionally, the degradation of the scaffold must be chosen carefully to match the rate of new tissue formation to avoid a mechanical property mismatch or large void formation [27.23]. Biodegradation is highly dependent on the polymer or protein of which the nanofibers are composed, as the molecular weight and concentration of polymer [27.23]. The size of nanofibers complicates this because the large surface area results in rapid degradation for surface-based processes such as hydrolysis. The degradation can be tuned by changing the poly-

mer chemistry or by changing the ratio of the polymers in blended or core-shell nanofibers; For example, it was found that 70 : 30 PCL/gelatin nanofibers degrade more slowly than 50 : 50 fibers, and were therefore better for nerve regeneration applications where a slow degradation rate is desired [27.23]. In another study, pure PCL nanofibers exhibited no noticeable weight loss after 17 days, whereas the PCL/collagen composite nanofibers lost 20% of their weight in the 17-day period [27.76]. Meng et al. showed the impact of surface area on degradation, as bulk PCL degraded slower than electrospun PCL nanofibers. Incorporation of multi-walled carbon nanotubes in the nanofibers increased the degradation rate, showing that nonpolymer additives can also be used to tune degradation [27.77]. Changing the percent composition of blended polymer nanofibers can also change the degradation from surface to bulk erosion. For self-assembled peptide nanofibers, the degradation products are amino acids that can be reused by the body, and enzymatically cleavable peptides can be incorporated. Typically, the scaffolds cause minimal immune response and there is limited inflammatory reaction [27.42].

27.3 Characterization of Nanofiber Biomaterials

27.3.1 Optical Characterization

Optical Microscopy

Bright-field optical microscopy is a standard imaging technique, but is not effective for viewing most types of nanofibers because the submicrometer dimensions limit optical contrast. Thus, nanofibers need an optical contrast-enhancement technique in order to be visualized, typically either phase contrast or differential interference contrast (DIC) microscopy. Both techniques are able to image nanofibers and are based on modulation of phase or polarization of light to render contrast. These techniques enhance the edges of specimens being observed due to small difference in optical properties associated with cell membranes, organelles, and nanofibers. The contrast created makes observation of otherwise transparent specimens possible. It can also reveal very thin constructs such as nanofibers (Fig. 27.17a) [27.39, 78]. However, when the nanofiber dimensions are below the resolving power of the microscope objective, it is not possible to make accurate measurements, such as nanofiber diameter.

Fluorescence microscopy enables the characterization of nanofibers when conjugated with a wide variety

of fluorophores. This is particularly useful when investigating the interaction between nanofibers and cells, as the nanofibers and many of the intracellular components can be fluorescently labeled (Fig. 27.17b). Fluorophores have traditionally been small molecules such as fluorescein isothiocyanate (FITC) and its derivatives, directly conjugated to the biomolecule of interest or conjugated to an antibody that targets the biomolecule of interest. However, more recently fluorophores have been genetically encoded, such as green fluorescent protein (GFP) and its derivatives, to create transgenes for the proteins of interest. This has enabled imaging of cells without application of chemical stains and enabled advances in imaging of live cells. Quantum dots are also another option for fluorophores, with the advantage of not photobleaching under typical imaging conditions. In the fluorescence technique, the fluorophore is illuminated with excitation light at a specific wavelength that causes emission of light at a longer wavelength (lower energy). When using samples with multiple fluorophores, it is necessary to prevent spectral bleed-through, which is the measurement of the emission spectrum of one fluorophore in the emission spectrum of another. This can be largely overcome through the

Fig. 27.17a–c Examples of nanofibers imaged using different types of optical microscopy. **(a)** Phase contrast image of collagen type IV nanofibers (scale bar is 40 μm). **(b)** Fluorescent image of a nanofabric consisting of fibronectin nanofibers labeled with antibodies conjugated to a green fluorescent dye and laminin nanofibers labeled with antibodies conjugated to a red fluorescent protein (scale bar is 100 μm). **(c)** 3-D image of collagen type I nanofibers conjugated with FITC green fluorescent dye and suspended in saline solution. Image was captured using a laser scanning confocal microscope and reconstructed in 3-D using image processing software. Panels **(a)** and **(c)** (after [27.39])

use of proper filtering of light such that a specific range of wavelengths are passed through to the imaging device [27.79]. Alternatively, a spectral image that records the emission intensity as a function of wavelength, followed by spectral unmixing, can be used to identify multiple fluorophores that have distinct emission wavelength maxima.

A number of advanced fluorescent imaging techniques have been developed to remove out-of-plane light and enhance the signal-to-noise ratio. Confocal microscopy eliminates out-of-focus light emitted from the sample by using a pinhole aperture placed in front of the detector (photomultiplier tube or digital camera). Only light from the focal plane of the sample is able to pass through the pinhole, which provides enhanced resolution. The confocal microscope captures a thin optical slice of the sample, enabling a 3-D image of the sample to be digitally reconstructed by imaging xy slices of the sample through subsequent z -axis focal planes (Fig. 27.17c) [27.80, 81]. Multiphoton microscopy is another technique that eliminates out-of-focus light, but instead of an aperture to block light, only a small volume at the focal plane of the objective is illuminated. An infrared laser with twice the wavelength (half the energy) of the excitation wavelength of a fluorophore is focused into a small volume using a high-numerical-aperture objective. This enables two lower-energy photons to simultaneously excite a higher energy state in the fluorophore. The result is an image similar to confocal microscopy, but with the advantage of being able to image deep into a tissue (up to ≈ 1 mm). Both confocal and multiphoton microscopy are widely used for imaging nanofibers and the interaction with cells in 3-D, but other new techniques are becoming available that can image nanofibers as well. Optical microscopy has traditionally been limited to res-

olutions of approximately one-half the wavelength of light (≈ 225 nm). However, a new generation of techniques are able to image at resolutions of ≈ 100 nm using structured illumination microscopy (SIM) and ≈ 25 nm using stochastic optical reconstruction microscopy (STORM).

Optical Spectroscopy

Optical spectroscopy techniques are able to provide information on the chemical composition of nanofiber biomaterials. Chemical bonds interact with light at specific frequencies, which can be used to identify the types and relative number of these bonds in a material. Raman spectroscopy, based on the inelastic scattering of photons, provides a molecular fingerprint of the chemical bonds in the nanofibers of interest. Raman scattering has been frequently used for characterization of carbon nanofibers and carbon nanotubes through monitoring of carbon's intrinsic D and G peaks in the Raman spectra [27.82]. Raman spectroscopy has also been applied to biological material, such as studying the unfolding of proteins [27.83]. Raman scattering methods could potentially be used in conjunction with protein nanofibers to observe processes such as fibrillogenesis or binding to a specific motif within a nanofiber. Fourier-transform infrared spectroscopy (FTIR) is used to identify the presence of specific chemical groups in a sample based on the energy absorption of the chemical bonds. FTIR quantifies the absorption of a wide range of IR wavelengths by the sample. The spectrum shows known patterns associated with specific chemical groups; For example, *Nirmala et al.* used FTIR to identify hydroxyl and phosphates groups in electrospun polyurethane nanofibers containing CaCl_2 at different concentration, before and after treatment with a simulated body fluid solution (Fig. 27.18) [27.84].

27.3.2 Electron Microscopy

Scanning Electron Microscopy (SEM)

SEM is frequently used to investigate the morphology and structure of nanofibers. **SEM** is capable of producing detailed images of nanofibers with a maximum resolution of ≈ 1 nm under ideal imaging condition. Images are formed by accelerating an electron beam onto the sample, which causes lower-energy secondary electrons to be emitted and detected. **SEM** is a useful technique to determine the diameter of nanofibers [27.73, 74, 85], nanofiber alignment, as well as cell–fiber interactions [27.73]. Traditionally, **SEM** required that the specimen be electrically conductive, so most nanofibers, either polymer or protein based, had to be coated with a conducting material such as gold, palladium or platinum. However, environmental **SEMs** now enable many nanofiber samples to be imaged without coating and in a hydrated state, better preserving the structure. In addition to imaging the surface, many **SEMs** are equipped with energy-dispersive x-ray spectroscopy (**EDS**) to identify the chemical composition of the material. This chapter includes multiple examples of **SEM** images used to characterize a wide range of nanofiber biomaterials, nanofiber scaffolds, and cell interactions with nanofibers (Figs. 27.3, 27.5, 27.6, 27.11, 27.12, 27.15, 27.20, 27.29, 27.32, and 27.33).

Transmission Electron Microscopy (TEM)

TEM is another powerful method that provides structural analysis with resolution < 1 nm. Unlike **SEM**, **TEM** detects electrons from an electron beam after they have passed through the sample. While **TEM** is limited to producing 2-D images, **TEM** images can yield structural information based on image contrast generated from differences in electron density, which is

Fig. 27.19a,b **TEM** image of an individual collagen–PCL composite nanofiber with collagen as the shell material and PCL as the support (a). (b) **TEM** image of a pure PCL nanofiber (after [27.56])

Fig. 27.18 FTIR spectra of different electrospun polyurethane nanofibers (after [27.84])

particularly useful when synthesizing nanofibers of different components. Regions of nanofibers that contain heavier atoms or are thicker tend to scatter electrons more than regions with lighter atoms and/or thinner regions [27.86]. Recent research has investigated the effects of coating synthetic nanofibers with natural bioactive agents to enhance cell–fiber interactions. Effective coating is most easily characterized using **TEM** because the different layers have different contrasts in the **TEM** image. This is illustrated in Fig. 27.19, where the authors coated PCL nanofibers with collagen [27.56]. **TEM** is also the best technique for looking at high-resolution interactions between cell membranes and nanofibers; For example, with **TEM** it is possible image the contact between cell membranes and nanofibers, and also to image nanofibers inside cells to determine subcellular localization.

27.3.3 Atomic Force Microscopy (AFM)

AFM is a scanning probe technique used to determine the topography of a surface and as well as analyze its mechanical and adhesive properties. This is achieved using a physical probe that is brought into contact with the sample during imaging. A unique capability of **AFM** is that it can be operated in ambient conditions as well as under water, including in solutions that simulate physiologic conditions. In topographical analysis, **AFM** images can be used to determine whether a nanofiber

Fig. 27.20a–f Scanning electron micrographs of (a) PA with CaCl_2 gel, (b) PA with HCl gel (scale bars 1 μm). Transmission electron micrographs of (c) PA with CaCl_2 gel, (d) PA with HCl gel. AFM topography micrographs of (e) PA with CaCl_2 gel, (f) PA with HCl gel (after [27.51])

sample has globular or fibrillar structure as well as give information on the fiber diameter, length, and cross-section [27.40, 41, 87]. This can be used to evaluate the size of single nanofibers and to determine how many layers of nanofibers are present in a scaffold [27.40]. AFM can obtain detailed information about nanofibers that may not be visible using SEM (Fig. 27.20). When analyzed by SEM, two different gels formed from self-assembled peptide amphiphile nanofibers (one formed with CaCl_2 and the other with HCl) exhibited similar characteristics [27.87]. AFM images revealed that gels formed with CaCl_2 were composed of longer fibers whereas gels formed with HCl were made of shorter, more bundled fibers [27.51].

The unique environmental capability of AFM enables it to image dynamic nanofiber processes; For

example, AFM is often used to monitor self-assembling peptide nanofiber formation, organization of those nanofibers into a scaffold, and refolding of β -sheet structure after sonication [27.40, 41]. As seen in Fig. 27.21b, after 3 min a solution of LKL16 peptide contained only globular species with a height of approximately 0.8 nm, indicating that the peptide was in the monomer state [27.41]. After incubation for 24 h, the presence of nanofibers can clearly be seen in the AFM image. Similarly, AFM images of RADA16 nanofibers over time show the progression of fiber/scaffold reassembly after sonication [27.40]. AFM topographic images of the self-assembling peptide nanofibers formed from the L- and D-LKL16 peptide clearly show the difference between the left-handed and right-handed twists formed during the self-assembly process (Figure 27.21a) [27.41].

An important AFM capability for tissue engineering applications is the measurement of force between the AFM tip and the nanofibers. Mechanical properties can be determined from the force versus cantilever deflection curve obtained when indenting the nanofibers. Details of this analysis are discussed in Sect. 27.3.4. Adhesive properties can be determined from the force versus cantilever deflection curve obtained when retracting the AFM tip from the nanofiber surface. The dynamics of adhesion can be determined with repeated indentation and retractions at various rates, and when the AFM tip has been functionalized with a ligand, the dynamics of specific binding interactions [27.88].

27.3.4 Mechanical Characterization

Nanofibers are mechanically characterized either as single fibers or as a collection of fibers organized into micro- to macroscale structures. For most applications, the properties of interest for macroscale structures are the tensile stress and strain, i.e., the stiffness, which can be determined using ASTM protocols for tensile testing. Characterizing the mechanical properties of single nanofibers is more challenging and requires the use of more advanced techniques. Further, in macroscale measurements the interactions between nanofibers (e.g., entanglement, adhesion, slippage, and abrasion) can greatly affect the measured mechanical properties. Here we focus on methods specific to nanofiber mechanical characterization at the nano- and microscales.

AFM nanoindentation is used to characterize the mechanical properties of individual nanofibers and nanofiber films, where the interfiber bonding has less of an effect than in macroscale measurements and the

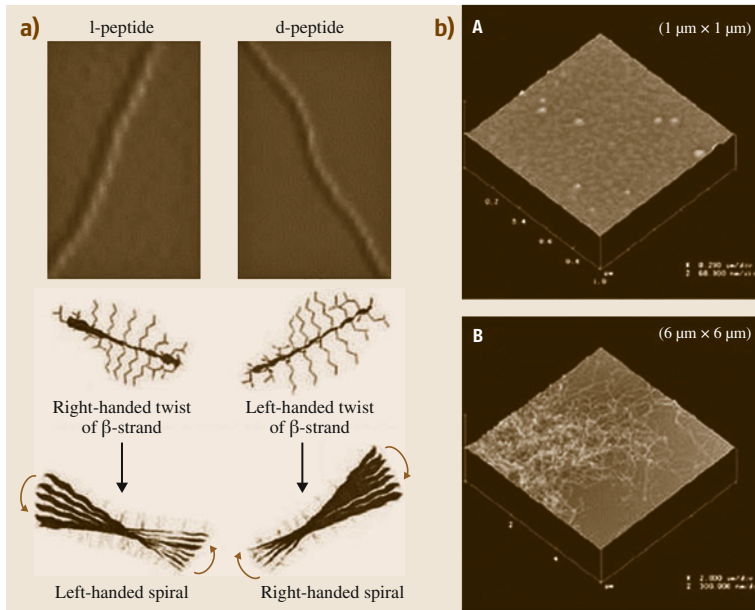

Fig. 27.21 (a) Amplitude AFM images of LKL16-nanofiber, LKL16-(D)-nanofiber and their plausible models. (b) Tapping-mode AFM images of LKL16 obtained after incubation for (A) 3 min and (B) 24 h at pH 9.2 [LKL16] = 40 μm ; z-scales (A) 60 nm, (B) 300 nm (after [27.41])

slippage of fibers is minimal. AFM is one of the best options for measuring the mechanical properties of soft nanofibers and their scaffolds (Fig. 27.22) [27.51, 89]. There are still many factors to consider in the evaluation of nanoindentation data on nanofibers such as:

1. The effect of the underlying substrate
2. The use of ambiguous tip shape and cantilever spring constant

Fig. 27.22 In an indentation measurement on films of nanofibers, interfiber forces are mostly normal to the fiber surface and interfiber cross-linking has less effect on apparent material stiffness (after [27.51])

3. Fiber surface roughness
4. Curvature of the fiber surface
5. Nonperpendicular loading
6. The adhesion force.

However, the effect of some of these factors can be limited; For example, the error can be reduced by choosing large enough nanofibers for analysis so that the effect of the underlying substrate can be limited and by calculating the spring constant and shape of the individual AFM tip [27.89].

Tensile testing is standard for macroscale samples, but is one of the most difficult mechanical tests to perform on single nanofibers due to the difficulty involved in trying to grip and pull a nanofiber. Typically, custom-designed systems are used to properly hold nanofibers and a highly sensitive force sensor and micropositioner are used to measure the stress versus strain; For example, to perform tensile tests single poly(ethylene oxide) (PEO) nanofibers were suspended across a wooden frame with an open center. One end of the frame was connected to a moveable optical stage and the other to a piezoresistive AFM cantilever (Fig. 27.23) [27.89]. The deflection of the cantilever was recorded as the stage was moved, and the Young's modulus was calculated to be approximately 45 MPa. Another tensile testing approach uses the AFM nanoindentation system in a different manner. In this case a nanofiber is attached to the nanoindenter tip and also to the substrate; it is then

Fig. 27.23 Schematic representation of the tensile test of a nanofiber using a piezoresistive AFM tip (after [27.89])

stretched using the stepper motor of the AFM, and the force applied and the fiber elongation can be measured.

The AFM is also the best device to perform bending tests on nanofibers because of its ability to apply small forces and measure small deformations; For example, nanofibers are suspended across ridges and grooves on

a surface [27.91]. The AFM cantilever is then used to stretch the fiber laterally by putting it next to the fiber and pulling it along the groove [27.91]. This technique determined that the three-point bend strength of collagen type I fibers is approximately 2.8 GPa and the strain is 12%.

Micropipettes have traditionally been used to characterize the mechanical properties of soft biological materials and can be adapted to characterize nanofibers. Glass microneedle-based mechanical characterization is similar to AFM in that bending of a calibrated cantilever is used to apply force (Fig. 27.24e). However, for the microneedles, the force applied to the nanofibers is measured by the deflection of an optical fiber, which can be quantified by the deviation of light transmitted through the optical fiber onto a photodetector [27.90, 92]. Force can also be applied through biomembrane force probe techniques (Fig. 27.24f). Essentially, nano-

Fig. 27.24a–f Schematics of several micromanipulation techniques used to measure the pN to nN forces needed to strain nanofibers. While DNA is used in these examples, nanofibers could also be manipulated using these methods. (a) Optical tweezers, (b) magnetic tweezers, (c) magnetic tweezers with an electromagnet configuration, (d) AFM, (e) glass microneedle, and (f) biomembrane force probe; all represent techniques to characterize single nanofibers (after [27.90])

fibers of interest are bound to lipid vesicles. The force on the nanofiber is the result of moving a bead attached to the other end of the fiber and can be quantified by determining the movement of that bead and the stiffness of the membrane, which can be controlled through the pressure in the suction pipette attached to the vesicle [27.93].

Another method for determining the mechanical properties of nanofibers is based on optical and magnetic tweezers. Optical tweezers (Fig. 27.24a) (i.e., optical trapping) enables the measurement of forces applied on particles trapped within a laser beam. This

technique is sensitive to the measurement of forces of the order of pN and nN. Particles ranging in size from tens of nanometers up to several micrometers in diameter can be trapped and manipulated [27.94]. Nanofibers can be attached to the trapped particles which are used to pull on the nanofibers to create stress versus strain data. Similarly, magnetic tweezers (Fig. 27.24b,c) are able to exert up to nN of force by using magnetic particles instead of optically trapped particles to apply force. The force experienced by the magnetic particle is proportional to the magnetic field gradient and the diameter of the particle [27.95].

27.4 Applications

Nanofiber biomaterials are a growing area of tissue engineering research and are being pursued for application in a wide range of tissues and organ systems. There are many advantages to using nanofibers, and how these are exploited depends largely on the nanofiber materials used, the tissue engineering application, and the desired outcome of the study. Here we focus on representative examples in cardiac, skeletal muscle, ophthalmic, and neural tissue engineering. In addition to these examples, there are multiple review articles that focus on nanofibers used in other applications including orthopedic [27.96–98], cartilage [27.99], and vascular [27.100] tissue engineering.

27.4.1 Cardiac Tissue Engineering

Heart failure remains the number one cause of death in the developed world, and because the heart cannot regenerate, transplantation remains the only viable therapy [27.101]. Scaffolds for cardiac repair need to restore electromechanical function of the heart muscle, which is a unique challenge not found anywhere else in the body. The most challenging criteria are specific to the nature of the myocardium (Fig. 27.25):

- Anisotropic structure
- Mechanical strength and elasticity to resist systemic blood pressure and contraction
- Electrical conductivity
- Dense vascularization.

Advances in nanotechnology and the availability of nanofibers offer new possibilities in cardiac tissue engineering. This section describes how nanofibers can be used to address some of the challenges of cardiac

tissue engineering and what is expected as research progresses.

Heart function relies on the orientation of the cardiomyocytes, which form highly aligned myofibers in the heart wall. Several techniques have been used to create anisotropic nanofiber scaffolds. Electrospinning can be customized to produce aligned fibers by using rotating collectors, such as discs [27.102], mandrels, and drums, or by using several aligned electrodes [27.103]. Orlova et al. described a simple way to collect aligned nanofibers of polymethylglutaramide through a rectangular hole in the collector, which were then used to grow an anisotropic sheet of cardiomyocytes [27.78]. Electrospun PLGA membranes were uniaxially stretched by Zong et al. and showed significant alignment of cardiomyocytes (Fig. 27.26) [27.25]. Rotary jet spinning [27.26] produces naturally aligned gelatin nanofibers that direct the anisotropic organization of cardiac tissue. Nanofiber sheets created by surface-initiated assembly of fibronectin can follow any pattern made from a microfabricated stamp, and thus can be used to engineer cardiac muscle with specific degrees of cell alignment and tissue anisotropy [27.39].

The cardiac mechanical environment is demanding because the heart beats more than two billion times over an average human lifetime. Any construct meant for cardiac tissue engineering will need to withstand mechanical strains of $\approx 20\%$ and millions of contraction–relaxation cycles, which requires fatigue resistance. At the same time, scaffolds must remain extensible and flexible and not hinder the contraction of cardiomyocytes. Natural cardiac ECM composed primarily of collagen type I has anisotropic mechanical properties with Young's modulus of 157 ± 84 kPa parallel and 84 ± 8 kPa perpendicular to the myofibers in

Fig. 27.25a,b Structural and mechanical aspects of cardiac anisotropy. **(a)** A schematic diagram illustrating the gross macroscopic appearance of a four-chamber mammalian heart. **(b)** A full-thickness specimen of adult rat right ventricular myocardium showing preferentially oriented cardiac muscle fibers, fluorescently labeled for F-actin and cell nuclei and imaged from the epicardial surface by confocal microscopy. Collectively, these structural, mechanical, and associated electrical properties comprise the interrelated aspects of cardiac anisotropy (after [27.104]) ►

the left ventricle of the heart [27.104]. PANI-containing gelatin fibers developed by Li et al. [27.19] showed moduli above 500 MPa, while Kai et al. [27.102] created PCL–gelatin composites with anisotropic properties of 5.41 ± 0.61 MPa parallel and 1.15 ± 0.09 MPa perpendicular to the nanofibers, closer to the values of natural cardiac ECM. Cardiac tissue engineering requires consideration of the mechanical properties of the constructs so they effectively mimic in vivo conditions.

The electrical environment of the heart is also demanding because cardiac function requires synchronized beating from the cardiomyocytes, organized in fibers and sheets [27.105]. Action potential propagation in the heart follows cardiomyocytes that are coupled together via gap junctions [27.106]. The electrical properties of a scaffold are critically important because abnormal electrical function can induce arrhythmia and lead to sudden cardiac death. Polyacetylene, polypyr-

role, polythiophene, and PANI belong to a category of electroactive polymers that can enhance electrical stimulation to the tissue in vitro; For example, electrospun PANI–gelatin [27.19], PANI and hyperbranched poly-L-lysine [27.107], and PANI/PCL [27.108] showed good biocompatibility of these electroactive scaffolds with cardiomyocytes. Li et al. also showed that electrospun nanofibers with PANI induced differentiation of mesenchymal stem cells into cardiomyocytes. It has been challenging to engineer aligned cardiac muscle in 3-D, but new techniques have been developed to fabricate nanofiber scaffolds for this application. The self-assembling nanopeptide RADA16 was modified with a cell adhesion sequence (RGDSP) and seeded in vitro with marrow-derived cardiomyocytes. The nanopeptides naturally assemble into a 3-D matrix that improves cell survival in vitro and cardiac function after transplantation, but the structure of the scaffold cannot be easily customized [27.109]. Researchers have also encapsulated an electrospun mesh of PGA within a collagen gel [27.110]. The composite sponges were seeded with cardiac stem cells after freeze-drying and dehydrothermal cross-linking. The constructs exhibited better cell attachment and proliferation, as well as a stronger compression modulus compared with collagen alone. As an alternative to making a bulk scaffold directly, it is also possible to take planar scaffolds produced by electrospinning or surface-initiated assembly and stack them to form thicker 3-D constructs; For example, Ishii et al. seeded rat cardiomyocytes onto electrospun PCL meshes and stacked up to five meshes to form a multilayered construct (Fig. 27.27). These engineered cardiac tissues maintained cell viability and exhibited synchronized beating [27.111].

Cardiac muscle needs to be perfused to support the high metabolic demand of contracting cells, yet it is currently not possible to engineer a microvascular network in tissue-engineered cardiac muscle. To address this, a number of studies have considered the effect of

different nanofibers on the proliferation and function of smooth muscle cells and endothelial cells [27.112,113], which are required for the growth of a vascular network. The presence of endothelial cells in particular is required to improve cardiomyocyte survival and organization [27.114]. Methods to induce angiogenesis in vitro rely on growth factors, chemical cues in the constructs, and other cell–scaffold interactions in order to trigger the formation of endothelial networks. Progress in tissue engineering is dependent on the discovery of new cellular pathways and a better understanding of the angiogenesis process so that these triggers can be included in the design of scaffolds for cardiac regeneration.

27.4.2 Skeletal Muscle Tissue Engineering

Skeletal muscle tissue engineering shares many similarities with cardiac tissue engineering because both are highly vascularized striated muscle. Applications include repair of skeletal muscle loss from traumatic injury, tumor ablation, and other diseases [27.115]. Developing scaffolds that mimic muscle tissue mechanical properties and that support myotube alignment and contraction is a major challenge. The development of nanofiber techniques to fabricate scaffolds structurally and functionally similar to native ECM can potentially meet this need [27.44].

Myoblasts, the precursors of myotubes, can sense microscale and nanoscale topographic features in the extracellular space. A comparative study of myoblasts cultivated on biodegradable PLLA electrospun nanofibers with microgrooved surfaces indicated that both microscale and nanoscale topographic features could cause myoblast alignment and promote myotube assembly, but nanoscale features promoted the assembly of longer myotubes (Fig. 27.28) [27.22]. Further, electrospun collagen type I nanofibers were better than collagen type I sponges in supporting myoblast growth,

Fig. 27.28a,b Myotube alignment and myotube assembly on PLLA nanofibrous scaffold. Low-magnification merged images of skeletal MHC staining on (a) randomly oriented substrates after 7 days and (b) aligned substrates after 7 days showing the global alignment and length of myotubes. Arrows indicate direction of nanofibers. Scale bars are 100 μm (after [27.24])

with the nanofibers able to support aligned myoblasts and maintenance of myogenic phenotype [27.100]. Electrospinning is the most common method used to fabricate nanofibers for skeletal muscle tissue engineering, although other methods are used including self-assembly and phase separation [27.44]. Synthetic and natural polymers that are commonly used include PCL, PLLA, and ECM proteins (Fig. 27.29) [27.22, 24, 100]. Electrospun PCL–collagen nanofiber meshes supported cell adhesion, proliferation, and differentiation. The

unidirectional alignment of the PCL–collagen nanofibers enhanced human skeletal muscle cell (hSKMC) alignment and myotube formation as compared with randomly oriented nanofibers [27.22]. Copper et al. electrospun aligned and randomly oriented polyblend chitosan–PCL nanofiber scaffolds and demonstrated that aligned nanofibers enhance muscle cell differentiation by upregulation of myogenic differentiation-specific genes, such as troponin T and myosin heavy chain [27.116]. The mechanical properties of these PCL blend nanofiber scaffolds were significantly different, with the tensile strength greater for unidirectional than randomly oriented nanofibers (Table 27.2).

27.4.3 Ophthalmic Tissue Engineering

Nanofibers have been used in ophthalmic tissue engineering for repair of the corneal stroma, ocular surface, and retina. The stroma is naturally composed of collagen type I nanofibers, ≈ 30 nm in diameter, which are bundled together into 200–2500 nm-thick sheets called lamellae [27.117, 118]. The collagen type I nanofibers are highly aligned, have a small diameter, and are regularly spaced, all of which allows for optimal cell alignment and corneal transparency [27.119]. When

an injury occurs to the stroma, this ordered structure is disrupted, leading to myofibroblast infiltration and corneal haze [27.120]. Nanofibers are the natural choice for tissue engineering a corneal stroma equivalent due to its inherent nanofiber composition. Aligned, collagen type I nanofibers, ≈ 30 nm in diameter, have been successfully electrospun using a dual plate glass substrate for collection [27.117]. Corneal fibroblasts uniaxially organized on the aligned collagen type I nanofiber scaffolds and expressed less α -smooth muscle actin (α -SMA, a myofibroblast marker) than those cultured on low-density nanofiber scaffolds, tissue culture plastic, and collagen type I gel (Fig. 27.30) [27.117, 121]. These types of constructs are being explored as an alternative to cornea transplantation.

Synthetic corneal prosthetics are clinically available but experience problems with integration into the eye. One approach to solving this problem is to replace the nonporous outer *skirts* of the synthetic corneas with nanofiber meshes that structurally mimic ECM proteins and allow for a larger surface area for cellular integration [27.123]; For example, a plasma-treated PCL nanofiber skirt for a polyvinyl alcohol (PVA) artificial cornea was able to promote limbal stem cell adhesion and proliferation for up to 10 days, indicating that the host cells on the periphery of the epithelium of the cornea could in fact penetrate and integrate [27.123].

Nanofiber biomaterials offer an alternative scaffold option for culturing limbal stem cells (LSCs) and to use as a transplant device to help LSCs survival; For example, copolymer PA 6/12 nanofibers were electrospun into scaffolds that had no significant effect on LSC growth, proliferation, and metabolic activity when compared with tissue culture plastic [27.122]. However, PKH26-labeled LSCs were able to migrate from the nanofiber scaffold onto the damaged ocular surface in an ocular injury mouse model and restore epithelial function (Fig. 27.31) [27.122]. Further, after transplantation, real-time polymerase chain reaction

(RT-PCR) for interleukin-2, interferon- γ , and inducible nitric oxide synthase (inflammatory markers) of the ocular surface indicated that cell-free nanofiber scaffolds were able to reduce the inflammatory response after in-

Fig. 27.31a–d Detection of PKH26-labeled LSCs on the damaged ocular surface after their transfer on a PA 6/12 nanofiber scaffold. (a) Control undamaged eye without labeled cells, (b) from the eye 2 days after operation, (c) 7 days and (d) 14 days after transfer. Red stained cells are still present, and the corneal epithelium is regenerated. Scale bars: 50 μ m (after [27.122])

jury [27.122]. This demonstrates how proper design of nanofiber biomaterials can be used to modulate cell and immune response.

The retina is another ocular tissue where nanofibers have potential applications in the treatment of vision disorders. Retinitis pigmentosa and age-related macular degeneration cause progressive deterioration of the retina and photoreceptors resulting in loss of vision [27.66]. Delivery of retinal progenitor cells (RPCs) is one of the most promising therapies; however, direct injection of RPCs is ineffective due to a high rate of cell death postinjection [27.66]. Nanofiber scaffolds are a possible delivery vehicle for RPCs to increase cell survival; For example, RPCs were cultured on electrospun PCL (100%), chitosan-graft-PCL at 20 and 40% chitosan, and tissue culture polystyrene. RPCs proliferated faster on 20% CS-PCL nanofibers compared with 100% PCL scaffolds and differentiated more readily towards retinal neurons [27.66]. This was confirmed through quantitative PCR for the retinal developmental markers β type III tubulin, map2, recoverin, rhodopsin, and protein kinase C- α . As these scaffolds are further developed, new therapies to treat retinal disease may be possible.

27.4.4 Neural Tissue Engineering

Neural tissue engineering is a research area where nanofiber biomaterials have been widely used to direct or promote differentiation of stem cells into neuronal cells, guide neuron growth and axon extension, and inhibit glial scar formation by astrocytes. Multiple studies have investigated the relationship between fiber diameter and orientation with the proliferation, differentiation, and elongation of neural stem cells and neurons (NSCs); For example, Yang et al. found that the alignment of mouse C17.2 neural stem cells on aligned PLLA nano- and micro-electrospun scaffolds caused cells to extend neurites that were aligned with the nanofibers [27.124].

Neural cell adhesion is a critical step toward nerve regeneration, and physicochemical modification of the surface of nanofibers is often required; For example, Koh et al. successfully modified PLLA nanofibers with laminin using covalent binding, physical adsorption, and blended electrospinning methods, which enhanced neurite extension of PC12 cells [27.125]. Nanofibers have also been modified with growth factors or neurotrophic factors to facilitate nerve regeneration. Horne et al. modified PCL nanofibers with brain-derived neurotrophic factor (BDNF), which promoted NSC proliferation and survival and directed cell fate towards neu-

ronal and oligodendrocyte specification [27.126]. Similarly, PLLA nanofiber scaffolds surface-modified with ECM proteins and basic fibroblast growth factor (bFGF) significantly induced neurite outgrowth compared with unmodified nanofibers [27.53]. The laminin-derived self-assembling peptide IKVAV, has also been shown to promote neurite sprouting and direct neurite outgrowth. The IKVAV polyacrylamide (IKVAV-PA) gel induced very rapid differentiation of cells into neurons, while suppressing the development of astrocytes [27.42].

Nanofiber scaffolds have also been developed and evaluated for long-term in vivo application; For example, Zhu et al. engineered nanofibrous conduits and implanted them into 1 cm lesion of rat sciatic nerve [27.127]. Electrophysiology, histological evaluation, and behavioral analysis showed that aligned nanofiber scaffolds promoted sciatic nerve regeneration after 2 and 12 months and had comparable therapeutic effect to nerve autografts. These scaffolds also showed that NSCs derived from human induced pluripotent stem cells (iPSCs) and embryonic stem cells (ESCs) and implanted in combination with these scaffold promoted axonal myelination and nerve regeneration [27.87].

Electroactive polymers have been used widely in nanofiber scaffolds due to the ability to apply electrical stimulation to engineered neural tissues. Polypyrrole (PPY) has been studied due to its biocompatibility, conductivity, and ease of synthesis; For example, Lee et al. cultured PC12 and embryonic hippocampal neurons on conductive nanofibers fabricated by growing PPY on electrospun PLGA nanofibers [27.64]. Electrical stimulation significantly enhanced the differentiation of PC12 cells on the PPY by increasing the number of neurite-bearing cells and the length of the neurites. Electrospun nanofibers of PCL and PLLA have been used as a template for polymerization of PPY for culture of dorsal root ganglion (DRG) neurons (Fig. 27.32) [27.128]. The PPY/PCL nanofibers had a smoother surface than the PPY/PLA nanofibers, and the maximum neurite length on aligned nanofibers ($1723 \pm 339 \mu\text{m}$) was greater than on randomly oriented fibers ($946 \pm 164 \mu\text{m}$). After electrical stimulation was applied for 6 days, the maximum neurite length increased to $2542 \pm 171 \mu\text{m}$ on aligned fibers, demonstrating the effect that electrical stimulation can have on neurite extension. Similarly, Ghasemi-Mobarakeh et al. fabricated PCL-gelatin (PCL-G) and PANI/PCL-G nanofibers and applied electrical stimulation through the conductive nanofibrous scaffold on cultured neurons. Cell proliferation and neurite outgrowth were significantly enhanced by electrical stimulation compared with nonstimulated controls [27.129].

Fig. 27.32 (a) Fluorescence micrograph of NF200 showing the DRG neurite field on random PCL-PPY core-sheath nanofibers. (b) Aligned PCL-PPY core-sheath nanofibers. (c) Fluorescence micrograph showing the DRG neurite field on aligned PCL-PPY core-sheath nanofibers. (The arrow indicates the alignment direction for the underlying nanofibers) (after [27.128])

To overcome the difficulties in electrospinning conductive polymers, blended nanofibers of conductive camphorsulfonic acid-doped emeraldine PANI (C-PANI) and gelatin were electrospun and resulted in homogeneous electrospun fibers [27.130]. The biocom-

patibility of PANI films on PC12 cells was significantly enhanced by grafting adhesive peptides, such as Tyr-Ile-Gly-Ser-Arg.

Conductive polymer nanofibers can enhance neurite formation in the absence of electrical stimulation; For example, Guo et al. synthesized and purified a novel electroactive silsesquioxane precursor, *N*-(4-aminophenyl)-*N'*-(4'-(3-triethoxysilyl-propyl-ureido)phenyl-1,4-quinonenediimine) (ATQD), from the emeraldine form of amino-capped aniline trimmers [27.131]. An adhesive oligopeptide, cyclic Arg-Gly-Asp (RGD), was covalently immobilized to the aromatic amine terminals of self-assembled monolayers (SAMs) of ATQD on glass substrates (ATQD-RGD). Similar to tissue-culture-treated polystyrene surfaces, ATQD-RGD supported adhesion and proliferation of PC12 cells, and stimulated spontaneous neurite outgrowth, in the absence of neurotrophic growth factors, such as nerve growth factor (NGF). Ghasemi-Mobarakeh et al. fabricated PCL-gelatin (PG) and PANI/PG nanofibers and applied electrical stimulation through the conductive nanofibrous scaffold of PANI/PG on the cultured nerve cells (Fig. 27.33). Cell proliferation and neurite outgrowth were significantly enhanced by electrical stimulation compared with nonstimulated scaffold [27.129].

Fig. 27.33a,b Morphology of nerve cells (1500 \times magnification) on PANI/PG nanofibrous scaffolds: (a) without electrical stimulation; (b) with electrical stimulation. Arrows show neurite extension of neurons (after [27.129])

27.5 Conclusions and Outlook

The field of tissue engineering is rapidly evolving, and nanofiber biomaterials look to have a promising future in this research area. Normal tissues consist of an ECM nanofiber network of proteins and other biopolymers that dynamically interact with cells. Nanofiber biomaterials enable the engineering of biomimetic scaffolds that recapitulate many of these structural, mechanical, and chemical characteristics. A major difference be-

tween nanofiber biomaterials and protein fibrils in the ECM is the way they are fabricated. As described, most synthetic and biopolymer nanofibers are created by electrospinning, rotary spinning or phase separation. In contrast, cells build ECM nanofibers by directed and self-assembly processes. Thus, it is likely that the newer processing techniques using self-assembling polypeptides and amphiphiles and surface-initiated assembly

of ECM proteins will lead to improved nanofiber scaffolds for tissue engineering. There is the opportunity to further innovate in the area of nanofiber fabrication with the need for better control of fiber chemistry, size, and surface chemistry. There is also the opportunity to innovate in scaffold fabrication and control of nanofiber alignment in 3-D to better mimic the organization of ECM fibrils in tissue. As these types of fabrication techniques are developed and cell interactions are better understood, new tissue engineering applications will become possible. Current progress in cardiac, skeletal

muscle, ophthalmic, and neural tissue engineering demonstrates the breadth of research being conducted and the many advances that have been achieved. However, the absence of Food and Drug Administration (FDA)-approved nanofiber biomaterials indicates that further improvements are needed before this technology reaches the clinic. Fortunately, the tremendous potential of nanofiber biomaterials means progress will continue as this technology is advanced towards the clinic as a viable therapeutic approach in regenerative medicine.

Nanostructured Materials for Energy-Related Applications

Arava L.M. Reddy, Sundara Ramaprabhu

Materials play a key role especially in the field of energy storage and conversion. Design of efficient and cost-effective materials for energy applications is of prime research focus. This chapter presents the recent trends in the energy-related applications of various carbon nanotubes (CNT) and their hybrid nanostructures. Development of CNT-based electrocatalysts for proton exchange membrane fuel cells and CNT-based electrodes for supercapacitors and Li-ion batteries are discussed.

Nanostructured materials have attracted great interest in recent years because of their unusual chemical, mechanical, electrical, and optical properties. The discovery of fullerenes [28.1] has significantly raised the general interest in carbon research activity. CNTs are currently the focus of intense research worldwide because of their unique properties that could impact various areas of science and technology. Various carbon-based materials

have been used in fuel cells, batteries, and other electrochemical applications for decades [28.2–4]. Several studies have shown the superiority of carbon nanotubes over other carbon-based electrodes for applications in fuel cells, supercapacitors, and batteries [28.4, 5] due to their superior physical and chemical properties. Some of the energy-related applications of CNTs are reviewed in the following sections.

28.1 Energy-Related Carbon Nanotubes

28.1.1 Catalytic Support in Proton Exchange Membrane Fuel Cells (PEMFC)

Fuel cells, which are energy-converting devices with high efficiency and low/zero emissions, have attracted increasing attention in recent decades due to high energy demands, fossil-fuel depletion, and environmental pollution. A fuel cell is an electrochemical device which converts chemical energy to electrical energy. It uses hydrogen (hydrogen-rich fuel) and oxygen to create

electricity. A single fuel cell consists of an electrolyte sandwiched between two thin electrodes (anode and cathode). Depending on the operation temperature and kind of electrolyte they employ, fuel cells are classified as follows:

1. Proton exchange membrane fuel cells (PEMFC)
2. Direct alcohol fuel cells (DAFC)
3. Alkaline fuel cells (AFC)
4. Phosphoric acid fuel cells (PAFC)

5. Molten carbonate fuel cells (MCFC)
6. Solid oxide fuel cells (SOFC)
7. Microbial fuel cells (MFC).

The primary components of a PEMFC are an ion-conducting electrolyte, a cathode, and an anode, as shown schematically in Fig. 28.1. Together, these are often referred to as the membrane electrode assembly (MEA). PEMFCs have attracted enormous research interest as power sources for vehicles and portable electronic devices [28.6]. They use a solid ion-exchange polymer as an electrolyte and porous carbon-containing platinum catalyst as electrodes, with hydrated protons as the charge carriers. The operating temperatures are below 120 °C, limited by the polymer properties. The most widely implemented electrolyte in PEMFC is Nafion (poly-perfluorosulfonic acid polymer), manufactured by DuPont, USA. Pt nanoparticles supported on carbon are used as electrocatalysts for both anode and cathode. PEMFC are typically fueled with pure hydrogen supplied from storage tanks or onboard reformers. Hydrogen fuel is channeled to the anode, where it catalytically splits into protons and electrons. The electrolyte membrane allows the protons to pass through to the cathode, while the electrons are forced to follow an external circuit, forming an electric current. At the cathode, the electrons and protons combine with oxygen to form water and heat. Highly porous carbon paper or carbon fabric treated with a hydrophobic poly-

mer (e.g., polytetrafluoroethylene (PTFE)) is typically used as the current collector, which also serves as a gas diffusion layer. To fabricate a fuel cell stack, graphite bipolar plates are placed between individual MEAs. The Pt content (Pt loading) in PEMFCs has been reduced dramatically over the past decade from ≈ 4 to ≈ 0.6 mg/cm², as a result of optimal dispersion of the Pt nanoparticles in the electrocatalyst layer of the fuel cell [28.7]. Due to Pt supply limitations, a further reduction in Pt loading by about fivefold needs to be achieved, for cost-effective large-scale automotive applications [28.8]. The various Pt, Pt-alloy, and non-Pt oxygen reduction catalysts for PEMFCs, together with the activity benchmark, have been extensively reviewed by Gasteiger et al. [28.8]. Recently, nanostructured Pt-M/C (M = Fe and Co) electrocatalysts have been synthesized by various routes and used for the oxygen reduction in PEMFCs [28.9–11]. The electrocatalytic activity of Pt depends on many factors such as high surface area and good electronic activity of the conductive catalyst support [28.12, 13].

At present, Pt dispersed on carbon is used as electrocatalyst in PEMFC. The morphology and size of CNTs make them very significant in catalytic applications due to their ability to disperse catalytically active metal particles [28.14]. The high accessible surface area, interesting electronic properties, and high stability suggest that CNTs are suitable materials for electrodes and catalyst support in PEMFCs [28.15], effectively reducing the Pt catalyst loading and improving fuel cell performance. Functionalization and oxidation of CNTs have been shown to be effective for better loading and dispersion of the metal particles [28.16–18]. Various methods have been followed in the literature to prepare metal-loaded CNTs [28.19, 20]. The various chemical and electrochemical depositions of platinum group metals (PGMs) and their applications in fuel cell technologies have been reviewed [28.21–23]. Pt nanoparticles have been electrodeposited on multi-walled carbon nanotubes (MWNTs) by the potentiostatic method, and the electrocatalytic activity for oxygen reduction has been studied [28.13, 24]. Pt- and Pt-Ru-loaded MWNTs have been used for the methanol oxidation in direct methanol fuel cells (DMFC) [28.25, 26]. In recent years, there has been considerable interest in the design and development of micro fuel cells based on various technologies for their application in portable devices [28.27–30]. Microfabrication technology has been applied in the design of small fuel cells [28.31]. Planar micro fuel cells have been developed using micropatterning technology [28.32].

Fig. 28.1 Schematic illustration of a PEMFC, comprising an electrolyte, an anode, and a cathode

28.1.2 Electrochemical Supercapacitors

In response to the changing global landscape, energy has become a primary focus of the major world powers and scientific community. There has been great interest in developing and refining more efficient energy storage devices. One such device, the supercapacitor, has matured significantly over the last decade and emerged with the potential to facilitate major advances in energy storage. Supercapacitors are electrochemical capacitors with high capacitance and power density, typically comprising two electrodes separated by an insulating material that is ionically conducting in electrochemical devices [28.33]. They store electric energy in an electrochemical double layer formed at the solid–electrolyte interface. A schematic diagram showing the principle of a supercapacitor is shown in Fig. 28.2. Positive and negative charges from the electrolyte accumulate at the surface of the electrodes and compensate for the electronic charges at the electrode surface. The resulting charge distribution is called an electric double layer or electrochemical double layer (ECDL). The capacity of an electrochemical supercapacitor inversely depends on the separation between the charge on the electrode and the countercharge in the electrolyte. To achieve high capacitance, porous electrode materials with large accessible surface area are used. Based on the electrode materials, electrochemical capacitors are classified into three main categories, being based on carbon, metal oxides, and polymeric materials [28.34]. Due to their high specific surface area, relatively low cost, availability, and established production technology, use of activated carbon materials as the electrode materials in supercapacitors has been intensively investigated during the last decades [28.33–37]. The experimentally measured capacitance of activated carbons is not in good agreement with the theoretical values, since a significant part of the surface area remains in micropores which are not accessible to the electrolyte ions [28.33]. Therefore, pore size distribution together with surface area is important for the determination of electric double layer capacitance [28.38]. CNTs with their narrow distribution of mesopore sizes, highly accessible surface area, low resistivity, and high stability have attracted great interest worldwide as electrode materials for supercapacitors [28.38–41]. Supercapacitors fabricated using CNT-nanocomposite electrodes have shown enhanced performance due to the high usage efficiency of specific surface area following from the disintegrated bundle structure of CNTs. Frackowiak et al. [28.40] reported improved supercapacitance of composite electrodes

Fig. 28.2

Schematic illustration of an electrochemical double layer (ECDL) supercapacitor and its equivalent circuit in a two-electrode system

based on MWNTs deposited with polypyrrole (PPY). Nanocomposites of electronically conducting polymers (ECs) and MWNTs have been used as electrode materials for supercapacitors, and the specific capacitance of these composite electrodes has been determined using different cell configurations [28.42]. Recently, supercapacitor electrodes fabricated using metal oxide/MWNT nanocomposite materials have shown increased specific capacitance with an improvement in cycle life and power density [28.43,44]. In recent years, supercapacitors coupled with batteries have been considered as promising hybrid devices to combine the best features of each [28.45].

28.1.3 Lithium-Ion Batteries

A battery is an electrochemical device that has the ability to convert chemical energy to useful electrical energy. The basic battery consists of an anode, a cathode, an electrolyte, separators, and the external case. Among various batteries, rechargeable lithium batteries have revolutionized portable electronic devices due to their superior energy density [28.46–55]. They have become the dominant power source for cellphones, digital cameras, laptops, etc. The rechargeable lithium battery does not contain lithium metal. The basic principle of rechargeable lithium batteries is electrochemical intercalation and de-intercalation of lithium in both electrodes. The cathode materials are transition-metal oxides (Li_xMO_2 , where M is the transition metal), while carbon materials are used as anodes. On charging, lithium ions are de-intercalated from the layered cathodes, pass across the electrolyte, and are intercalated

Fig. 28.3
Scheme of
a common
lithium ion
battery

between the graphite layers in the anode (Fig. 28.3). The reverse process takes place during discharge.

Starting from micro-sized graphite powder or coke, various carbon structures including carbon nanowires, nanotubes, few layers of graphene, and fullerenes have been tried as negative electrodes for rechargeable lithium batteries due to their low cost and low operational voltage [28.56–64]. Highly reversible and irreversible capacities have been obtained for single-walled carbon nanotubes (SWNTs) [28.64]. Although carbon nanotubes exhibit twice the lithium storage compared with graphite, problems of surface-layer formation and safety limit their application. Carbon nanotubes do not seem to offer a major route to improved electrodes for lithium-ion batteries. In the search for alternatives to graphite/carbon nanotubes that will combine inherent protection against lithium deposition with low cost, low toxicity, and the ability to be fabricated as a nanomaterial delivering fast lithium insertion/removal, attention has focused on in-

sertion metal alloys, e.g., Li_yM ($\text{M} = \text{Sn}, \text{Pb}, \text{Si}, \text{In}$, etc.) [28.65–74]. Such alloys have specific capacities which exceed that of the conventional graphite anode, for example, $\text{Li}_{4.4}\text{Sn}$ (993 mAh/g versus 372 mAh/g). However, the severe volume change which accompanies the alloy forming–decomposition process ($\approx 300\%$) causes progressive cracking and leads to pulverization of the metal particles, thereby inducing losses of contact between them [28.65–70]. Therefore, although greatly appealing in terms of storage capacity, lithium alloy electrodes are difficult to use in practice. Thus, processes based on intercalation/de-intercalation are inevitably limited in capacity, and the process based on insertion alloys is limited by cycle life. In the search for other options using lithium in the solid state that are not constrained by the requirements of intercalation/insertion, it has been shown that lithium can react with a range of transition-metal oxides by a process termed conversion. Various transition-metal oxides have been widely studied as electrode materials for rechargeable lithium-ion batteries because of their high theoretical capacity, safety, environmental benignity, and low cost [28.75–82]. However, the poor electronic conductivity of metal oxides limits their use in high-performance lithium ion batteries. One of the other challenging issues is to tackle their capacity decay with cycling, resulting from large volume expansion during the lithium uptake/release process. Extensive research efforts are presently being devoted to overcome these problems by using electronically conductive additives and carbon coatings [28.83–86].

28.2 CNTs as Support Material for Electrocatalysts in PEMFC

Wide application of PEMFCs is hindered by their high cost. It is generally believed that the large amount of depleting platinum required as a catalyst in PEMFCs is one of the main reasons why fuel cells are excluded from commercialization. In the past two decades, continuous efforts have been devoted to increase the utilization of Pt and reduce the amount of Pt used in PEMFCs. Electrocatalysts with small size and high dispersion result in high electrocatalytic activity [28.87]. This suggests that it is highly desirable to have good Pt supporting materials with high surface area, which will enhance the Pt dispersion and hence reduce the catalyst loading, thereby improving fuel cell performance [28.88–91]. CNTs are attractive materials for catalyst support in PEMFCs due to their morphology

and interesting properties such as nanometer size, high accessible surface area, corrosion resistance, good electronic conductivity, and high stability [28.92]. Several methods have been developed to decorate CNTs with catalytic metal nanoparticles [28.15, 93, 94]. However, it is important to develop techniques to improve adhesion through surface modification such as functionalization of CNTs before the decoration of metal nanoparticles [28.95, 96]. CNT-supported Pt (Pt/MWNTs, Pt/SWNTs, and Pt/MWNCs (multi-walled carbon nanocoils)) electrocatalysts have been extensively prepared by the chemical reduction method using a Pt salt and prefunctionalized CNTs, synthesized by pyrolysis of acetylene/methane over hydrogen-decrepitated MmNi_3 hydride catalysts [28.95–97]. The pretreated

Fig. 28.4 SEM and TEM images of MWNT, SWNT, and MWNC synthesized by catalytic decomposition of acetylene/methane over alloy hydride catalyst (after [28.97])

CNTs were functionalized with carboxylic acid groups attached to act as anchoring sites for better adherence of Pt nanoparticles onto the CNT surface, thereby giving better performance at higher current densities.

Morphological characteristics of CNTs were obtained using scanning electron microscopy (SEM) and transmission electron microscopy (TEM). Figure 28.4 shows SEM and TEM images of different types of CNTs synthesized by pyrolysis of acetylene/methane over hydrogen-decrepitated MmNi_3 hydride catalysts. The crystallinity of the samples was obtained by x-ray powder diffraction (XRD) analysis, performed with monochromatic $\text{Cu} - \text{K}_\alpha$ radiation. Figure 28.5 shows the XRD pattern of as-prepared MWNTs using alloy hydrides as catalysts. The peaks are indexed to the reflections of hexagonal graphite. A few peaks corresponding to the catalytic impurities are also seen. The removal of metallic impurities by acid treatment is observed from the XRD patterns of purified MWNTs (Fig. 28.5b). The broader diffraction peaks of Pt along

with hexagonal graphitic reflections for Pt/MWNTs are shown in Fig. 28.5c. Figure 28.6 shows SEM, TEM, and high-resolution TEM (HRTEM) images of Pt/MWNTs, Pt/SWNT, and Pt/MWNC. TEM images of Pt/CNTs show a more or less uniform distribution of noble-metal particles ($\approx 3\text{--}5\text{ nm}$) on the CNTs. The HRTEM image clearly shows lattice planes of Pt particles, indicating the crystalline nature of the catalytic Pt. The amount of Pt loaded on the CNT support was qualitatively evaluated to be 20% from energy-dispersive analysis (EDAX).

Half-cell reactions were carried out in three-arm electrochemical cell using PSGSTAT-30 (AUTOLAB). In the preparation of the working electrode, about 5 mg Pt/CNTs and 5 μL diluted Nafion (0.05 wt % Nafion) in ethanol were mixed using an ultrasonic bath. A measured volume of this mixture was then pipetted onto a glassy carbon electrode (0.03 cm^2) substrate and dried at room temperature for 24 h. The thickness of the film was estimated to be less than $0.1\text{ }\mu\text{m}$, with platinum

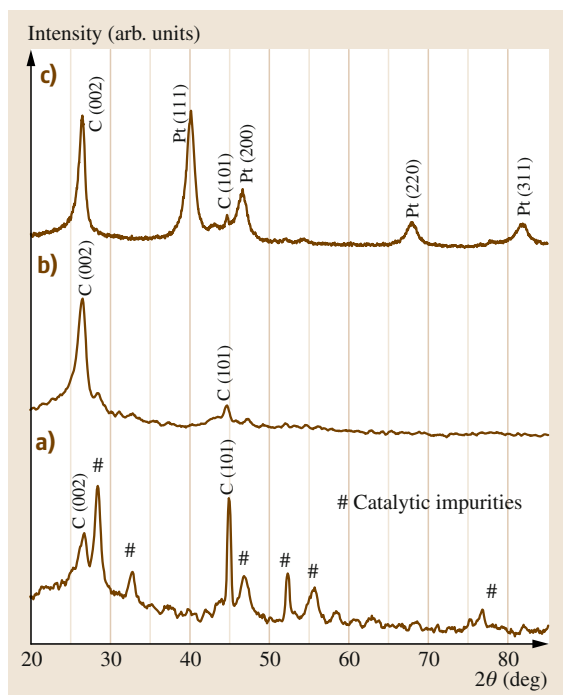

Fig. 28.5a–c Powder x-ray diffractograms of (a) as-grown MWNTs, (b) purified MWNTs prepared by pyrolysis of acetylene over MmNi_3 alloy hydride catalyst, and (c) Pt/MWNTs (after [28.95])

loading of $15 \mu\text{g Pt}/\text{cm}^2$. A thin film is necessary to minimize diffusion resistance in the Nafion film. For comparison, x wt% Pt/MWNTs and y wt% Pt/C, with $x + y = 100$, where $x = 0, 25, 50, 75$, and 100 electrodes were prepared under the same conditions. Pt foil and saturated calomel electrode (SCE) were used as counter and reference electrodes, respectively. Initially, the electrode was operated by applying potential between -0.2 and $+1.2$ V at 0.05 V/s for 20 min in 0.1 M HClO_4 solution to eliminate any contamination in the Nafion membrane. Hydrodynamic voltammograms of different electrodes were recorded by scanning its potential from -0.25 to $+1.0$ V at 0.02 V/s in oxygen-saturated 0.1 M HClO_4 . The electrolyte and reference electrode were refreshed every 4–6 h to avoid contamination such as chloride during the test. Desorption of underpotentially deposited hydrogen in a stationary voltammogram was used to evaluate the electrochemically active surface area (ECSA) of the Pt catalyst on the electrode. The ECSA of an electrocatalyst is a measure of the number of electrochemically active sites per gram of catalyst. The ECSA is an important parameter to

compare different electrocatalytic supports of electrode materials, being determined by integrating the area under the potential window for H^+ adsorption/desorption peaks after subtracting the charge from the double layer region. Figure 28.7 shows cyclic voltammograms for H adsorption on different composites of Pt/C and Pt/MWNTs. Characteristic peaks in the negative region ($0-0.1$ V) are attributed to atomic hydrogen adsorption on the Pt surface and reflect the ECSA of Pt. The integrated area of the cyclic voltammogram represents Q_{H} (the charge arising from hydrogen evolution reactions) and can be used to determine the ECSA by employing the expression [28.98, 99]

$$\begin{aligned} \text{ECSA} \left(\frac{\text{cm}^2}{\text{g}} \text{ of Pt} \right) &= \frac{Q_{\text{H}} \left(\frac{\mu\text{C}}{\text{cm}^2} \right)}{\left[210 \left(\frac{\mu\text{C}}{\text{cm}^2} \right) \times \text{Electrode loading} \left(\frac{\text{g of Pt}}{\text{cm}^2} \right) \right]} \quad (28.1) \end{aligned}$$

Initially, the characteristic peaks increase with increase of Pt/MWNT content in the composite electrodes, reaching a maximum for the 50 wt% Pt/C + 50 wt% Pt/MWNTs composite electrode, which shows a remarkably larger peak reflecting a high surface area. With further increase of the Pt/MWNTs concentration in the composite electrode, a decrease in the characteristic peak is observed. The ECSA of Pt/C, Pt/SWNTs, and 50 wt% Pt/C + 50 wt% Pt/SWNTs composites have been found to be $56 \text{ m}^2/\text{g}_{\text{Pt}}$, $102 \text{ m}^2/\text{g}_{\text{Pt}}$, and $118 \text{ m}^2/\text{g}_{\text{Pt}}$, respectively [28.95, 96].

A full PEMFC has been constructed using the above-described electrocatalysts, and the performance of the fuel cell voltage output as a function of electrical current density drawn, or the polarization curve studied. The current–voltage characteristics of a PEMFC fabricated with different types of CNT-supported Pt electrocatalysts as cathode catalysts were studied using a PEMFC test station comprising a single stack fuel cell. A commercial 20 wt% Pt on carbon (Pt/C) obtained from E-TEK Inc. was used as the anode with Pt loading of $0.25 \text{ mg}/\text{cm}^2$. To study the effect of the electrocatalytic activity of the Pt/CNTs on the performance of PEMFC, active material with composition 50 wt% Pt/CNTs and 50 wt% Pt/C was taken as the cathode catalyst. The membrane electrode assembly (MEA) was obtained by pressing the cathode and anode on either side of pretreated Nafion 1135 membrane at pressure of $50 \text{ kg}/\text{cm}^2$ and 130°C for 2 min [28.95, 96]. Polarization curves were obtained from the single-cell PEMFC using these MEAs at dif-

Fig. 28.6 TEM and HRTEM images of Pt-dispersed MWNT, SWNT, and MWNC (after [28.95, 96])

ferent temperatures under operating pressure of 1 bar (Fig. 28.8). Prior to polarization studies, the electrodes were activated between open-circuit potential and high current densities. This activation cycle is necessary to activate the catalyst for the oxygen reduction reaction. In the low-current-density region, the rapid voltage drop in the potential–current curve, generally known as activation polarization, reflects the sluggish kinetics intrinsic to the oxygen reduction reaction at the cathode surface. As the current density increases, a mild drop in voltage is observed because of the cell resistance. Mass transport limitations account for the rapid drop seen at higher current densities. Under the same operating conditions, the PEMFC with the cathode catalyst containing 50 wt % Pt/MWNCs shows the maximum performance. A maximum power density of $\approx 480 \text{ mW/cm}^2$ at working temperature of 60°C

was observed when using the Pt/MWNC electrocatalyst, whereas the maximum power densities when using

Fig. 28.7 Cyclic voltammograms for Pt/C-Pt/MWNTs composite electrodes recorded in 0.1 M HClO_4 at scan rate of 0.02 V/s (Pt loading $15 \mu\text{m}^2/\text{cm}^2$; RHE, reversible hydrogen electrode) (after [28.95]) ►

Pt/MWNT, Pt/SWNT, and Pt/C electrocatalysts were only ≈ 310 , ≈ 260 , and ≈ 140 mW/cm², respectively.

28.2.1 Nonnoble Metal Based Electrocatalysts for Fuel Cells

Apart from the issue of high cost of catalyst and other fuel-cell system components (polymer electrolyte membrane, bipolar plates, power system), fuel cells suffer from insufficient performance durability, arising mainly from cathode catalyst agglomeration, oxidation, catalyst migration, loss of electrode active surface area, corrosion of the carbon support, etc. In the case of DMFC, in addition to all the above issues, Pt at the cathode also endures a performance loss resulting from the mixed potential due to methanol diffusion through the membrane from the anode side of the cell [28.100, 101]. Further, in fuel cells, the hydrogen produced via steam or partial oxidation reforming of hydrocarbons or renewable fuels typically contains 0.5–2.0 vol.% CO. However, Pt electrodes in PEMFC are extremely sensitive to even low levels of CO (50 ppm) [28.102, 103]. Hence, the search for efficient, durable, and most importantly, inexpensive catalysts as alternatives to Pt and Pt-based materials and as a support material is always in the limelight [28.104–106]. Recently, cobalt was confirmed as an effective promoter for improving the catalytic activity of mixed oxide catalysts [28.107]. Additionally, cobalt-based catalysts showed a very high activity promoting CO oxidation at low temperature [28.108–110]. Furthermore, catalytic performance depends on the nature of the support, active site, and preparation techniques. Although ideally the Pt catalyst should be replaced at both fuel-cell electrodes, the substitution of the cathode catalyst for the oxygen reduction reaction (ORR) with a nonprecious material is likely to result in significantly greater reduction of the Pt needed for fuel cells [28.111]. Recently, *Bashyam* and *Zelenay* demonstrated a new class of low-cost polypyrrole (PPY)-Co-carbon (Co loading 0.06 mg/cm²) nanocomposite catalysts for the PEMFC cathode by using PPY as a matrix for entrapping cobalt and generating active ORR sites, and Pt-Ru-carbon (Pt-Ru loading 6 mg/cm²) at the anode for hydrogen oxidation using a 2.0 atm back-pressured cell [28.112].

The performance with the novel MWNT-supported PPY-Co electrocatalyst for the oxygen reduction reaction along with Pt-Ru/MWNTs electrocatalyst for oxidation of hydrogen and methanol at the anode and Pt-Sn/MWNTs electrocatalyst for oxidation of ethanol at the anode in a PEMFC, direct methanol fuel cell

(DMFC), and direct ethanol fuel cell (DEFC) were studied [28.113].

Figure 28.9 shows SEM, TEM, and HRTEM images of PPY-Co-dispersed MWNTs ORR catalysts. Uniform dispersion of PPY over MWNTs has been achieved by in situ polymerization technique by oxidizing monomer,

Fig. 28.9 (a) SEM image of Co-PPY/MWNTs. (b), (c) TEM images of CoPPY/MWNTs and (d) EDX analysis of Co-PPY/MWNT (after [28.113])

Fig. 28.10 (a) PEMFC, (b) DMFC, and (c) DEFC performance at 70–90 °C with cathode catalyst containing Co-PPY/MWNT (loading 0.5 mg/cm²) and anode catalyst containing Pt-Ru/MWNT (loading 0.25 mg/cm²) at ambient pressure (after [28.113]) ◀

and nanoparticles of Co could be dispersed on PPY-MWNTs composite. Uniform dispersion of PPY on MWNTs and nanoparticles of cobalt over PPY-MWNTs composites have been achieved for the first time. The amount of Co loaded on the PPY-MWNT support with reference to carbon was measured to be about 10% by EDX analysis (Fig. 28.9). Figure 28.10 shows the polarization curves of PEMFC, DMFC, and DEFC, respectively, at 70 °C, 80 °C, and 90 °C. After activation cycles, PEMFC generates 0.15 A/cm² at 0.5 V and maximum power density of 120 mW/cm² with catalyst loadings of 0.25 mg/cm² of Pt-Ru and 0.5 mg/cm² of Co on the anode and cathode, respectively. Bashyam and Zelenay [28.112] have reported a maximum power density of 140 mW/cm² for carbon-supported Co-PPY with catalyst loading of 6.0 mg/cm² of Pt-Ru (anode) and 0.06 mg/cm² of Co (cathode) at operating pressure of 2.8 atm. Although the present current density is about 7% less than the previous reported value [28.112], the present results were obtained with low platinum loading (about 24 times lower) at the anode, and at ambient pressure. The suitability of PPY-Co-dispersed MWNT ORR catalyst for use in alcohol-based fuel cells with appropriate anode electrodes was also tested (Fig. 28.10b). DMFC with Pt-Ru/MWNT (1.5 mg Pt/cm²) at the anode and Co-PPY/MWNT (2.5 mg Co/cm²) at the cathode resulted in a maximum power density of 52 mW/cm² at operating temperature of 90 °C with oxygen pressure at 1 atm, which is better than the value of 32 mW/cm² at 70 °C reported by Praburam et al. for Pt/C with 2 mg Pt/cm² at the cathode and Pt-Ru loading of 2.1 mg/cm² at the anode [28.114]. This better performance is attributed mainly due to the high oxygen reduction activity of the nonprecious Co-PPY-MWNT at the cathode electrode compared with Pt/C. Further, Pt-Sn/C has been proved to be a good candidate for oxidation of ethanol among other electrocatalysts such as Pt-Ru/C, PtW/C, PtPd/C, and Pt/C [28.115]. The performance values of DEFC are quite encouraging even with less loadings of Pt-Sn at the anode apart from complete elimination of precious metals at the cathode. DEFC could generate a maximum power density of 33 mW/cm² at 90 °C (Fig. 28.10c). Although the power density is less than the value of 55.8 mW/cm²

recently reported with Pt-Sn/C catalyst [28.115], the present result was obtained at significantly lower absolute pressure of oxygen (1 atm versus 2.0 atm) with nonprecious Co-PPY-MWNTs at the cathode electrode rather than Pt/C.

The results obtained from the systematic studies of PEMFC using Pt/CNTs electrocatalysts for the oxygen reduction reaction show significant improvement

in performance due to the good accessibility and dispersibility of the Pt nanoelectrocatalysts on the CNT support, resulting in more efficient Pt usage for the oxygen reduction reaction. The excellent catalytic activity of the novel MWNT-supported Co-PPY composites as electrode material for the oxygen reduction reaction has been attributed to the uniform dispersion of Co nanoparticles over the PPY-MWNT architecture.

28.3 CNTs as Supercapacitor Electrode Materials

Depending on the charge-storage mechanism, supercapacitors are basically classified into two types: electric double layer capacitors (EDLCs) based on carbon electrodes [28.116–120] and pseudocapacitors with certain metal oxides [28.121–126] or conducting polymers as electrode materials [28.127–134]. While the storage mechanism in carbon-based EDLCs is through electrostatic forces, fast Faradaic redox reactions are responsible for the charge-storage mechanism in pseudocapacitors. Carbon-based supercapacitor electrodes have been attractive due to their high surface area and porous nature [28.116–120]. Recently, both single-walled and multi-walled carbon nanotubes (SWNTs, MWNTs) have been recognized as potential electrode materials for electrochemical supercapacitors, owing to their special properties such as high chemical stability, low mass density, low resistivity, narrow distribution of mesopore sizes, and large surface area [28.135, 136]. However, due to the microtexture, defects, micropore volume, and catalyst contamination of carbon nanotubes (CNTs), their specific capacitance is restricted to low values. Hence, there have been considerable efforts to improve the capacitance of CNT-based supercapacitor electrodes by various techniques such as activating CNTs with heat/acid treatment [28.137] to improve the micropore volume of CNTs, and modification of CNTs with conducting polymers [28.138] or with certain transition-metal oxides [28.139, 140]. Thus, the hybrid of an electric double layer system and a Faradaic pseudocapacitive system could be a good candidate for a supercapacitor with high specific capacitance and energy density. Transition-metal oxides attached to CNTs have been studied recently and are expected to show improved capacitive behavior due to their enhanced stability and high conductivity. Among the transition-metal oxides, hydrous ruthenium dioxide has been recognized as one of the most promising candidates for electrodes in electrochemical capacitors as it

can store charges reversibly by redox reaction [28.140, 141]. However, the high cost of RuO₂ has prompted the research community to focus on other transition-metal oxides such as MnO₂, NiO, etc., mainly for reasons of cost-effectiveness. Of the various nonnoble metals or transition-metal oxides studied, TiO₂ and SnO₂ enjoy a special place because of their lower cost and environmentally benign nature. On the other hand, among the conducting polymers, polyaniline (PANI) and polypyrrole (PPY) have been considered as the most promising materials for this application due to their excellent capacity for energy storage, easy synthesis, higher conductivity, and lower cost than many other conducting polymers. However, long-term stability during cycling is a major demand for industrial application of electrically conducting polymers (ECPs). Swelling and shrinkage of ECPs is well known and may lead to degradation of the electrode during cycling. This occurs because the doping of the polymers requires insertion/de-insertion of counterions, which cause a volume change. Thus, the mechanical stress in the polymer film is directly related to the cycle life of polymer-based capacitors. Various metal oxides (RuO₂, TiO₂, and SnO₂) dispersed MWNTs and polymer (PPY and PANI) dispersed MWNTs composites have been synthesized, and the supercapacitive performance of these composite electrodes has been studied systematically [28.142, 143]. MWNTs have been functionalized with nanocrystalline RuO₂, TiO₂, and SnO₂ by a simple chemical reduction method, and PPY and PANI dispersion on MWNTs was done by in situ polymerization technique. The supercapacitive behavior of these nanocrystalline composite electrodes has been studied using cyclic voltammetry, galvanostatic charge-discharge, and electrochemical impedance spectroscopy measurements.

RuO₂-supported MWNTs (RuO₂/MWNTs) nanocomposites were prepared by the chemical reduction

method using a Ru salt and pretreated MWNTs. Functionalized MWNTs were dispersed in a solution of 1 : 1 volume ratio of isopropanol and water by ultrasonic agitation. $\text{RuCl}_3 \cdot 3\text{H}_2\text{O}$ (2 : 1 MWNTs to Ru wt. ratio) was added to the above mixture and ultrasonication continued for 1 h. The blank product of the reaction was filtered and washed repeatedly with distilled water to remove excess chloride ions. The $\text{RuO}_2/\text{MWNTs}$ was dried in a vacuum oven at 100°C for 12 h. Part of the final product was calcined at 350°C for 2 h. TiO_2/MWNT composites were prepared using the sol-gel method as follows: Functionalized MWNTs were dispersed in dilute nitric acid (pH 0.5) by ultrasonic agitation. This solution was then transferred to a round-bottomed flask, and titanium tetraisopropoxide (Aldrich, 97%) was added dropwise, maintaining the volume ratio of titanium tetraisopropoxide to water at 1:4. The sol obtained was stirred for 2 days in air at room temperature (RT). The obtained turbid suspension was centrifuged at 6000 rpm, and the resultant residue was washed twice with distilled water. As-synthesized $\text{TiO}_2/\text{MWNTs}$ composites were heat treated at temperatures of 350°C for 2 h in air. $\text{SnO}_2/\text{MWNTs}$ nanocomposites were synthesized by dissolving 1 g tin(II) chloride (SnCl_2) in 40 ml distilled H_2O followed by addition of 1.0 ml HCl (38%). Subsequently, 10 mg of the functionalized MWNTs was dispersed in the above solution. This mixture was sonicated for 5–10 min and then stirred for 60 min at RT. The precipitate was then separated from the mother liquor by centrifugation and was washed with distilled H_2O for several times, then dried at 70°C under vacuum for 6 h. Part of the final product was calcined at 350°C for 2 h.

PPY/MWNTs composites were first prepared by chemical oxidative polymerization of a monomer (pyrrole) on the surface of MWNTs in order to overcome the problems encountered with the electrochemical method. The electrochemical method is limited in terms of mass production of the materials, and also it is not suitable for preparing composites with a large proportion of polymer. Composites were prepared by immersion of the MWNTs (0.1 g) into an aqueous solution of monomer and addition of an oxidant to this solution. PPY was deposited on MWNTs by chemical polymerization of 0.5 ml pyrrole with 1.2 g FeCl_3 in 50 ml 0.1 mol/l HCl. The PANI/MWNTs nanocomposite was synthesized by polycondensation of 0.4 ml aniline by 0.4 g $\text{K}_2\text{Cr}_2\text{O}_7$ in 50 ml 1 mol/l HCl. The nanocomposite materials were then filtered and washed with large amount of water and subsequently with ethanol to re-

move the residual oxidant. Finally, all composites were washed with acetone and dried at 60°C . The content of MWNTs in the composites was determined gravimetrically. All the above-prepared composites were characterized by powder XRD SEM, EDAX, and TEM measurements.

Figure 28.11 shows the XRD pattern of as-prepared MWNTs using alloy hydrides as catalysts. The peaks are indexed to the reflections of hexagonal graphite. A few peaks corresponding to the catalytic impurities are also seen. The XRD of purified MWNTs (Fig. 28.11b) shows the removal of metallic impurities by acid treatment. The XRD pattern of $\text{RuO}_2/\text{MWNTs}$ nanocomposite material (Fig. 28.11c) shows the reflections of RuO_2 along with that for graphitic carbon, whereas Fig. 28.11d,e presents the XRD patterns of $\text{TiO}_2/\text{MWNTs}$ and $\text{SnO}_2/\text{MWNTs}$ composites showing the reflections of corresponding oxides along with

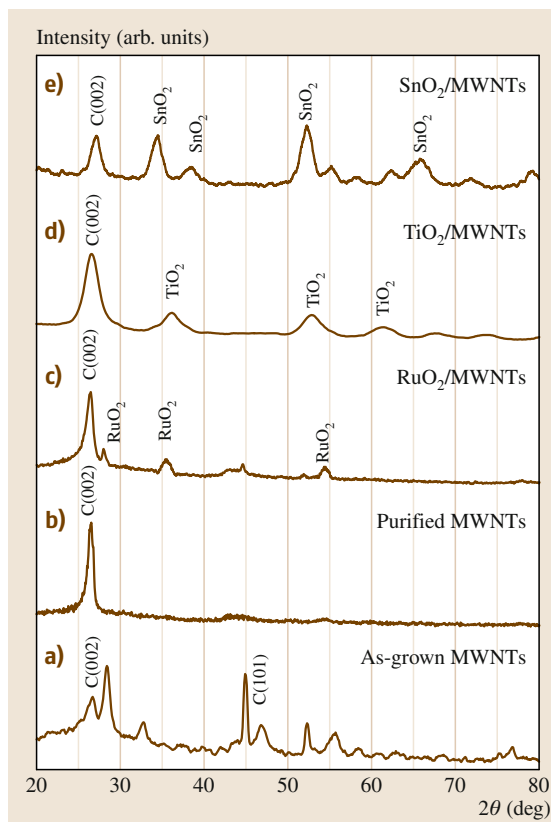

Fig. 28.11a–e Powder XRD patterns of (a) as-grown MWNTs, (b) purified MWNT, (c) $\text{RuO}_2/\text{MWNTs}$ nanocomposite, (d) $\text{TiO}_2/\text{MWNTs}$, and (e) $\text{SnO}_2/\text{MWNTs}$ nanocomposite (after [28.142])

Fig. 28.12 SEM and TEM images of SnO₂/MWNTs, RuO₂/MWNTs, and TiO₂/MWNTs nanocomposite (after [28.142])

that of graphitic carbon. The broad peaks reveal the presence of nanostructured metal oxide crystals.

Figure 28.12 shows SEM, TEM, and HRTEM images of SnO₂/MWNTs, RuO₂/MWNTs, and TiO₂/MWNTs nanocomposites, respectively. TEM images of SnO₂/MWNTs, RuO₂/MWNTs, and TiO₂/MWNTs nanocomposites indicate the uniform distribution of nanocrystalline metal oxide particles with size of about 3–5 nm on the MWNTs. The lattice planes of SnO₂, RuO₂, and TiO₂ nanoparticles are seen clearly in the respective HRTEM images, indicating the crystalline nature of the catalytic particles. SEM and TEM images of PPY/MWNTs and PANI/MWNTs clearly show uniform dispersion of polymer over MWNTs (Fig. 28.13).

A supercapacitor test cell was fabricated with two MWNT composite electrodes separated by a thin polymer in 1 M H₂SO₄ solution. The electrodes, which

were pellets of 12 mm diameter, were separated by a thin polymer (15 mm diameter) and were sandwiched in a Swagelok-type stainless steel (SS) cell with SS current collectors. The electrochemical properties and capacitance measurements of MWNT composite electrodes were studied in a two-electrode system by cyclic voltammetry, galvanostatic charge–discharge, and electrochemical impedance spectroscopy in an electrochemical workstation (CHI 660B).

28.3.1 Cyclic Voltammetry

The cyclic voltammetry (CV) responses of the different electrode materials at scan rate of 2 mV/s are shown in Figs. 28.14 and 28.15. Voltammetry testing was carried out at potentials between –1.0 and 1.0 V using 1 M H₂SO₄ aqueous electrolyte solution. The MWNTs present the typical box-like curve expected for an ideal

Fig. 28.13 (a) SEM and (b) TEM images of PANI/MWNTs. (c) SEM and (d) TEM images of PPY/MWNTs (after [28.143])

capacitor. However, there are oxidation peaks observed in the CV for metal oxide-dispersed MWNTs electrodes, which are attributed to redox reactions due to the functional groups on the nanotubes [28.40]. There

is a reasonable symmetry to the curves for MWNTs electrodes, which may be due to the capacitance arising solely due to the double layer. However, in metal oxide/MWNTs and polymer/MWNTs electrodes, the lack of symmetry to the curves is probably due to a combination of double layer and pseudocapacitances contributing to the total capacitance. The area of the curve also increased with supercapacitor electrodes using RuO₂, TiO₂, SnO₂, PANI- and PPY-dispersed MWNTs, indicating enhancement of the specific capacitance for these electrodes. Since the measurements were made on symmetric assemblies of materials, by the basic circuit relationship for series capacitors, what is measured is actually $\frac{1}{2}$ of the capacitance of the free-standing electrode. The specific capacitance has been obtained from the CV curve according to

$$C_{sp} = \frac{i}{s m} , \tag{28.2}$$

Fig. 28.14 Cyclic voltammograms of pure MWNTs, RuO₂/MWNTs, TiO₂/MWNTs, and SnO₂/MWNTs nanocomposite electrodes, at scan rate of 2 mV/s in 1 M H₂SO₄ aqueous electrolyte; mass of each electrode was 10 mg (after [28.142]) ◀

where i is the average cathodic current, s is the potential sweep rate, and m is the mass of each electrode.

28.3.2 Galvanostatic Charge–Discharge

The specific capacitance of the MWNT electrodes was also determined by galvanostatic charge–discharge technique. Galvanostatic cycling of supercapacitor cells was performed at constant current of 2 mA/10 mA between 0 and 1 V. Figures 28.16 and 28.17 show the galvanostatic charge–discharge behavior of the pure MWNTs, RuO₂/MWNTs, TiO₂/MWNTs, SnO₂/MWNTs, PANI/MWNTs, PPY/MWNTs nanocomposite and aligned MWNT electrodes, respectively. The discharge curves are almost linear in the total range of potential with constant slope, showing perfect capacitive behavior. The capacitance of the cell was deduced from the slope of the $V-t$ curves using the equation

$$C = \frac{I}{(dV/dt)} \quad (28.3)$$

The specific capacitance (F/g) of the MWNTs electrode was calculated according to

$$C_{sp} = 2 \frac{C}{m}, \quad (28.4)$$

where C is the experimentally measured capacitance of the supercapacitor (28.3) and m is the amount of each electrode material.

28.3.3 Electrochemical Impedance Spectroscopy

Electrochemical impedance spectroscopy (EIS) measurements were carried out at direct-current (DC) bias of 0 V with sinusoidal signal of 10 mV over the frequency range from 40 kHz and 10 MHz. Figures 28.18 and 28.19 present complex-plane impedance plots for purified MWNTs, RuO₂/MWNTs, TiO₂/MWNTs, SnO₂/MWNTs, PANI/MWNTs, PPY/MWNTs nanocomposite and aligned MWNT electrodes, respectively. At lower frequency, the imaginary part of impedance sharply increases, which is typical of the capacitive behavior of the electrode. The impedance plot should theoretically be a vertical line parallel to the imaginary axis. In fact, a difference between this theoretical behavior and the experimental result can be observed. The impedance behavior of undoped MWNTs comes close to that of an ideal capacitor. A slight variation from the ideal capacitive behavior could be attributed to the pore size distribution of MWNTs [28.144].

Fig. 28.15 Cyclic voltammograms of PANI/MWNTs and PPY/MWNTs nanocomposite electrodes at scan rate of 2 mV/s in 1 M H₂SO₄ aqueous electrolyte; mass of each electrode was 10 m (after [28.143])

Fig. 28.16 Galvanostatic charge–discharge of pure MWNTs, RuO₂/MWNTs, TiO₂/MWNTs, and SnO₂/MWNTs nanocomposite electrodes at applied constant current of 10 mA in 1 M H₂SO₄ aqueous electrolyte; mass of each electrode was 10 mg (after [28.142])

However, the impedance behavior of RuO₂/MWNTs, TiO₂/MWNTs, SnO₂/MWNTs, PANI/MWNTs, and

PPY/MWNTs nanocrystalline composite electrodes shows a deviation from the ideal capacitor response, with much lower impedance than pure MWNTs electrodes. The presence of a small semicircular loop for MWNT electrodes at higher frequencies is due to charge-transfer resistance of the electrode [28.35].

Fig. 28.17 Galvanostatic charge–discharge of PANI/MWNTs and PPY/MWNTs nanocomposite electrodes at applied constant current of 10 mA in 1 M H₂SO₄ aqueous electrolyte; mass of each electrode was 10 mg (after [28.143]) ◀

Equivalent series resistance (ESR) of 7, 4, 3, and 5.5 Ω are measured for pure MWNTs, RuO₂/MWNTs, TiO₂/MWNTs, and SnO₂/MWNTs nanocomposites, respectively. The alternating-current (AC) impedance method has also been used to measure the specific capacitance of the electrodes, which is influenced by the frequency especially for porous electrodes where almost no current flows down the pore at higher frequencies.

The energy density (E) of the supercapacitor can be calculated by using

$$\begin{aligned} E &= \int V \, dq, \\ C &= \frac{q}{V}, \\ q &= CV, \\ dq &= C \, dV + V \, dC = C \, dV, \quad \text{if } dC = 0, \\ E &= C \int V \, dV = \frac{1}{2} C (\Delta V)^2, \end{aligned} \tag{28.5}$$

where C is the capacitance, V is the operating potential window (1.0 V), and m is the amount of active material in the supercapacitor (including positive and negative electrodes).

The specific power density (P) of the supercapacitor can be calculated according to

$$P = \frac{I \Delta V}{m}, \tag{28.6}$$

where I is the constant current for charge–discharge, V is the potential range of a supercapacitor, and m is the mass of active material in the symmetric supercapacitor (including positive and negative electrodes).

The average specific capacitances measured using the three electrochemical techniques of the pure MWNTs, RuO₂/MWNTs, TiO₂/MWNTs, SnO₂/MWNTs, PANI/MWNTs, and PPY/MWNTs nanocomposite electrodes are 67, 138, 160, 93, 321, and 236 F/g, respectively (Table 28.1). The increase in the

Fig. 28.18 Complex-plane impedance spectra of pure MWNTs, RuO₂/MWNTs, TiO₂/MWNTs, and SnO₂/MWNTs nanocomposite electrodes in 1 M H₂SO₄ aqueous electrolyte/mass of each electrode, 10 mg [28.142] ◀

capacitance of MWNTs is mainly due to the functionalization of MWNTs with carboxyl groups, and for RuO₂/MWNTs, the increase is due to uniform dispersion of metal oxide particles over functionalized MWNTs. Since the specific double layer capacitance arises from the ionic double layer at the electrode–electrolyte interface, the accessibility of the active layer depends on the diffusion of solvated ions and more precisely on the pore size distribution. The central hollow core of the CNTs is also accessible for double layer charging, and thus the purified MWNTs with opened tips along with the unique network of mesopores formed by the entanglement of CNTs would have acted as sites for accumulation of charges. The enhancement of the specific capacitance can be attributed to the presence of RuO₂, TiO₂, and SnO₂ nanoparticles attached to the surface of MWNTs, which in turn modify the microstructure and morphology of MWNTs, allowing the metal oxides to be available for the electrochemical reactions and improve the efficiency of the composites. The progressive redox reactions occurring at the surface and bulk of transition-metal oxides through Faradaic charge transfer between electrolyte and electrode result in the enhancement of the specific capacitance of metal oxide-dispersed MWNT electrodes compared with pure MWNT electrodes. Of the various nonnoble metals or transition-metal oxides studied, TiO₂ enjoys a special place because of its cost-effectiveness and environmental friendliness.

28.3.4 Lithium-Ion Batteries

The nanoscale approach to electrochemical energy storage applications such as in lithium batteries has been of great interest because of their unique properties leading to improved performance [28.50, 145]. Innovative material chemistry has been the key to various advancements in lithium rechargeable batteries [28.47, 146]. Among various transition-metal oxide electrode

Fig. 28.19 Complex-plane impedance spectra of PANI/MWNTs and PPY/MWNTs nanocomposite electrodes in 1 M H₂SO₄ aqueous electrolyte; mass of each was 10 mg (after [28.143])

materials, manganese oxide (MnO₂) has been studied as an electrode for lithium batteries with high storage capacity, in addition to its low cost, environmental friendliness, and natural abundance [28.147–150]. However, its potential applications in practical Li-ion batteries are limited due to its poor electrical conductivity and large volume expansion during repeated lithium cycling process. One-dimensional (1-D) nanostructured morphologies of these electrodes with controlled size, crystallinity, and chemical composition have been designed to overcome some of these challenges [28.151, 152]. However, the conductivity of these 1-D nanowires remains an issue. Coaxial 1-D nanowires with tin oxide core and indium oxide shell nanostruc-

Table 28.1 Comparison of specific capacitance of supercapacitors obtained by different techniques

Electrode material	Cyclic voltammetry (F/g)	Galvanostatic charge–discharge (F/g)	Electrochemical impedance spectroscopy (F/g)	Average specific capacitance (F/g)
MWNTs	68	69	64	67
RuO ₂ /MWNTs	147	133	134	138
TiO ₂ /MWNTs	166	148	166	160
SnO ₂ /MWNTs	95	91	93	93
PANI/MWNTs	300	325	338	321
PPY/MWNTs	248	236	224	236

tures have been shown to be promising Li-ion battery electrodes [28.153]. Coaxial nanowires/nanotubes will lead to multiple functionalities by combining the physical properties of different materials. To build Li batteries with improved capacity and power capabilities, coaxial nanowires/nanotubes of multiple materials with specific electrochemical and physiochemical properties need to be fabricated. Careful engineering of hybrid coaxial electrode material having high storage capacity metal oxide and highly conducting CNT will lead to enhanced Li storage properties. The tubular morphology offers a unique combination of high porosity and low internal resistance. Such a coaxial electrode configuration will have:

1. Improved electronic conductivity due to the presence of CNT
2. Homogeneous electrochemical accessibility and high ionic conductivity by avoiding agglomerative binder and other conductive additives
3. Well-directed 1-D conductive paths due to perfect coaxial alignment
4. A dual lithium storage mechanism (insertion/deinsertion in case of CNTs and formation and decomposition of Li_2O in case of MnO_2 nanotubes) [28.154].

Figure 28.20 presents SEM images of MnO_2/CNT hybrid nanostructures, clearly showing the uniform coaxial nanostructure prepared by a combination of simple vacuum infiltration and chemical vapor deposition technique through a template approach. MnO_2 nanotube walls were found to be ≈ 10 nm thick with good crystallinity and smooth surface. The structure

Fig. 28.20a–c Textural characterization of MnO_2/CNT hybrid coaxial nanotubes. (a) Low- and (b) high-resolution SEM images showing the coaxial nature of the nanotube. (c) SEM image and schematic representation of a single coaxial nanotube; the MnO_2 shell and carbon nanotube core are clearly seen (after [28.154])

of the coaxial nanotubes, such as the MnO_2 shell thickness and nanotube length, could be easily controlled by varying the infiltration time, enabling the electrochemical properties of the coaxial nanotubes to be tuned. CNTs protrude from both ends of the nanotubes, enabling effective contact with the gold thin-film current collector. Recently, coaxial nanowires of MnO_2 /PEDOT have been synthesized by the co-electrodeposition method [28.155]. However, in case of the MnO_2 /CNT structure, the presence of the CNT core has superior advantages in terms of electrical conductivity, mechanical stability, and electrochemical performance. Also, high-temperature annealing results in high crystallinity of the coaxial nanostructure. The growth process for the coaxial nanotubes follows a typical template synthesis, wherein a manganese precursor initially combines with the template by impregnation and results in nucleation and growth following an annealing treatment. This forms the MnO_2 shell. The chemical vapor deposition (CVD) process allows CNTs to grow in the inner cores left by the MnO_2 shells. Upon template removal, coaxial nanotubes with CNT core and MnO_2 shell are obtained.

Apart from fast Li insertion/de-insertion, high electronic conductivity of the electrode materials is necessary to develop high-performance lithium batteries. The electrochemical performance of MnO_2 /CNT coaxial nanotubes as cathodes in Li batteries has been evaluated using galvanostatic charge–discharge measurements. Voltage versus specific capacity curves were obtained by cycling the cell at constant rate of 50 mA/g between 3.2 and 0.02 V versus Li/Li^+ (Fig. 28.21). A first discharge capacity of 2170 mAh/g and a reversible capacity of ≈ 500 mAh/g after 15 cycles were observed for MnO_2 /CNT hybrid coaxial nanotubes. A large irreversible capacity is observed, which could be due to drastic, lithium-driven, and structural or textural modifications, as observed for transition-metal oxide electrodes. The large irreversible capacity occurring only in the first cycle may be caused by decomposition reactions of the electrolyte and the formation of a solid–electrolyte interphase (SEI) film on the surface of the manganese oxide electrode [28.156]. A high reversible capacity observed for MnO_2 /CNT hybrid coaxial nanotubes compared with MnO_2 nanotubes indicates reduced structural changes. The reaction mechanism of different materials with lithium varies from classical Li insertion/de-insertion in the case of carbon-based materials to Li-alloying processes in the case of metal/alloy. With reference to transition-metal oxides, the reaction mechanism of manganese oxide

with lithium has been proposed to be [28.154]

Hence, the process involves the formation and decomposition of Li_2O , accompanying the reduction and oxidation of metal nanoparticles. Extraction of lithium from Li_2O is extremely difficult but has been shown

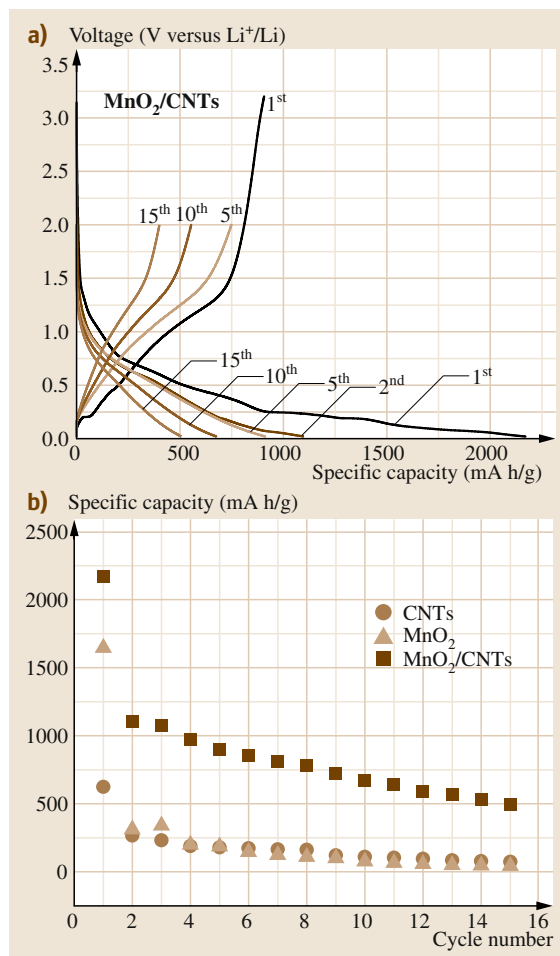

Fig. 28.21a,b Electrochemical properties of MnO_2 /CNT hybrid coaxial nanotubes as positive electrodes in Li battery. (a) Charge–discharge voltage profiles for MnO_2 /CNT nanotube electrodes cycled at rate of 50 mA/g between 3.2 V and 0.02 V versus Li/Li^+ . (b) Variation in discharge capacity versus cycle number for MnO_2 /CNT nanotubes, MnO_2 nanotubes, and carbon nanotubes (after [28.154])

to be possible with the use of nanosized materials. Bulk MnO_2 typically exhibited capacity no more than 120 mAh/g. Higher capacity values of nanofibers compared with their bulk counterparts were proposed to be derived from the large surface areas of the nanosized materials. However, there has been an inconsistency in the electrochemical behavior of MnO_2 nanotubes, presumably due to the different mechanisms of lithium insertion versus conversion reactions.

Thus, the coaxial hybrid structure formed by the highly conductive CNT core offers enhanced electronic transport to the MnO_2 shell and acts as a buffer to alleviate the volume expansion. CNTs provide additional sites for lithium storage, resulting in a dual mechanism of lithium storage, leading to enhanced reversible ca-

capacity for MnO_2/CNT hybrid coaxial nanotubes by an order compared with template-grown MnO_2 nanotubes.

An overview of synthesis methods for various carbon nanostructure has been presented. It is shown that CVD methods are promising for producing large quantities of CNTs. MWNTs, SWNTs and MWNCs have been synthesized by catalytic decomposition of appropriate hydrocarbons over alloy hydride catalysts obtained through hydrogen decrepitation route. The enormous potential of CNTs in Science and Technology has been illustrated by giving a short review of the several possible applications of CNTs with emphasis on their energy-related applications such as catalyst support material in PEMFC, supercapacitor electrode materials and Li-ion battery electrodes.

Nanomaterials

29. Nanomaterials in Civil Engineering

Jaesang Lee, Seunghak Lee, Eunhyea Chung, Vincent C. Reyes, Shaily Mahendra

Manufactured nanomaterials (MNM)s with unique physical and chemical properties have attracted a great deal of attention as key materials to underpin future scientific and technological advancements. Applications of MNMs can also provide breakthroughs in the construction industry by reinforcing mechanical properties, decreasing vulnerability to chemical corrosion and accidental damage, and providing supplementary functions such as anti-biofouling and hydrophilicity. With the enhancement of material performance and functionality, use of MNMs enables (partial) nonutility generation, low carbon emission, and self-assessment of structural health to increase the sustainability of buildings and infrastructures. On the other hand, recent research into the safety of MNMs has raised concerns about their adverse biological and environmental effects. There is a high probability that MNMs used in construction will have hazardous effects on human and ecological receptors, considering that MNMs incorporated into construction materials would be released via multiple exposure routes during their entire lifecycle (manufacturing, construction, demolition, and recycling/disposal). Consequently, to responsibly utilize the potential benefits of nanotechnology in construction, multidisciplinary efforts are required to develop proactive strategies to mitigate the environmental release of MNMs and guidelines to manage their environmental risks throughout construction-related activities.

Nanotechnology, as a new industrial revolution, has brought myriad opportunities to a variety of scientific, engineering, and technology sectors. The *bottom-up* synthetic strategy in the transitional zone between atom and molecule creates nanodimensional materials with novel physical and chemical properties, offer-

ing great potential for diverse applications including (photo)catalysts, electronic and electrochemical materials, energy conversion and storage devices, mechanical composites, and optical instruments [29.1–5].

The incorporation of various manufactured nanomaterials (MNM)s into the matrices of conventional

Fig. 29.1a,b Annual number of research articles published in the subject areas of (a) MNM-containing concrete/cement and (b) MNM-containing steel. The literature search was performed at the Scopus website using the keywords “Nano” and “Cement” or “Concrete” (a) and “Nano” and “Steel” and “Strength” or “Corrosion” (b)

construction materials leads to drastic advancement in vital characteristics including mechanical strength, fatigue and damage resistance, durability, and lightness [29.6–9]. MNMs as additives improve cohesive and tensile strength, flexibility, forgability, and weldability to enable facile construction and processing operations [29.8, 10]. MNMs incorporated into construction materials add new auxiliary functions such as photo-induced pollution control, antimicrobial activity, and heat- and sound-absorbing capacity [29.11–13]. Use of MNMs contributes to increased energy efficiency in commercial and residential buildings (e.g., highly insulating materials and energy-generating coatings) [29.14, 15]. Coatings of MNMs provide corrosion resistance, fire retardation, and water repulsion to protect construction materials from weathering, aging, and contamination, eventually promoting their long-term serviceability [29.8, 16, 17]. MNMs embedded in construction materials are also applied in sensing and monitoring functions to assess construction safety and structural health [29.18, 19].

Contrary to the general perspective on the promising applications of nanotechnology, technical viability has been relatively less explored in the construction industry, which is attributed to:

1. Lack of informative research to ensure the potential benefits and identify the functionalities,
2. Uncertainties associated with nanoscale materials' longevity and environmental health and safety,

3. Conservative nature of construction industry, leading to limited adoption of new technology, and
4. Economical feasibility.

Nevertheless, use of MNMs in the construction industry is expected to increase rapidly, as shown by the increasing number of research articles published on the subject of *nanconstruction* in Fig. 29.1 because of:

1. Recent advancement in harnessing unique nanoscale properties,
2. Rapid expansion of commercial interest in nanoenabled products,
3. Several research projects underway to assess and control potential hazards associated with engineered nanomaterials (NMs),
4. High performance and versatility of MNMs imparted at low additive ratios, and
5. Decreasing cost of base NMs due to their mass production.

In particular, despite the benefits of incorporating MNMs into construction materials, it is highly probable that concerns about their potential to become harmful environmental contaminants after their unwanted discharge limit their utility [29.20–22]. This underscores the need for assessment, standard protocols, and regulatory guidelines to address the environmental health and safety issues associated with manufacturing, transportation, use, and disposal of construction materials and products containing MNMs.

29.1 Applications of MNMs in Construction

The unique properties of MNMs can be exploited in construction for a variety of applications that encompass reinforced structural materials, low-maintenance and ecofriendly materials, multifunctional paints and coatings, renewable energy generation systems, and intelligent sensor/actuator devices (Table 29.1). The current and potential applications of MNMs in construction are described below, and some selected examples for MNMs used in construction and related MNM-containing products are illustrated in Figs. 29.2 and 29.3.

29.1.1 Concrete and Cement

Concrete is one of the most common manmade materials in the world. Conventional concrete is relatively strong in compression because fine and coarse aggregates such as sand and natural gravel in concrete efficiently carry the compressive load. However, traditional concrete has heterogeneous micro- and mesoporous structures through the random packing of concrete mixture of aggregates, cement, and water. Thus, it is weak in tension and flexure due to the complex internal pore

Table 29.1 MNM applications in the construction industry

Construction materials	Manufactured nanomaterials	Expected functions	References
Concrete/cement	Carbon nanotubes SiO ₂ nanoparticles Fe ₂ O ₃ nanoparticles TiO ₂ nanoparticles Ni nanoparticles CaCO ₃ nanoparticles	Crack prevention Abrasion resistance Stress level monitoring Self-cleaning Whitening Reinforcement Cement hydration improvement	[29.7–9, 23–26]
Steel	Cu nanoparticles Mg nanoparticles V nanoparticles Mo nanoparticles	Weldability Corrosion resistance Strength improvement Ductility Fracture toughness	[29.8, 10]
Plastic	Carbon nanotubes Nanoclays	Electric/thermal conductivity Flame retardancy High compressive strength Rot resistance	[29.27–31]
Window	WO ₃ nanoparticles LaB ₆ nanoparticles SnO ₂ nanoparticles Ag/TiO ₂ nanocomposites TiO ₂ nanoparticles SiO ₂ nanoparticles Al nanoparticles	Infrared-absorbing UV and heat blocking Light transmittance control Antireflectivity Photo-induced depolluting Stain-proofing Antifogging Scratch and wear resistance Fire-protective	[29.11, 14, 32–38]
Coatings	SiO ₂ nanoaerogols Carbon nanoparticles Ag nanoparticles TiO ₂ nanoparticles ZnO nanoparticles Fe ₂ O ₃ nanoparticles Zn nanoparticles	Thermal insulation UV and heat blocking Antimicrobial activity Dirt-proofing Corrosion inhibition Fire resistance	[29.14, 16, 20, 39–45]
Solar cells	TiO ₂ nanoparticles CdSe quantum dots C ₆₀ fullerene Carbon nanotubes	Nonutility electricity generation	[29.15, 46, 47]
Lighting	GaN nanoparticles GaAsP nanoparticles	LED phosphors	[29.48, 49]
Sensors	BaTiO ₃ nanoparticles Carbon nanotubes	Real-time monitoring of concrete strength and structural health	[29.18, 19, 50]

structure of the concrete. There are several possible explanations for the improvement of mechanical properties by MNMs [29.7]. Firstly, nanosized materials fill the cement pores and serve as packing materials in concrete. Secondly, nanoparticles (NPs) promote cement hydration through tight binding with the cement hydrate. Finally, NMs efficiently inhibit the growth of large crystals (e.g., Ca(OH)₂).

NPs have been applied to improve compressive strength during the past decade. Research into SiO₂, TiO₂ or Fe₂O₃ NPs used as a concrete additive material has shown that these nanosized particles serve

as a filling agent to increase the strength of the concrete and improve its abrasion resistance [29.23–25]. Addition of silica NPs as a part of the mixture also enhances the durability of the concrete by blocking water penetration. SiO₂ NPs can control the degradation of (CaO)·(SiO₂)·(H₂O), which is the product of the cement hydration process, by blocking water entry into the pores [29.8]. In addition, the weight of concrete would be reduced by using silica fume. Hematite (Fe₂O₃) NPs can be used as a monitoring material to quantify the stress levels by measuring section electrical resistance as well as a packing material [29.8]. Research into

Fig. 29.3a–d MNM-containing construction products and their applications. (a) Concrete (source: US Department of Transportation Federal Highway Administration); (b) window glass (source: NBNL); (c) rooftop solar panel (source: US Department of Energy); (d) bridge (source: MCEER, the State University of New York Buffalo)

carbon-encapsulated nickel NPs incorporated into concrete also demonstrated an increase in the compressive strength of the cement due to the intense antiparallel ordering caused by a magnetic dipole interaction [29.7].

TiO₂ NPs have other supplementary functions when applied to cement/concrete, such as sterilizing and self-cleaning, as well as filling the pores [29.26]. TiO₂ as an ultraviolet (UV)-responsive photocatalyst yields reactive oxygen species (ROS) under light irradiation, resulting in destruction of volatile organic compounds, NO_x, and bacterial membranes. Due to the UV-activated hydrophilic conversion, rain droplets attracted to an outdoor surface containing nano-TiO₂ particles form a water layer which can wash away airborne pollutants, as airborne pollutants trapped in a TiO₂ particle matrix undergo further oxidative degradation under sunlight illumination. Since TiO₂ particles form a white pigment, nano-TiO₂-added concrete has the additional advantage that it can retain whiteness during the lifetime of the concrete. Incorporation of nano-TiO₂ into concrete has already been commercialized in the construction industry. The Jubilee Church in Rome was constructed from precast nano-TiO₂-integrated concrete panels, which is sometimes called *white concrete* [29.8]. Prior to the Jubilee Church, nano-TiO₂ was incorporated into road surfaces, and it was found that the NO_x concentration was significantly decreased near the constructed road [29.8].

CaCO₃ NPs have also been suggested as supplementary materials for addition to cement. Strength development during the initial period of cement hydration is significantly improved when nano-CaCO₃ is added [29.9]. The mechanism behind the improved cement hydration rate by nano-CaCO₃ needs to be further investigated, but the difference in the impact on hydration between micro-CaCO₃ and nano-CaCO₃ provides evidence that the size of the calcium carbonate particles plays a significant role in the hydration process. Another possible use of calcium carbonate as a biosealant in concrete is being studied [29.8]. Anaerobic microorganisms are incorporated into concrete mixing water, and subsequently excrete calcium carbonate, which fills the cement pores and results in improved compressive strength. Similarly, self-healing concrete in which microcapsules containing healing agents and catalysts are embedded is being investigated to solve crack problems of concrete [29.51]. When cracks form in the concrete, the capsules would be ruptured. The released healing agent then contacts the catalyst, and the crack will be filled through polymerization.

Traditionally, steel has been incorporated in conventional concrete as a *reinforcement bar (rebar)* in order to strengthen the concrete in tension and flexure, but the process of placing steel bars and introducing wet concrete is time consuming and expensive. Cracking due to rebar corrosion or freeze–thaw cycles is also an issue for steel-reinforced concrete. Glass, plastic, or steel fibers have sometimes been added to produce reinforced concrete. These materials can either replace the steel rebars entirely or be added to concrete already reinforced by steel bars. Concrete reinforced with fibers, for example, carbon graphite fiber, which is a corrosion-proof and very high strength-to-weight material, is less expensive and has still higher tensile strength. Nanosized fibers were recently studied as an alternative reinforcing material for concrete. Reinforced concrete was produced by introducing nano- and micro-sized carbon fibers [carbon nanotubes (CNTs)] and centimeter-sized carbon graphite fibers, exhibiting improved mechanical properties [29.6, 52]. Incorporation of CNTs is expected to show advantages over traditional fibers in reinforced concrete due to their distinct structural properties. CNTs are known as the strongest and stiffest materials in terms of tensile strength and elastic modulus, respectively. Therefore, they would improve the mechanical properties of the concrete. Also, the small size of CNTs should make them fill the cement pores and interrupt crack formation and growth at very early stages. On the other hand, the high aspect ratio of CNTs would play a role in preventing crack propagation, because higher energy would be required to propagate the crack around the nanotubes. In addition, CNTs can be chemically functionalized to interact with adjacent cement component. A recent study demonstrated that CNTs in concrete act as a nucleus to bind tightly with cement hydrate (C-S-H) around functionalized nanotubes [29.53].

In spite of their many advantages, there are economic and technical limitations to the use of CNTs in reinforced concrete. The cost of CNTs is still high and not competitive with other fiber materials. Furthermore, CNTs tend to form aggregates due to van der Waals forces, thus additional processes are required to achieve uniform distribution of individual tubes. Another issue with CNTs is weak bonding between the nanotubes and the cement matrix. Several research studies have been conducted to tackle these problems by functionalizing the nanotubes or through the use of surfactants and sonication to achieve uniform dispersion [29.27].

29.1.2 Steel

Steel has served as a reinforcement material in concrete or as a structural component in bridges, highways, or buildings by itself. In addition to its corrosion resistance, steel is also selected based on properties such as strength or weldability. Welding is one of the steel fabrication processes and creates a sector called the *heat-affected zone (HAZ)* adjacent to welds. The material properties of the HAZ are altered by heat-intensive cutting or welding processes, thus the HAZ and welds are brittle and can fail easily when a sudden dynamic load (e.g., seismic load) is applied. Addition of nanosized particles such as magnesium and calcium improves the weld toughness of steel as well as decreasing the size of the HAZ to 1/5 of that of conventional welded steel [29.8]. Not only improvement of toughness at welded joints, but also cost-saving due to the decreased material requirement to meet allowable limits is also expected when research currently underway is completed.

High-strength steel experiences delayed fracture problems, in which the steel material becomes brittle and fractures following exposure to hydrogen when strong tension is applied. Vanadium and molybdenum NPs have been incorporated to reduce the effects of hydrogen embrittlement and, therefore, to improve the delayed fracture problem of high-strength steel materials, especially high-strength bolts [29.8].

Many efforts have been made to improve the corrosion resistance of steel using nanotechnology, but very few products are available in the construction market. One of them is MMFX2 steel, which has a distinct nanostructure. A laminated lath structure resembling plywood in MMFX2 makes the steel corrosion resistant by hindering microgalvanic cell formation. In addition, according to the manufacturer, the unique features of the product provide improved strength, ductility, and toughness compared with conventional steel products. MMFX2 steel is currently used in many construction sites including bridges, parking structures, buildings, and highways. The Federal Highway Administration, the US Navy, and the American Iron and Steel Institute developed high-performance steel for bridges in 1990s. This new steel has higher fracture toughness, improved weldability, and better corrosion resistance than conventional steel by incorporating copper NPs, which are known to reduce the surface roughness of steel [29.10]. Another steel product available in the commercial market, but not for construction applications, is Sandvik Nanoflex. Although the manufacturer does not provide

detailed information about the product, it is reported that very hard NPs are incorporated in the Sandvik Nanoflex steel matrix. Therefore, Sandvik Nanoflex has good corrosion and wear resistance and high modulus of elasticity.

Several ongoing research efforts focus on production of nanoscale fabricated metals, which are stronger than conventional steel or titanium. Such metals would be fabricated by weaving the material to produce ultra-fine lattice structures or refining the cementite phase of steel to nanosize to produce cables [29.8]. The expected properties of such products are improved strength and reduced weight, and one of their applications could be as a structural component of suspension bridges.

29.1.3 Plastic

Multi-walled CNTs as a proxy for carbon black show improved performance as a filler material, drastically increasing the mechanical strength and electric and thermal conductivity of plastic composites [29.27, 28]. CNTs incorporated into plastics also function as a flame retardant to enable rapid heat dissipation, preventing the possible release of hazardous gasses under fire [29.29]. Addition of nanoscale ceramic materials (e.g., nanoclays) to the polymer matrices creates lightweight nanocomposite plastics with high compressive strength [29.30]. Wood-plastic composites produced by manipulating fiber-to-fiber bonding at the nanoscale, which require much less maintenance and have a long service life because of their high rot resistance, gain improved mechanical properties through modifications using carbon nanofibers and nanoclays [29.31].

29.1.4 Window Glass

Incorporation of MNMs into glass matrices allows the production of windows to control the passage of light and heat through the walls of buildings. Such applications can increase energy efficiency by reducing heat loss to conserve building heating energy (e.g., low-emissivity glass) and by blocking solar heat to curtail energy consumption for air-conditioning and ventilation (e.g., heat absorbing and solar control glass). Due to its strong visible and infrared absorption, nanosized tungsten oxide (WO_3) improves the heat reflectivity of a window to simultaneously reflect in-room heat back inside and mitigate solar heat gain through the window, and further enables variable light transmission [29.32]. Window glass containing lanthanum hexaboride (LaB_6)

NPs that selectively capture the heating wavelengths from 750 to 1300 nm secures sufficient natural daylight while maintaining uniform room temperature in hot weather seasons by transmitting visible light and blocking unwanted infrared light from the solar spectrum [29.11]. Nanostructured indium tin oxide (ITO) (or indium antimony oxide) film also creates highly transparent infrared-absorbing coatings on window glass, being commercialized under the product name AdNano ITO [29.11, 54]. Ultrafine TiO_2 , ZnO, and $\text{TiO}_2/\text{CeO}_2$ uniformly cast on glass surfaces produce UV-reflecting windows by filtering out the UV fraction of sunlight without significantly decreasing visible light transmittance [29.8, 14, 33, 34]. In this case, rutile TiO_2 NPs with low photoactivity are in common use to avoid unwanted photocatalyzed destruction of surrounding matrices, as ZnO NPs are surface-modified with silica to facilitate homogeneous dispersion on the surface [29.14].

Light transmittance through the window can be controlled by photochromic coatings or layers that reversibly change their inherent color in response to incident light [29.55]. Photochromic films formed of MNMs including metal NPs, hybrid metal/metal oxide NPs, and quantum dots (QDs) can produce *smart windows* that react to light conditions, controlling the intensity of incident light, being translucent in the visible region to brighten interior spaces, or being reflective in the infrared region to retard thermal transfer [29.35, 36, 56–58]. Photochromic films containing platinum, palladium, or gold NPs exhibit coloration/color fading characteristics under light irradiation [29.57]. Dark-blue color rapidly develops on TiO_2 films in combination with phosphotungstic acid ($\text{H}_3\text{PW}_{12}\text{O}_{40}$) under UV irradiation and disappears in the presence of oxygen as an electron acceptor in the dark condition, as MoO_3 or WO_3 films coated with gold or platinum also undergo reversible UV-induced coloration on the window [29.35, 36]. In particular, TiO_2 film loaded with silver NPs on the window enables repeatable multicolor photochromism in which the initial brownish-grey color rapidly changes to the color of the excitation wavelength under irradiation by monochromatic visible light [29.58]. In addition to the photosensitive smart window, thermochromic glass that includes polymeric layers doped with various transition metals (e.g., Fe, Co) or metal/metal oxide nanocomposites (e.g., Au/VO_2) also modifies the transmission and reflection properties, adapting to the surrounding temperature to create a nonelectrically activated window to regulate daylight depending on the background thermal conditions [29.59, 60].

Antireflective coating of silica NPs causes micro- and nanoroughness on the glass surface, reducing the magnitude of visible light reflected and offering a clear view from inside to outside [29.14]. Vertically oriented pure rutile TiO_2 nanorods on glass substrate also form an antireflective coating [29.61]. Note that 20% of the incident light is reflected at the TiO_2 –air interface, while the reflection at the uncoated glass–air interface is as low as 4%. Alternating layers of SiO_2 and TiO_2 NPs that exhibit a large refractive index contrast significantly improve light transmission through the window [29.14, 62].

Deposition of nano- TiO_2 on window glass offers a self-cleaning function under irradiation by sunlight or indoor light, because TiO_2 can photosensitize production of ROS such as OH radicals, valence-band holes, and relevant efficient oxidation of organic substrates [29.2, 63]. The photocatalyzed reactions initiating on nanosized TiO_2 -coated glass lead to photooxidation of hydrocarbons and photokilling of pathogenic microorganisms attached to the window and from the surrounding atmosphere [29.37, 64]. In particular, metal or nonmetal doping allows TiO_2 NPs to utilize visible light for photocatalytic ROS generation. Photoinduced hydrophilic conversion occurring on a TiO_2 surface, which makes water spread out over the surface rather than remain as droplets, mitigates accumulation of hydrophobic dirt, as the increased density of surface hydroxyl groups under exposure to UV light enables antifogging and stain-proofing actions of the TiO_2 -modified window [29.65, 66]. Such a photo-driven process for surface hydrophilization can be kinetically accelerated on TiO_2 -based composite layers (e.g., TiO_2/WO_3 or $\text{TiO}_2/\text{SiO}_2$) [29.67, 68].

Inclusion of metal-oxide NPs can improve the mechanical strength, thermal stability, and chemical durability of window glass. Incorporation of aluminum nanopowders enhances the mechanical strength, microhardness, and chemical resistance of glass without significantly changing its optical properties [29.38], as silica NPs make windows highly scratch and wear resistant [29.14]. Nanoscale silica layers sandwiched between two glass panels form fire-protective window glass in which silica NPs swell, converting to mechanically reinforced and opaque forms in the event of a fire [29.8].

29.1.5 Coatings

Coatings utilizing MNMs are expected to impart diverse supplementary functionalities to construction-related

surfaces and produce the desired protective and resistant surfaces on existing construction materials. Use of MNMs for thermal insulation leads to energy conservation and carbon emission reduction through efficient heat management. Due to the large surface-to-volume ratio and high porosity, nanoporous silica as an insulator enables significant air entrapment within a layer of minimal thickness, thereby effectively hindering heat transfer across the layer [29.14, 20]. Aerogels or nanofoams of metal oxides (e.g., silica and alumina) that contain nanoscale pores primarily filled with air (> 90%) can be employed for ultrathin and lightweight insulating coatings (relative to conventional insulating layers of polystyrene or cellulose) [29.14, 20]. Three-dimensional and highly branched networks of SiO₂, TiO₂, or carbon NPs show exceptional insulative performance because nanosized cells, pores, and particles within the unique nanostructures produce substantially limited pathways for thermal conduction (through the interconnected NPs) and thermal energy transport (through the enclosed air molecules) [29.8, 14, 20].

Metallic NPs (e.g., silver and gold) produce antimicrobial coatings on diverse construction materials including cement/concrete, steel, plastic, and glass [29.14, 39–41]. The antimicrobial activity of silver NPs embedded in paint leads to efficient inactivation and sterilization of pathogenic microbes on the substrate surface [29.12]. Silver or gold NPs dispersed in polymer matrices form antibacterial metal/polymer nanocomposite coatings, hindering microbial adhesion on the substrate material [29.40, 41]. Thin films of metal-oxide-based semiconductor NPs (e.g., TiO₂ and ZnO) on pavements, walls, and roofs function as antifouling and self-cleaning coatings under solar irradiation to depollute airborne contaminants, protect construction products from stains and dirt, and inhibit growth of bacteria and mold on the surface [29.42, 69]. Micro- and nanopatterning reduce the surface energy and associated adhesion [29.70], offering water-repellant surfaces for construction products and making them less susceptible to dirt accumulation.

Thin films of ceramic NPs (e.g., SiO₂), which are highly resistant to oxidation, can function as physical barrier layers to protect metallic construction materials against corrosion [29.16]. TiO₂ NPs surface-modified with fluoroalkylsilane form hydrophobic coatings on the surface of stainless steel to prevent moisture-induced corrosion [29.17], as photogenerated conduction-band electrons are transferred from TiO₂ coatings to the corroding metals, providing corrosion resistance properties under solar irradiation [29.71].

Ultrafine metal-oxide particles (e.g., SiO₂, ZnO, and Al₂O₃ NPs) can serve as nanofillers for polymer-based coatings, thereby preventing infiltration of oxygen, water, and corrosive chemicals through the voids and cracks present in the polymer matrices [29.43]. Polymer encapsulation of nanosized Zn or Fe₂O₃ as anodic-type corrosion inhibitors leads to prolonged anticorrosion performance on the coated steel [29.43]. In particular, composite materials having metal-oxide core (e.g., CeO₂, SiO₂, TiO₂, and ZrO₂ NPs) with polymer shell responsive to an electric or mechanical trigger can produce *smart* corrosion-proof coatings by acting as nanoreservoirs to store organic corrosion inhibitors and release the entrapped reagents when external signals are applied [29.16]. In addition to corrosion resistance, nanosized SiO₂, TiO₂, and Sb₂O₃ as nonflammable fillers or additives reduce the thermal transfer rate, and improve the existing fire-resistant properties of polymer coatings or decorative paints [29.44, 45].

Flexible solar panels that utilize silicon-based photovoltaic or dye-sensitized TiO₂ solar cells are being integrated into roofing membranes and mounted on windows, converting solar energy to generate electric power available for homes and buildings. The solar energy coating as a partial nonutility power producer achieves improved efficiency of renewable energy generation through the incorporation of semiconductor QDs (e.g., CdSe and InAs) [29.15] and carbon-based NMs (e.g., C₆₀ and CNTs) [29.46].

29.1.6 Lighting

A light-emitting diode (LED) employs inorganic semiconductor NPs (e.g., GaN, ZnSe, and GaAsP) with different band-gaps and produces various colors of light as a result of electroluminescence [29.48, 49]. LED devices are rapidly replacing conventional fluorescent and incandescent light bulbs because LEDs require low electric energy for lighting, provide long service life, and guarantee safe end-of-life management (i.e., no release of toxic metals).

29.1.7 Sensors

Nano- and microelectromechanical systems (NEMS and MEMS) can be applied as miniaturized implantable devices to allow real-time in situ monitoring and accurate assessment of the health status of construction materials/structures (e.g., cracking and stress) and environmental conditions (e.g., temperature, humidity, and pressure) [29.72]. In addition to nondestructive evalu-

ation, NEMS and MEMS can also enable an effective strategy for quality management in cement/concrete construction by in situ observation of the cement hydration process, cement/concrete hardening, and strength development [29.73]. Piezoelectric materials such as BaTiO₃ and PbTiO₃ that can convert mechanical force and stress to an electric charge create *intelligent aggregates* or *smart aggregates* that can be embedded into concrete blocks to monitor initial concrete strength and structural health [29.18]. Uniform dispersion of

piezoelectric ceramic NPs into the polymer matrices forms sensor coatings to detect crack initiation and development and track the structural response to impact damage [29.74]. CNT/polyelectrolyte thin films fabricated by the layer-by-layer (LBL) method cause a change in electrical resistance in response to mechanical stress (i.e., piezoresistive characteristics), suggesting potential application as a high-resolution strain-sensing system in concrete structures [29.50].

29.2 Environmental Release of MNMs Used in Construction

With the projected rapid increase in MNM use for construction materials, the possible release into the environment and associated human exposure have become areas of growing concern [29.75–80] (Fig. 29.4). Although numerous studies have reported toxicological impacts of NMs, a knowledge gap still remains with respect to the environmental risk of NMs associated with their exposure pathways for the potential receptors (ecosystems and human beings). In particular, while a limited body of literature has focused on the environmental fate, behavior, exposure, and toxic effects of MNMs as raw materials prior to further processes toward an end-product [29.76, 77, 80–82], there are few safety and health considerations and lifecycle studies regarding MNMs incorporated into construction products and the resultant MNM wastes generated during construction activities. The identification of possible sources, environmental release scenarios, and exposure routes of MNMs used in construction is critical in assessment of their overall environmental hazard and risk,

and development of countermeasures. Therefore, the possible exposure scenarios via multiple routes for environmental discharge of MNMs used in construction are considered herein based on previous published studies and typical construction practices.

29.2.1 Construction Material Manufacturing

It is highly probable that the manufacturing stage will be the major source for environmental release of MNMs during the whole lifecycle of NM-containing construction products. MNMs that are not properly bound or incorporated into the basic materials such as concrete, steel, glass, etc. can directly disperse into the surrounding environment. During specific manufacturing processes including coating, molding, compounding, and incorporation, unintentional emission of MNMs into the atmosphere can occur as the primary pathway for environmental discharge, resulting in possible exposure of manufacturing workers via inhalation; For

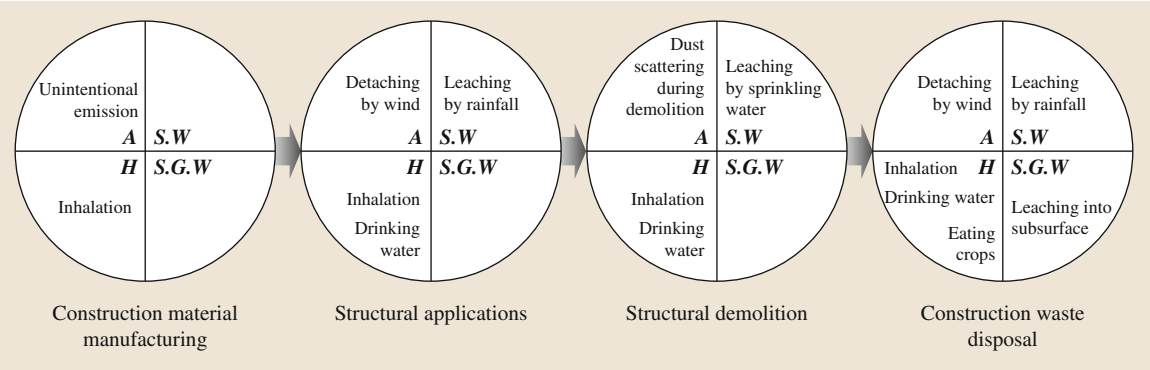

Fig. 29.4 Primary pathways into the environment and corresponding exposure routes to humans expected during the lifecycle of MNMs used in construction (A for air; S.W. for surface water; S.G.W. for soil and groundwater; H for human)

example, airborne NPs could be blown away during weighing of raw materials, and the aerosol type of fullerenes and CNTs could be emitted while treating carbon NMs in a sonicator for better dispersion in liquid media [29.83]. The risk assessment worksheet on the DuPont Light Stabilizer reported that nano-TiO₂ particles could be released during the packaging process over the acceptable level [29.84]. Sepiolite nanoclay used as a filler material in construction nanocomposites would be likely released into the air during early manufacturing processes of mining and transporting [29.85]. In closed manufacturing facilities, indoor air control using ventilation systems, dust collectors, and personal protective equipment such as masks, coveralls, and gloves locally mitigate exposure of workers to MNMs released from manufacturing and related processes.

29.2.2 Structural Applications

MNMs could be released into the environment from buildings and associated infrastructures constructed with nanorelated materials. Use of NM-containing construction products makes individuals and communities in commercial and residential buildings more susceptible to exposure to MNMs [29.31]; For instance, they could be exposed to MNMs incorporated into wallpapers, glasses, paints, etc. through inhalation, dermal contact, or accidental digestion. Wear and abrasion of such structures by accidents (e.g., fire, car crash or earthquake) or weather (e.g., rainfall, snow, and wind) can cause immediate or gradual weathering of MNMs from basic construction materials, increasing the potential for adverse effects on environment and human health. TiO₂ NPs used in exterior paints of building facades as a whitening pigment have been found in building runoff after rainfall [29.79]. MNMs suspended in runoff could be deposited on the topsoil in the surrounding area, and could be delivered to ecological receptors including plants, soil invertebrates, and soil microbes. MNMs released from structures could be transported through sewerage systems to enter adjacent surface waters, posing an immediate threat to aquatic habitats and deteriorating drinking-water quality. Also, MNMs could possibly infiltrate into the subsurface in significant quantities to reach and contaminate groundwater.

29.2.3 Structural Demolition

Partial or complete demolition of structures containing MNMs would also result in personal ex-

posure to and environmental discharge of MNMs. Pulling down buildings and infrastructures proceeds in a relatively less controlled way, whether it is achieved by nonexplosive (using bulldozers, cranes, or hydraulic excavators) or explosive (or implosive) demolition practices. Consequently, it would be difficult to protect workers from the possible uptake of nano- and ultrafine particles and control their emission to the atmosphere during demolition activities. In addition to particulate emissions, water sprinkled on demolition waste to reduce dust levels could cause dissolution and suspension of MNMs and their subsequent transport to the aquatic environment. Demolition debris could emit hazardous wastes when NM-related components are not separated or eliminated beforehand. Proactive steps by trained specialists should be taken to preferentially dispose of NM-containing products such as windows, coatings/paintings, and sensor devices prior to the overall demolition operation.

29.2.4 Construction Waste Disposal

In general, construction (and demolition) wastes are transported to designated landfills equipped with engineered liner systems and leachate treatment facilities. However, environmental exposure to MNMs and associated adverse health effects would potentially arise if construction wastes containing MNMs are not properly treated and disposed of, e.g., dumped in shallow unlined pits or piled up in the open air. Furthermore, there is a high likelihood that construction debris, if disposed of with MNMs not encapsulated within sound structures, would discharge MNMs in the presence of prolonged exposure to rainfall or wind; For example, concrete debris exhibits high vulnerability to wind- or rainfall-induced erosion on the cleaved surfaces, which could lead to detachment of MNMs from NM-concrete debris in construction wastes and associated environmental release of free MNMs. Once MNMs in free particulate form are leached out from construction wastes, they would enter environmental media through various pathways. While MNMs initially undergo dispersion in air or in solution or suspension in runoff, it is highly probable that most MNMs released into the environment would penetrate into the subsurface and eventually reach groundwater aquifers. Despite limited mobility in soil (relative to air and aqueous media), CNTs and TiO₂ NPs could migrate significant distances through porous media (soil and groundwater) in the presence of dissolved organic matter in the pore water [29.81, 86].

For the overall risk assessment, further research should focus on the fate, behavior, and transport of MNMs in multiple environmental media [e.g., air, groundwater, sediment, (surface and subsurface) soil, or surface

water] and environmental transformation processes for MNMs and associated modifications of their chemical structures, reactivity, mobility, bioavailability, and toxicity.

29.3 Potential Adverse Biological Impacts and Toxicity Mechanisms

The development of MNMs for the construction industry may produce unintentional environmental and human health impacts as a result of their unique chemical, biological, catalytic, and photoactive properties. Toxicological studies of these materials have shown that MNMs display a wide variety of toxicity mechanisms to organisms at every trophic level [29.87]

(Fig. 29.5). Therefore, release from nanoenabled construction materials and structures could pose a risk to microorganisms (which provide valuable ecosystem services including primary productivity, nutrient cycling, and waste degradation) and higher organisms. These toxic responses include cell wall disruption (e.g., single-walled nanotubes, SWNTs), DNA/RNA damage

Fig. 29.5a,b Possible toxicity mechanisms of nanomaterials in (a) mammalian and (b) bacterial cells

(e.g., multi-walled nanotubes **MWNT**), direct cell membrane oxidation (e.g., nC_{60}), dissolution of toxic metal components (e.g., **QDs**), and **ROS**-induced oxidative stress (e.g., TiO_2) (Table 29.2).

29.3.1 TiO_2

TiO_2 **NPs** possess unique photocatalytic properties as **UV** light or sunlight irradiation of particles produces **ROS**, which can cause inflammation, cytotoxicity, and **DNA** damage in mammalian cells [29.88–98]. In addition, slight variations in TiO_2 morphology affect their uptake through cell membranes by stimulation of phagocytosis, and encourage endogenous **ROS** generation as an immune response within the cell matrix [29.94, 99]. Compared with their bulk counterparts, they exhibit differential toxicity [29.100]; for example, in one study, nano- TiO_2 displayed greater induction of apoptosis and white blood cell generation [29.101].

TiO_2 elicits similar **ROS**-derived toxicity in unicellular microorganisms. Solar irradiation enables the antimicrobial activity of TiO_2 towards various bacteria, including *Escherichia coli*, *Micrococcus luteus*, and *Bacillus subtilis*, and fungi, such as *Aspergillus niger* [29.13, 102, 103]. Membrane damage and particle adhesion are implicated as other mechanisms of toxicity [29.104]. Additionally, nano- TiO_2 appears to have a synergistic effect with other co-contaminants; For example, nano- TiO_2 toxicity and metal bioaccumulation were increased in the marine invertebrate *Daphnia magna* after simultaneous exposure with copper [29.105], and in carp species after simultaneously exposure with cadmium [29.106].

29.3.2 Quantum Dots

QDs contain toxic heavy metals such as cadmium, lead, and zinc in core/shell configurations [29.107] and have been recognized as among the most toxic materials [29.108]. The release of core metals has been accepted as the predominant mechanism of **QDs'** toxicity towards mammalian cells [29.109–114] and bacteria [29.115, 116]. In human cells, toxicity can manifest as **ROS** damage to organelles and release of inflammation signaling proteins [29.117, 118]. In whole-organism toxicity trials, mice displayed particle accumulation in the spleen, liver, and kidneys [29.119], while microorganisms, such as bacteria and algae, experience growth inhibition, cytotoxicity via lipid peroxidation, oxidative stress, and cellular particle uptake [29.115, 116, 120].

Toxicity, however, is not solely the result of metal ion release; some coating materials themselves may also be toxic [29.95, 117, 121]; For example, intact **QDs** can impair calcium influx and exocytotic mechanisms in murine brain cells [29.122]. It was also observed that eukaryotic cells experience oxidative stress, nucleic acid damage, and cytotoxicity resulting from internalization or membrane association with **QDs** [29.118, 119, 123]. Furthermore, gene expression studies in algae show that **QDs** elicit different responses compared with exposure to their respective ions [29.124].

29.3.3 Carbon Nanotubes

CNTs (**SWNTs** and **MWNTs**) pose a potential hazard [29.125] because they exert acute toxicity through **ROS** generation, inflammation, cell cycle arrest, and increased apoptosis in human and mammalian cells [29.126–128]. Trails of human cells exposed to chronically low doses show accumulation within cells and no adaptive protective mechanism development [29.129]. Extensive testing of whole organisms has been performed for **CNTs**. In rodent toxicity experiments, exposure through inhalation resulted in pulmonary toxicity such as inflammation, fibrosis, and epithelioid granulomas [29.125, 130]. In contrast, exposure through oral dosing resulted in increased weight gain, morphological changes to the liver, and increases in lipid hydroperoxide [29.131].

Both **SWNTs** and **MWNTs** can also exhibit antimicrobial properties. Recent studies have shown **CNTs** to inhibit bacterial processes in river water, activated sludge, and wastewater effluent, which are likely sinks for **CNTs** released into the environment [29.132, 133]. The mechanism of microbial toxicity of **SWNTs** appears to be direct damage to cell walls [29.133, 134], while **MWNTs** cause toxicity via oxidative stress [29.135, 136]. The antimicrobial properties appear to also be related to aggregate size [29.137] and interactions with bacterial extracellular polymeric substances (**EPS**) [29.132].

29.3.4 C_{60} Fullerene

C_{60} water-stable aggregates (referred to as nC_{60} [29.138]) display toxicity to human and mammalian cells ranging from lipid peroxidation to necrosis and inflammatory responses [29.138–152]. Meta-analysis of rodent lung exposure data suggests that levels as low as the mg/m^3 range can elicit a toxic response in mammalian cells [29.153, 154]. nC_{60} aggregates dis-

play broad antimicrobial activity independent of the preparation method, i.e., solvent mediated, sonication, or prolonged stirring in water [29.145, 147, 155]. Recent studies confirmed that nC₆₀ toxicity to bacteria was due to direct oxidation of the cell upon direct contact rather than by ROS-dependent oxidative stress [29.146, 156]. Oxidative stress exerted by nC₆₀ leads to lipid peroxidation, which is also responsible for cytotoxicity in eukaryotic organisms [29.141, 151, 157]. C₆₀ derivatives such as fullerol and carboxyfullerene, designed to enhance their aqueous availability, are capable of puncturing the cell membrane [29.158] and behaving as oxidizing agents in biological systems [29.159].

29.3.5 SiO₂

The effect of silica NPs on human and mammalian cells has been studied extensively because of their extensive use in biomedical and industrial applications [29.154, 163, 166–170, 176, 177]. Exposure to nanosized SiO₂ triggers lipid peroxidation and membrane damage to human lung cancer cells [29.178], induces tumor necrosis genes in rats [29.170], and exerts carcinogenic activity [29.179]. While microbial toxicity occurs at higher doses as compared with mammalian cells [29.154, 180], nanosized silica causes toxicity via ROS gener-

ation [29.154] and impedes cell division in unicellular algae [29.163]. While the exact mechanism of toxicity is unclear, it has been related to size and relative surface area, where particles with greater surface area were more toxic to both mammalian [29.181, 182] and algal cells [29.183]. Regarding toxicity to microorganisms, studies suggest that toxicity is related to direct attachment and interaction of the particles [29.164, 165, 183].

29.3.6 Copper/Copper Oxide

Cu and CuO NPs induce oxidative stress, which can result in membrane, protein, and DNA damage in bacteria, algae, yeasts, mice, and human cells [29.91, 97, 160, 171, 184]. Oxidative toxicity results from ROS generation by copper ions via Fenton or Haber–Weiss reactions [29.185]. Furthermore, Cu NPs can exert toxicity over a range of lethal and nonlethal doses; For example, studies in mice showed that low, subtoxic doses of Cu NPs elicited the same cell stresses characteristic of higher doses [29.173]. While Cu NP toxicity is primarily linked to the bioavailability of free ions in the exposure media [29.161, 172], recent studies have found that ions cannot explain the total toxicity, and unique nanoproperties may also contribute to toxicity [29.162].

29.4 Mitigation of Environmental and Health Impacts

The most pressing challenges facing the construction industry community in using nanoenabled construction materials include manufacturing of safe materials without significant modifications of their unique desired properties, applications of NM-containing materials with minimal hazard during their service life, and recycling and disposal to reduce waste materials and prevent soil and groundwater contamination. Thus, it is important to discern the chemical compositions, structures, and associated properties of NMs that are essential for their characteristic toxicological activities and environmental behaviors. Such investigation provides basic information for the design of safer products under consideration of exposure control (e.g., protective coatings and magnetic composites) and adoption of greener substitutes for toxic MNMs. The assessment of exposure routes, environmental fate, and transport for MNMs used in construction, with development of analytical methodologies to trace MNMs in multimedia, should be critical in controlling environmental pollution related to construction activities and establishing the strategy

for waste management (e.g., separation/collection, recycle/reuse, and disposal).

29.4.1 Manufacturing

Chemical structure–activity relationships that elucidate which specific properties of MNMs are critically associated with their environmental behavior and toxicological activity are urgently required. In the absence of empirical data on various MNMs, these will provide a foundation to develop strategies to mitigate hazards and assess exposure scenarios and pathways. Physicochemical and structural properties associated with MNMs affect their fate, behavior, and transformation in environmental matrices (e.g., adsorption/desorption, aggregation, chemical redox reaction, deposition, or dissolution), which will directly bear on bioavailability, bioaccumulation, and toxicity [29.186].

Structure–activity relationships, with research into the toxicity mechanisms of MNMs, can offer basic design concepts for environmentally safe nanocomposites;

For instance, encapsulation in polymer resins or surface functionalization hinders direct contact of carbon-based NMs (e.g., fullerene and SWNTs) as a key step in damage to bacterial cells, significantly diminishing their antimicrobial activity. Durable coating with inorganic film renders metal oxides (e.g., CuO and Fe₃O₄) and QDs resistant to weathering. Also, the predictive relationships may suggest the urgent need to remove potential toxic components from MNMs and switch to alternative materials.

Development of MNMs with easy degradation or recovery in response to specific environmental conditions may minimize environmental hazards in the event of accidental release during transportation, construction, or demolition. Incorporation of MNMs in pH- or temperature-responsive polymers can cause rapid hydrophobic conversion and resultant precipitation after their release into an aquatic environment, as encapsulation by nanomagnetite enables facile magnetic separation. Versatile MNMs can cover multiple functions to replace several MNMs without significant loss of functionalities (e.g., TiO₂ NPs as white pigment and TiO₂ coatings for light-transmittance control, self-cleaning, and superhydrophilicity), eventually decreasing the quantity of MNMs used in construction. Efforts to improve manufacturing processes should be initiated to increase production yields of NM-based construction products and highly promote their desirable properties with minimal generation of nanoscale wastes.

29.4.2 Application

In-depth studies should be carried out on the vulnerability of MNMs to redox reactions, corrosion and passivation, and photochemical and biological transformations encountered during the lifetime of nanoenabled products. The physical, chemical, and/or biological conversions may lead to modifications of MNMs' properties associated with their adverse biological effects and environmental mobility. Thus, it is important to identify the effects of physicochemical environmental parameters such as pH, salinity, and natural organic matter, and biological media compositions/metabolisms on the reactivity, distribution, bioavailability, and toxicity of MNMs.

Off-site fabrication, preassembly, and modularization of construction components containing MNMs in well-controlled conditions can minimize unwanted personal and environmental exposure. The effective longevity and projected life expectancy of MNM-containing construction products under conditions encountered should be considered for sustainable applications, based on laboratory and field studies to predict their resistance to aging, abrasion, chemical corrosion, cracking, and weathering. Leaching tests should be done to assess the possibility that MNMs incorporated into construction materials (e.g., TiO₂ in self-cleaning exterior and pavements, QDs in photovoltaic cells, and CNTs in concrete) may undergo separation from the matrices in some damaging conditions (e.g., fire, water, wind, and flood), dispersing into the surrounding atmosphere or entering stormwater runoff.

29.4.3 Recycling/Disposal

Recycling of MNM-containing construction materials, which aims to reduce the consumption of raw MNMs and minimize MNM-containing wastes, requires various prerequisite steps, including the development of efficient strategies to extract and collect MNMs from complex matrices (with minimal modification of the pristine properties), characterization of spent MNMs and evaluation of their capacity for reactivation, and assessment of the applicability of the reclaimed MNMs in terms of their original functionalities.

Since collective efforts are still underway to establish regulatory frameworks to specifically address MNM disposal, there should be special considerations for safe MNM waste disposal and recycling procedures. In an effort to prevent potential secondary contamination through landfill clay liners to the underlying aquifer, barrier reinforcement will be recommended to prevent infiltration of NM leachate and resultant groundwater pollution. Product labeling to identify and trace MNMs and relevant guidelines are needed to ecoresponsibly dispose of and recycle waste products that include MNMs and waste MNMs themselves. Following disposal, appropriate interception and remediation approaches may need to be developed depending on the MNM source, release dynamics, and disposal scenario.

29.5 Conclusions

Due to the potential for enhancement in material properties and functionalities, application of nanotechnology in construction is expected to create intelligent materials and systems, present opportunities for energy savings, and enable environmentally responsible products, buildings, and construction activities. Smart, nanoenabled products can detect and respond to changes in indoor environmental conditions, providing user-adapted control of key environmental parameters, e.g., dimming light and altering temperature and humidity. Nanosensor assemblies embedded in buildings and infrastructures can remotely monitor and assess their structural health and vulnerability. Self-healing materials, which are still in early stages of development, are capable of autonomous crack management to recover original mechanical properties (e.g., preventing crack development through slow release of a bonding agent from polymer capillaries embedded in the concrete matrices).

Use of MNMs for thermal insulation (e.g., SiO₂ NPs and aerogel) and light transmittance control (e.g., WO₃ NPs) can significantly contribute to energy conservation, considering that energy consumption by commercial buildings and residential houses (including heating, lighting, and air ventilation) accounts for approximately 40% of all energy used in the USA. Incorporation of MNMs such as fullerenes, CNTs, and graphenes [29.46, 47] advances energy conversion and storage systems including hydrocarbon-based fuel cells, thermo- and photovoltaic cells, batteries, and capacitors. Solar light activation of TiO₂ to generate ROS enables pollution-controlling and self-cleaning coatings, reducing energy associated with maintenance for surface-treated pavements, windows, and walls [29.26, 61, 64]. Due to the improved resistance to abrasion, corrosion, fire, and fatigue, MNM-containing construction materials could possibly outperform conventional materials in terms of durability and longevity, indirectly reducing energy consumed to repair, restore, and replace damaged materials.

Applications of MNMs as alternatives to toxic components prevent environmental hazards through the potential discharge and exposure during manufacturing, transporting, construction and renovation, and disposal. The opportunities for material replacement include silver and iron oxide NPs for cadmium, cobalt, and lead as pigment in paint [29.12], silica NPs for poly-

chlorinated biphenyl (PCB) insulators [29.14], TiO₂ NPs for perfluorochemicals as stain repellents [29.17], and CNTs for halogenated flame retardants [29.29]. QD-based light-emitting diodes (LEDs) [29.48, 49] and CNT- or ZnO nanowire-based sensors and actuators [29.187, 188] possibly mitigate hazards associated with accidental release of mercury used in fluorescent lamp bulbs, pressure gages, thermometers, and switches. MNM-containing products enable buildings and infrastructures to capture or exploit natural heat and light (e.g., heat-absorbing windows, solar panels, and energy coatings) [29.11, 32], eventually reducing carbon emissions associated with heating and ventilation. Use of MNMs allows structural materials to be lighter and thinner without a significant loss of the desirable properties, mitigating wasteful use of raw materials and enabling resource-efficient production in construction.

As there are growing concerns that use of MNMs for the development of new construction products could increase possible environmental risk, it is critical to understand their potential mobility, properties, and impacts in and across air, water, soil, and biota. Analytical methodologies to detect and monitor MNMs (separate from or incorporated into construction materials) at environmentally relevant concentrations within complex environmental media and characterize their chemical and morphological features remain underdeveloped. Assessment of long-term global exposure to MNMs used in construction needs to be conducted, as the current focus of the potential adverse health effects is confined to manufacturing and construction workers. Considering that constructed infrastructure coexists with the natural environment, ecodesign strategies to enhance the environmental compatibility of materials and environmentally responsible lifecycle management of MNMs to minimize their unwanted environmental impacts also need to be prioritized. Overall, despite the current expectations regarding the promising opportunities of MNMs in construction, there are immediate concerns among the academic and industrial communities about the negative environmental implications. This highlights the need to encourage proactive research including green design and manufacturing, use and disposal practices, and recycling and reclamation strategies to ensure the ecoresponsibility and sustainability of both the nanotechnology and construction industries.

30. Plasmonic Nanomaterials for Nanomedicine

Renat R. Letfullin, Thomas F. George

Plasmonic nanoparticles are being researched as a noninvasive tool for ultrasensitive diagnostic, spectroscopic, and, recently, therapeutic technologies. With particular antibody coatings on nanoparticles, they attach to abnormal cells of interest (cancer or otherwise). Once attached, nanoparticles can be activated/heated with ultraviolet (UV)/visible/infrared (IR), radiofrequency (RF) or x-ray pulses, damaging the surrounding area of the abnormal cell to the point of death. Here, we describe an integrated approach to improved plasmonic therapy composed of nanomaterial optimization and the development of a theory for selective radiation nanophotothermolysis of abnormal biological cells with gold nanoparticles and self-assembled nanoclusters. The theory takes into account radiation-induced linear and nonlinear synergistic effects in biological cells containing nanostructures, with focus on optical, thermal, bubble formation, and nanoparticle explosion phenomena. On the basis of the developed models, we discuss new ideas and new dynamic modes for cancer treatment by radiation-activated nanoheaters, which involve nanocluster aggregation in living cells, microbubbles overlapping around laser-heated intracellular nanoparticles/clusters, and the laser thermal explosion mode of single nanoparticles (*nanobombs*) delivered to cells.

30.1 Introduction

In recent years, there has been a tremendous increase in research at the nanoscale for materials (see, for example, [30.1], and references in this handbook). One particular area is the application of plasmonic nanoparticles to enhance the diagnostic and treatment methods available for cancer [30.2–8]. The application of nanotechnology for laser thermal-based killing of abnormal cells

(e.g., cancer cells) targeted with absorbing nanoparticles (e.g., gold solid nanospheres, nanoshells or nanorods) is becoming an extensive area of research. Studies have shown that, by coating the surface of nanoparticles with a specific protein (a *targeting agent*, normally an antibody), the nanoparticles will bind to a complementary protein such as found on a cancer cell [30.3, 7–12], as

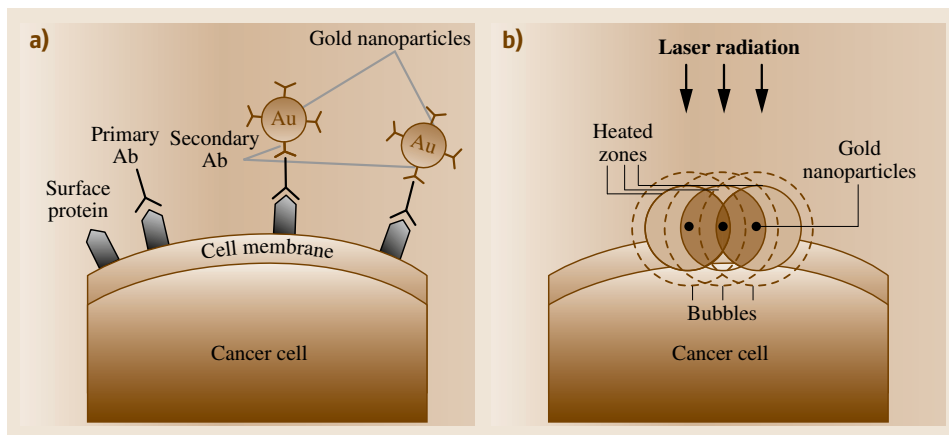

Fig. 30.1a,b Principle of selective nanophotothermolysis of cancer cell. **(a)** Cancer cell targeted with primary antibodies (Ab) which are selectively attached to secondary antibodies conjugated with gold nanoparticles. **(b)** Schematic of laser-induced heating effects around the particles

shown in Fig. 30.1a. After the nanoparticles are bound to the cancerous cells, they can be heated with electromagnetic radiation (UV/visible/IR, RF or x-ray pulses), inducing a variety of effects around the particles [30.7, 9, 11, 12], as shown in Fig. 30.1b. The heated particle can cause the cell to experience hyperthermia, resulting in surface-protein denaturing [30.13] and changing membrane permeability [30.14]. Alternatively, the nanoparticle itself can heat to the point of melting, evaporation or explosion [30.5, 6], causing further damage to cells. These effects can be used to increase the sensitivity of photoacoustic diagnosis or aid in therapy, such as selective photothermolysis, by selective thermal killing of tumor cells into which absorbing nanoparticles have been incorporated. The potential advantages of these new photothermal sensitizers heated with short laser pulses may include:

- Selective cancer-cell targeting by means of conjugation of absorbing particles (e.g., gold nanospheres, nanoshells or nanorods) with specific antibodies
- Localized tumor damage without harmful effects on surrounding healthy tissue
- Absorption at longer wavelengths in the transparency window of most biotissues
- No undesired side-effects (e.g., cytotoxicity or cutaneous photosensitivity)
- Relatively fast treatment involving potentially just one or several laser pulses.

Progress towards the development of selective nanophotothermolysis technology requires the investigation of new physical concepts and new approaches to the study of short/ultrashort laser pulse interactions with biological systems containing nanostructures. In this chapter, we develop a theory for laser-induced linear and non-linear synergistic effects in biological cells containing nanostructures with focus on cluster aggregation, bubble formation, and nanoparticle explosion phenomena. The theory is based on our experience in theoretical studies relevant to nanoparticles [30.1, 5, 6, 12, 15–24].

30.2 Nanooptics – Lorenz–Mie Formalism

The optimal wavelength of laser radiation and optimal size range of nanoparticles for effective laser killing of cancer cells can be found by using an extended Lorenz–Mie diffraction theory, taking into account the plasmon-resonance absorption effect in metal nanoparticles. In the most general case, calculations based on the Mie theory are reduced to searching for the scattering matrix of j particles, $S^j(\theta, \phi)$, consisting of four complex functions, $S_i^j(\theta, \phi)$ ($i = 1, \dots, 4$), describing the amplitude

and phase of a scattered scalar wave in any direction. Forward scattering ($\theta = 0^\circ$) contains the attenuation process of an electromagnetic wave, and for the case of spherical particles, $S_3^j = S_4^j = 0$. We can limit the description to a single scattering amplitude function

$$S^j(0) = S_1^j(0) = S_2^j(0) = \frac{1}{2} \sum_{l=1}^{\infty} (2l+1) (a_l^j + b_l^j). \quad (30.1)$$

The Mie coefficients a_l and b_l contain the characteristics of the dispersal medium and are calculated through the cylindrical Bessel function of the first kind $\psi_l(y)$ and the Hankel function of the second kind $\xi_l(\rho)$, both with half-integral indices

$$\begin{aligned} a_l &= \frac{\psi'_l(y)\psi_l(\rho) - \tilde{m}\psi_l(y)\psi'_l(\rho)}{\psi'_l(y)\xi_l(\rho) - \tilde{m}\psi_l(y)\xi'_l(\rho)}, \\ b_l &= \frac{\tilde{m}\psi'_l(y)\psi_l(\rho) - \psi_l(y)\psi'_l(\rho)}{\tilde{m}\psi'_l(y)\xi_l(\rho) - \psi_l(y)\xi'_l(\rho)}. \end{aligned} \quad (30.2)$$

Here, $\tilde{m} = m_0/m_1$ is the relative value of the refractive index of the medium; $m_0 = n_0 - i\chi_0$ and $m_1 = n_1 - i\chi_1$ are the complex refractive indices of the particle material and the aqueous suspension, respectively; $\rho = 2\pi r_0/\lambda$ is the Mie parameter; and $y = 2\pi r_0 n_0/\lambda$, $\psi_l(u) = (\pi u/2)^{1/2} J_{l+1/2}^{(1)}$, $\xi_l(u) = (\pi u/2)^{1/2} H_{l+1/2}^{(2)}$, and $\psi'_l = d\psi_l(u)/du$. With knowledge of $S^j(0)$, it is possible to calculate the integrated optical performance of the particles (i.e., the dimensionless efficiency coefficients of scattering, $K_{\text{sca}}^j(\rho, \tilde{m}) = \sigma_{\text{sca}}^j(\rho, \tilde{m})/\sigma_0$, absorption, $K_{\text{abs}}^j(\rho, \tilde{m}) = \sigma_{\text{abs}}^j(\rho, \tilde{m})/\sigma_0$, and attenuation, $K_{\text{att}}^j(\rho, \tilde{m}) = \sigma_{\text{att}}^j(\rho, \tilde{m})/\sigma_0$, of the radiation at a given wavelength) as

$$\begin{aligned} K_{\text{att}}^j(\rho, \tilde{m}) &= \frac{4\pi}{k^2} \text{Re} \left[S^j(0) \right], \\ K_{\text{sca}}^j(\rho, \tilde{m}) &= \frac{2}{\rho^2} \sum_{l=1}^{\infty} (2l+1) \left\{ |a_l^j|^2 + |b_l^j|^2 \right\}, \\ K_{\text{abs}}^j(\rho, \tilde{m}) &= K_{\text{ext}}(\rho, \tilde{m}) - K_{\text{sca}}(\rho, \tilde{m}), \end{aligned} \quad (30.3)$$

where $k = 2\pi/\lambda$ is the wavenumber, and $\sigma_{\text{sca}}^j(\rho, \tilde{m})$, $\sigma_{\text{abs}}^j(\rho, \tilde{m})$, $\sigma_{\text{att}}^j(\rho, \tilde{m})$, and σ_0 are the scattering, absorption, attenuation, and geometric cross-sections of j particles, respectively.

In a simulation of electromagnetic wave propagation in a dispersed medium, our previously developed effective algorithm [30.25] was used. Here, the cylindrical functions of real or imaginary arguments and their derivatives, which occur in the expressions for the Mie coefficients a_l and b_l (30.2), are calculated as the ratio of the function and its derivative by using the recurrence relationships for direct and inverse recursions. Such an approach allows us to make an effective and accurate determination of the optical properties of a dispersal medium over a broad range of Mie parameters, $\rho = 2\pi r_0/\lambda = 0.001-1500$, below the diffraction limit simultaneously with small and large values of the real n_0 and the imaginary χ_0 parts of the refractive index of the particle's and surrounding medium substance.

30.3 Optical Properties of Gold Nanoparticles in Biological Media

The Lorenz–Mie formalism (30.1–30.3) requires the use of two dimensionless input parameters, $\rho = 2\pi r_0/\lambda$ and $\delta = \rho\tilde{m}$, where \tilde{m} is the relative value of the complex refractive index of the nanoparticles in the surrounding medium at the wavelength λ . We examine the effects of the medium refractive index on the light-absorbing properties of gold particles in suspension as well as attached to a surface. Four media are used, namely water, cytoplasm, cell membrane, and collagen. The refractive indices of the media at the different wavelengths and the results of the Mie theory calculations of the maximum light-absorption factor (K_{abs}), wavelength (λ_{max}), and radius (r_{max}) for gold particles in media of different refractive indices are listed in Table 30.1. Results of computer simulations of the absorption coefficient K_{abs} as a function of the wavelength and radius of gold nanoparticles in various biological media are plotted in Fig. 30.2. Figure 30.2a shows the absorption spectrum of the gold particle over the visible range $\lambda = 400-700$ nm, and Fig. 30.2b illustrates

the dependences of K_{abs} on particle size for different surrounding biomedias.

As follows from calculations, the optical properties of the gold nanosphere in low-absorbing biological media are substantially different from the case of the surrounding water medium. The maximal peak of the absorption factor increases continuously with increase in the refractive index of the surrounding media, and the color of the incident light changes from green to red; i.e., there is a red-shift effect of the absorption maximum with refractive index (Fig. 30.2a). Maximum absorption by gold nanoparticles is observed for the surrounding collagen medium, where the absorption cross-section of the gold nanoparticle exceeds its geometric cross-section by a factor of 5 for the optimal wavelength 549 nm. The presence of the low-absorbing biological surroundings also shifts the optimal radius of the gold nanoparticle for effective absorption to a smaller size region from 35 nm for the water medium to 26 nm for the collagen case (Table 30.1).

Table 30.1 Mie theory optima for the absorption factor (K_{abs}), wavelength (λ_{max}), and radius (r_{max}) for gold particles in biomedica of different refractive indices used in the simulations

Surrounding medium	λ (nm)	Refractive index n_1	K_{abs} (max)	λ_{max} (nm)	r_{max} (nm)	Surrounding medium	λ (nm)	Refractive index n_1	K_{abs} (max)	λ_{max} (nm)	r_{max} (nm)

	120	750	3.75	[30.26]
Gold nanorods	11.4	800	14.0	
	17.9	825	14.5	

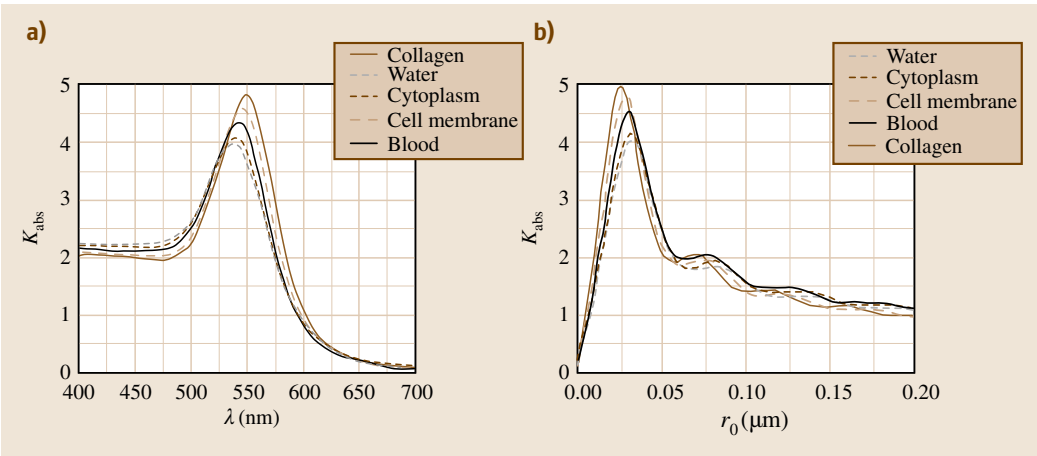

Fig. 30.2 (a) Absorption spectrum of the gold nanoparticle over the visible range $\lambda = 400\text{--}700\text{ nm}$. (b) Absorption efficiency K_{abs} , as a function of particle size for different surrounding biomedica

Thus, the absorption efficiency of gold nanoparticles is considerably higher in the low-absorbing biological media in comparison with the surrounding water medium.

The optical properties of the nanoparticles depend on the shape and internal structure of the particle as well. Table 30.2 contains results of calculations for the absorption efficiency of gold nanospheres, silica–gold

nanoshells, and gold nanorods. For gold nanoparticles, the highest absorption efficiency is observed for nanorods; however, silica–gold nanoshells are tunable over the longer wavelengths in the transparency window of most biotissues. We should note that other materials can exhibit strong absorption efficiency, e.g., silver nanospheres, which show strong absorption around 394 nm in the UV range of spectrum.

30.4 Kinetics of Heating and Cooling of Nanoparticles

30.4.1 Time Dynamics of the Nanoparticle Temperature

In this section, we use the heat transfer equation with several simplifying assumptions to calculate the nanoparticle temperature as a function of time. It has been shown by *Letfullin* et al. [30.20] that a one-temperature model (OTM) is appropriate for plasmonic nanoparticle heating for lasers of pulse durations in the femto-, pico-, and nanosecond ranges. The first approximation used in this model is that the electron and lattice temperatures are equal (due to fast transfer of electron heat to the phonon subsystem). This provides the following heat-mass transfer rate equation for a single lattice temperature $T_s(t, r)$ that describes the laser interaction with the particle and surrounding medium

$$\frac{d}{dt}T_s(t, r) = \frac{\mu_s(T_s)}{\rho_s C_s(T_s)} \Delta T_s(t, r) + \frac{Q(t, r)}{\rho_s C_s(T_s)} - j_D(T_s)S_0 + \frac{3L}{r_0 C_s(T_s)} \frac{dr_0}{dt}. \quad (30.4)$$

Here, $\Delta = \partial^2/\partial x^2 + \partial^2/\partial y^2 + \partial^2/\partial z^2$ is the Laplace operator; $\mu_s(T_s)$, $C(T_s)$, L , ρ_s , and r_0 are, respectively, the heat conductivity of the surrounding medium and the specific heat, evaporation heat, density, and radius of the nanoparticle. The second assumption is that the particle is heated uniformly across the volume of the particle, i.e., $\Delta T_s(t, r) = 0$, provided that each point inside the particle volume has the same temperature $T_s(t)$. This homogeneous heating approximation can be applied if the heat diffusion time τ_D is less than the duration of the laser pulse: $\tau_D = r_0^2/4\chi < \tau_L$, where r_0 is a particle radius, χ is the thermal diffusivity of the particle material, and τ_L is the laser pulse duration. For gold nanoparticles with $r_0 = 20$ nm and $\chi = 1.18 \times 10^{-4}$ m²/s, τ_D is about 10^{-12} s. This is appropriate for heating of metal nanoparticles by pico- and nanosecond laser pulses and allows the use of a simplified relationship for the power density of the energy generated $Q(t, r_0)$ in the particle

$$Q(t, r_0) = \frac{3K_{\text{abs}}(r_0, \lambda)I_0 f(t)}{4r_0}. \quad (30.5)$$

Here, $K_{\text{abs}}(r_0, \lambda)$ is the absorption efficiency of the nanoparticle, $f(t)$ is the time profile of the laser pulse, and I_0 is the incident intensity of the laser pulse. The experiments analyzed utilize Gaussian beam profiles in the form $f(t) = e^{-(at-b)^2}$; the coefficients are adjusted to create a pulse profile with the pulse duration of the laser used in the experiments. Another approximation

limits heat loss to diffusion from the particle surface into the surrounding medium, defining the energy flux density $j_D(T_s)$ as

$$j_D(T_s) = \frac{\mu_\infty T_s}{(\alpha + 1)r_0^2 C_s(T_s)\rho_s} \left[\left(\frac{T_s}{T_\infty} \right)^{\alpha+1} - 1 \right], \quad (30.6)$$

where μ_∞ and T_∞ are, respectively, the heat conductivity and temperature of the surrounding medium at equilibrium; α is an exponent set to make the dynamics between the particle and medium more realistic; $\alpha > 1$ relates to high thermophysical characteristics of the surrounding medium, while $\alpha < 1$ relates to low thermophysical characteristics such as insulators; $\alpha = 1$ is a good approximation for biological media, which are of interest in the present chapter. The last assumption is that the particle temperature remains below the temperature of evaporation, which sets the last term in (30.4) to zero. The result (30.7) determines the particle temperature in terms of the energy accumulation from the incident laser radiation in the first term and energy loss due to heat diffusion into the medium in the second term

$$\frac{d}{dt}T_s = \frac{3K_{\text{abs}}(r_0, \lambda)I_0 f(t)}{4r_0 \rho_s C_s(T_s)} - \frac{\mu_\infty T_s}{(\alpha + 1)r_0^2 C_s(T_s)\rho_s} \left[\left(\frac{T_s}{T_\infty} \right)^{\alpha+1} - 1 \right]. \quad (30.7)$$

30.4.2 Comparison of Single-Pulse and Multipulse Modes of Heating

The extent of the particle heating by radiation depends on many factors, divided primarily into three categories: (1) particle material, size, and shape; (2) laser pulse wavelength, energy density, duration, pulse shape, and generation frequency; and (3) properties of the surrounding medium. Even with the many factors involved in an experimental setup that contribute to the individual heating characteristics of a nanoparticle, several factors stay relatively constant across many experimental situations. Specifically, spherical gold nanoparticles are commonly used because they are relatively easy to fabricate, nontoxic, easily conjugated to antibodies, and strong absorbers [30.27]. Nanosecond pulse-width lasers with pulse firing frequencies of 10 Hz are often used because they are widely available and cheaper than pico- and femtosecond lasers or lasers with higher firing

¹ HOYA ConBio MedLite C Series and IV Series Nd:YAG lasers have a maximum generating frequency of 10 Hz, so the generation frequency for lasers when not provided was assumed as 10 Hz.

² It is common to use an effective radius (r_{eff}) when the particle is of nonstandard shape; this is the radius of a sphere that provides the equivalent volume as an arbitrary shape.

frequencies. Additionally, water or phosphate-buffered saline (PBS) solution is used as a surrounding medium due to strong similarities with a biological cell. Several experiments that use these factors are studied in our analysis [30.7, 8, 12, 28–31].

In experiments, Zharov et al. [30.7] used nanoparticle heating for bacterial killing. Spherical gold nanoparticles of diameter 10, 20, and 40 nm were heated with laser light, and it was determined that, at 3–5 J/cm², only 1–3 pulses are required for harmful effects on bacteria, while at 0.5–1 J/cm², at least 100 pulses are required to produce harmful effects. Pitsillides et al. [30.9] explored micro- and nanoparticles for selective cell therapy, finding that, for 20 nm-diameter gold nanospheres irradiated by 20 ns, 532 nm pulses at 0.5 J/cm², there is a much greater correlation of the number of particles attached to the cell than of the number of pulses when considering cellular damage. Zharov et al. [30.12] investigated bubble formation from nanoparticles. Using a smooth distribution of 40 nm-diameter gold nanospheres on a cell, they found that that 30 pulses of 0.5 J/cm² or one pulse of ≈ 2 J/cm² results in complete cell death. Alternatively, with cluster formation, cell damage occurs after 100 laser pulses at 80 mJ/cm². Peng et al. [30.28] focused on the effects of laser irradiation on particle size and peak absorption wavelength. They showed, using a Nd:YAG laser and 21 nm spherical gold nanoparticles, that irradiation causes the particles to fragment to an average diameter

of 4.9 nm, changing the peak absorption wavelengths. Kalambur et al. [30.29] used iron oxide nanoparticles to compare RF heating with multipulse laser heating and determined that multipulse lasers produce a higher cellular uptake of particles, enabling greater cellular damage. Hleb and Lapotko [30.30] used gold nanorods to determine high-energy effects of lasers on nanorods and nanospheres, such as how long the particles maintain photothermal properties (before deterioration) and the effects of multiple pulses in the form of a pulse train, determining that very rapid pulse repetition leads to increased bubble effects. Lastly, Takahashi et al. [30.31] used gold nanorods irradiated with multipulse near-IR lasers to find that selective cell damage is achievable.

One of the greatest potential benefits from multipulse lasers is accumulative heating in the target. If multipulse lasers could be used to quickly accumulate heat in nanoparticles with many consecutive low-energy pulses, then the laser energy density would not be a prohibitive aspect of the treatment. Multiple low-energy-density pulses could be used rather than a single high-energy-density pulse to achieve the same nanoparticle temperature, sparing healthy cells from excessive heating as well as ensuring that the energy density required for treatment is below the medical standard of 100 mJ/cm² [30.12].

The focus of this section is to compare and contrast the effects of multipulse (set of short pulses) versus single-pulse laser heating of nanoparticles. The laser

heating of nanoparticles is very sensitive to the time structure of the incident pulsed laser radiation, i.e., the pulse shape and duration, and the number of pulses per unit time. We limit the maximum temperature of the theoretical calculations to the melting point of the material ($T_M \approx 1336$ K for bulk gold material and remaining above 1100 K for gold particles larger than 5 nm in diameter [30.32]) so that the particles will not undergo advanced phenomena of heating (evaporation, melting or explosion), but require that the nanoparticles surpass 433 K as required for protein denaturing [30.27].

The summary data obtained from experimental papers [30.7, 8, 12, 28–31] can be found in Table 30.3, while the additional input data we use for our calculations are listed in Table 30.4. We modified the energy density when the particle temperature exceeds the melting point of the material to reduce the particle temperature into our range of interest.

Peng et al. [30.28] used an incident energy density (0.13 J/cm²) at a wavelength of 532 nm that causes particles to exceed the melting point, resulting in fragmentation. To make a case for reducing the incident energy density, we performed calculations to determine how changing the energy density would change the time–temperature profile of the nanoparticle heating and cooling. Our calculations show that changing the energy density has no effect on the time it takes for the particle to heat to the maximum temperature. Figure 30.3 demonstrates this with three different time–temperature

Fig. 30.3 Time–temperature profiles for 21 nm-diameter (solid) and 4.9 nm-diameter (dotted) gold particles in water irradiated by a 6 ns, 0.13 J/cm² pulse at 532 nm and a 21 nm-diameter gold particle irradiated by the same pulse at 0.0325 J/cm² (dashed) profiles for: a 21 nm-diameter gold sphere irradiated by a 0.13 J/cm² pulse (solid line) and 0.0325 J/cm² pulse (dashed line), and a 4.9 nm-diameter gold sphere irradiated by a 0.13 J/cm² pulse (dotted line). Changing the energy density from a 0.13 pulse to a 0.0325 J/cm² pulse has no effect on the time required for the particle

Fig. 30.4 Time-temperature profiles for 21 nm-diameter nanospheres with incident laser pulse duration of 6 ns at energy density of 0.13 J/cm² (solid) and 0.0325 J/cm² (dotted) and nanorods with effective diameter of 23.6 nm irradiated by a 10 ns, 0.01 J/cm² pulse (dashed)

Fig. 30.5 Calculated time-temperature profiles for five different pulse durations used in single-pulse mode heating. Three gold nanosphere cases: [30.7] – 12 ns pulse (dashed); [30.9] – 20 ns (dash-dot-dotted); and [30.28] – 6 ns (solid). Two gold nanorod cases: [30.30] – 10 ns (dash-dotted); and [30.31] – 7 ns (dotted)

to reach its maximum temperature, which occurs 9 ns after the incident pulse in both cases.

The cooling time for the particle is slightly affected by the magnitude of the maximum temperature and is thus linked to the energy density. Heating the particles to 1500 and 800 K, respectively, for 0.13 and 0.0325 J/cm² pulses, we find that the cooling time is only slightly longer for the higher-energy-density pulse. For the 0.13 J/cm² pulse, the particle cools back to ambient temperature 11.4 ns after the peak, while for the 0.0325 J/cm² pulse the particle takes 10.6 ns after the maximum to cool.

Single-Pulse Mode

To analyze the effects due to varying characteristics of the experiments, in this section we compare theoretical calculations for those experiments that have contrasting characteristics, such as pulse duration, particle size and shape, and medium in the single-pulse mode of heating. Considering particle shape – between gold nanorods and gold nanospheres – we extrapolate from Jain et al. [30.26] that changing the particle shape significantly alters the peak absorption wavelengths and the respective coefficients of absorption, but these can be equated to spherical particles with an effective radius and aspect ratio, $AR = \text{length/diameter}$. In [30.30], the gold nanorods with $r_{\text{eff}} = 11.8$ nm and $AR = 3.2$ have an absorption efficiency around 11.5 when irradiated with 725 nm light [30.26]. Contrasted with the gold nanospheres in [30.28] ($r_0 = 11.5$ nm, $K_{\text{abs}} = 1.29$ at $\lambda = 532$ nm), a much lower energy density can be used to reach the same ablation temperature for the nanorods due to the extremely high absorption efficiency. Figure 30.4 shows the time-temperature profiles from [30.28] for nanospheres ($d = 21$ nm) under 0.13 and 0.0325 J/cm² pulses at 532 nm, as well as the temperature profile for the nanorods ($r_{\text{eff}} = 11.8$ nm, $AR = 3.2$) from [30.30] irradiated by 0.01 J/cm². This figure demonstrates how a much lower energy density can result in higher nanorod temperatures when compared with nanospheres of equivalent radius. The tunable characteristics of nanorods allow greater adjustment of the wavelength that will result in maximum absorption efficiency and how high the absorption efficiency will be, thus making nanorods potentially more effective for ablative treatments than nanospheres. As we will show in the next section, in terms of accumulative heating with a multipulse mode of irradiation, the difference between nanorods and nanospheres is not significant.

Another characteristic of the experimental setups [30.7, 9, 12, 28–31] is a laser pulse duration of roughly 10 ns. Figure 30.5 shows time-temperature pro-

files for five different pulse durations ranging from 6 to 20 ns. It follows from our calculations that, during the laser pulse, the transfer of heat from the nanoparticle into the surrounding media is slight, and the particle rapidly reaches its maximum temperature. The heating rate is about 10^2 K/s, depending on the pulse duration and incident energy density. The temperature of the particle continues to rise even after the end of the laser pulse. Using [30.30] as an example, the highest temperature of 1048.6 K for a 10 ns pulse is observed at a heating time of 15.2 ns, when the laser pulse has already degraded. After then, the transfer of heat from the particle to the surrounding medium becomes critical, since the energy source is no longer present in the system. The temperature of the particle and surrounding medium remains high (above 425 K) up to 24.6 ns after the pulse is fired, exceeding the laser pulse duration by 2.5 times. The total time for one cycle (heating from the initial temperature of 300 K to a maximum temperature and then cooling back to the initial temperature) is 32.8 ns, over thrice the pulse duration. Varying the pulse duration changes the maximum temperature of the particle as well as the time span of heating and cooling.

Due to the nature of the experiments and the intended application of the method for treatment of cancer inside the human body, the medium characteristics cannot be changed. Furthermore, the ability to change the material of the nanoparticle is also limited due to toxicity, but in the case of metal nanoparticles, they should all exhibit similar heating and cooling kinetics to those seen in gold and iron(III) oxide (Fe_3O_4). As we have shown above, the particle size, particle shape, and laser energy density do not significantly change the temporal behavior of nanoparticle heating and cooling, but just the magnitude of the maximum temperature reached. The laser pulse duration changes the maximum particle temperature as well as the temporal span of heating and cooling, following relatively predictable multiplicative values with respect to the pulse duration: the maximum temperature is at 1.46 times the pulse duration; the temperature remains above 425 K until 2.2 times the pulse duration; and the entire heating and cooling cycle takes about 3.23 times the pulse duration. These aspects could be useful for further single-pulse investigations, but they do not come into play when considering the multipulse heating of nanoparticles discussed below.

Multipulse Mode

Using the scaled-down energy density values determined in previous sections and a function to simulate multiple pulses, we have calculated the time profile

Fig. 30.6 Multipulse time-temperature profiles for [30.7] (solid), [30.12] (dotted), and [30.29] (dashed) with modified pulse generation frequencies

of the nanoparticle temperature in a multipulse heating mode to determine what would enable accumulative heating of nanoparticles. To simulate multiple pulses, we use the same function as in the single-pulse simulations, but with the addition of several values of b to shift each consecutive pulse

$$f(t) = e^{-(at-b_1)^2} + e^{-(at-b_2)^2} + e^{-(at-b_3)^2}.$$

Three multipulse cases are shown in Fig. 30.6, demonstrating particle heating and cooling over time for the conditions of [30.7, 12, 29] as listed in Table 30.3. These simulations utilize a 37 and 62.5 MHz generation frequency due to the large time gap (relative to the pulse width) between each incident pulse when using the 10 Hz generation frequency specified in the references. These profiles demonstrate visually that, even at relatively high generation frequencies, multiple pulses do not produce any accumulative heating effect over time. The particle reaches the peak temperature and falls to equilibrium (300 K) in roughly three times the pulse duration, but the time delay between the pulses in experiments exceeds the pulse duration by five to ten million times.

Several of the experimental papers show effects from multipulse laser heating that are not present in the single-pulse laser mode, even though the pulse generation frequency for the multipulse mode is well below the MHz generation frequency. Zharov et al. [30.7] dis-

cussed bacterial killing and find that, at $3\text{--}5 \text{ J/cm}^2$, only 1–3 pulses are required for bacterial damage, while at $0.5\text{--}1 \text{ J/cm}^2$ more than 100 pulses are required. We feel the reason for these effects are that at $3\text{--}5 \text{ J/cm}^2$ the particles undergo phenomena beyond simple heating and ablation of the surrounding cell due to the extremely

high temperature of the nanoparticle, and thus have a large area of effect. In the case of $0.5\text{--}1 \text{ J/cm}^2$ pulses, the nanoparticles can still surpass the melting threshold, but without extreme particle phenomena (such as explosion) being observed. In either case, each pulse is incident on ambient-temperature particles, raising their temperature to the critical temperature for cell death. Additionally, the energy densities involved are well above the medical standard of 100 mJ/cm^2 , so such results are helpful to show the high-energy phenomena and potential treatment options. However, the methods of implementing treatment require refinement before direct medical applications can be developed. Our current investigation to determine the potential of accumulative heating effects in metal nanoparticles is an attempt at localizing damage to cancer cells by using low-energy density lasers while still killing the cancer cells.

After determining that most other experimental characteristics (such as pulse duration, particle size, etc.) have no ability to create an accumulative heating phenomenon of interest in metal nanoparticles, the pulse generation frequency used in multipulse scenarios was tested with a high-pulse generation frequency experiment by Hleb and Lapotko [30.30]. This experiment uses two pulses of 10 ns duration that are separated by 20 and 150 ns time intervals (50 and 6.67 MHz , respectively). Figure 30.7 shows three different multipulse calculations based on the experimental setup used in [30.30] for gold nanorods ($r_{\text{eff}} = 11.8 \text{ nm}$,

$AR = 3.2$, $K_{\text{abs}} = 11.5$ at 725 nm) in water irradiated by 0.01 J/cm² using 10 ns pulses with generation frequency of 50, 66.6, and 80 MHz. We exclude the case with pulse separation of 150 ns due to the previously shown rapid cooling of metal nanoparticles (32.8 ns for a 10 ns pulse in [30.30]) as well as the experimental result by Hleb and Lapotko [30.30] that there are no additional effects from two pulses separated by 150 ns over a single pulse. Even at the high pulse generation frequencies shown, the 10 ns pulse does not create an accumulative heating effect in the metal nanoparticles. Furthermore, changing the pulse duration concurrently with high-frequency pulse generation simulations only changes the magnitude of the maximum particle tem-

perature but does not enable the accumulative heating effect in the metal nanoparticles of interest to our investigation.

Multipulse Heating of Healthy and Cancerous Cell Organelles

Using the multipulse form described above, we also tested the heating and cooling kinetics of biological cell organelles to determine the ability to selectively destroy cancer cells. Acquiring data for organelles (nucleus, mitochondrion, and ribosome) is difficult due to the wide variety of situations under which they must act; the added complexity of the large number of cancers makes finding very specific data difficult. Using a variety of

Fig. 30.8 Ribosomal time-temperature profiles at various diameter values. Multipulse laser parameters: 12 ns duration, 0.1 J/cm^2 at $\lambda = 700 \text{ nm}$; $b_1 = 2.5$, $b_2 = 6$, $b_3 = 9.5$, $b_4 = 13$, $b_5 = 16.5$, $b_6 = 20$, and $b_7 = 23.5$

cited dimensions and organelle properties (Tables 30.5–30.7), we have calculated the *average* organelle size to determine the theoretical effects of the multipulse mode of laser irradiation on the organelle temperature with the same procedure as detailed above.

The cell organelles demonstrate the heat accumulation effect due to the multipulse mode of heating as shown in Figs. 30.8 and 30.9. The ribosomal heating in Fig. 30.8 contrasts with heating for the nuclei and mitochondria in Fig. 30.9; the ribosomes do not experience accumulative heating to the extent that nuclei or mito-

chondria do, based primarily on the much smaller size. Even with the small size, within the first few pulses the accumulative heating effect is apparent, which contrasts with any nanoparticle simulations previously discussed. The much higher values of specific heat in the organelles and the thermal conductivity of the medium is what causes the organelles to undergo accumulative heating, whereas metal nanoparticles do not experience accumulative heating, even at high-frequency pulse generation rates. This gives an advantage for organelles in using the multipulse versus single-pulse mode, since

Fig. 30.9 Both single- and multipulse laser heating for *average* organelles. Average values: healthy nucleus ($7.17 \mu\text{m}$), cancerous nucleus ($8.97 \mu\text{m}$), healthy mitochondria ($1.1 \mu\text{m}$), and cancerous mitochondria ($0.82 \mu\text{m}$). Single-pulse laser parameters include a 0.1 J/cm^2 pulse at 700 nm wavelength

Fig. 30.10 Multipulse mode of heating of bone tissue. A representative multipulse function is drawn with a solid line, and the heating kinetics with a dashed line, showing five 30 mJ pulses of 60 ns pulse width repeating every 300 ns

the laser energy density per pulse can be reduced dramatically below the safety standard for medical usage of lasers. In this case, any desired final temperature of the organelle can be reached easily by adjusting the number of pulses at low-energy density per pulse.

While the organelles demonstrate a similarity in the heat accumulation effect, both the mitochondria and nuclei respond differently to the pulsed mode of heating. As shown in Fig. 30.9, healthy and cancerous mitochondria do not respond differently in a significant way to laser heating, while the healthy nucleus is heated 40 K higher than the cancerous nucleus. The difference in heating characteristics is due to several behavioral properties: the size of the nucleus is much larger than mitochondrion, mitochondrion has been shown to shrink when in cancerous cells, and the nucleus of cancerous cells is known to grow relative to their healthy cell size. The dynamics of size on temperature results in the mitochondria being heated to a higher temperature, but with very little specificity. Alternatively, nuclei are heated to a lower temperature at a higher specificity level, though the healthy nuclei are the first to get damaged. The potential method of selectively heating cancerous organelles to kill cancer cells is shown to be ineffective with our calculations due to the higher heating temperatures of mitochondria and the lower heating of cancerous nuclei. With that in mind, the effects of accumulative heating are very apparent.

The results of the simulation using cell organelles demonstrate the slow rate of the cooling kinetics of the biological particles. This allows for accumulation of heat by a multipulse heating mode for hard tissue, such as bone and teeth as well, as shown in [30.22, 23]. Here, the bone hydroxyapatite particles were heated by single- and multipulse laser pulses of 2.12 μm wavelength. Figure 30.10 shows the results for bone tissue temperature increase by five 0.03 J pulses. To reach the same maximum temperature in the bone tissue ($T_{\text{max}} = 1460 \text{ K}$) using a single pulse requires a much higher energy per pulse of about 0.15 J. Thus, the multipulse mode could be utilized to attain the higher temperatures required for tissue ablation using many pulses with low individual energies. This gives a large amount of control over the individual pulse energies, which is especially important in medical and dental laser applications where regulations may limit the maximum pulse energies for different procedures.

Summary of the Heating Kinetics

We have performed time-dependent simulations and detailed analyses of different nonstationary laser-nanoparticle interaction modes to determine the accumulative heating potential of metal nanoparticles irradiated by multipulse lasers. Our analysis of the single-pulse mode of heating of metal nanoparticles in a biological cell environment has shown that alterations to the particle size, shape, and material (metal) all have

effects on the magnitude of the maximum particle temperature. Additionally, modifications to the laser energy density or wavelength can be used to change the maximum particle temperature. The most substantial change within single-pulse heating is the effect of pulse duration on the time dynamics of particle heating and cooling. By increasing the pulse duration, the maximum nanoparticle temperature decreases, but heating and cooling both take longer and allow for a longer time period when the nanoparticles are above the denaturing temperature of 433 K. This increased duration of high particle temperature could prove beneficial to ensure cellular damage. Alternatively, decreasing the pulse duration increases the maximum temperature reached by the nanoparticles while decreasing the time for heating and cooling. Such laser parameter modifications could allow for easier and more refined treatment than modification of particle size or shape, while still having dramatic implications for the effectiveness of the treatment.

Our simulations have shown that, at the instant when the laser pulse stops, the cooling rate reaches almost the same values as a heating rate due to the large surface

area of the nanoparticle and high thermal conductivity of the surrounding aqueous medium. This becomes crucial for the multipulse mode of heating the metal nanoparticles. From our analysis of multipulse metal nanoparticle heating, we have determined that the multipulse mode of heating does not create accumulative heating effects in metal nanospheres or nanorods (diameters of 5–40 nm) due to the rapid cooling kinetics of metal nanoparticles in an aqueous environment.

However, changing the target material to biological particles, such as cell organelles or hard tissue particles with much higher values of specific heat, causes the biological particles to undergo accumulative heating, whereas metal nanoparticles do not experience accumulative heating, even at high frequency generation rates. The accumulative heating effect provides an advantage for organelles and biological tissue in using the multipulse versus single-pulse mode, since the laser energy density per pulse can be reduced dramatically below the safety standard for medical usage of lasers. In this case, any desired final temperature of the biotissue can be reached easily by adjusting the number of pulses at low energy density per pulse.

30.5 Spatial Distribution of Temperature Fields Around the Nanoparticle

30.5.1 Theoretical Model

For simulations of the spatial distribution of temperature in and outside the nanoparticle, we solve the heat-mass transfer equation (30.4) in a quasistationary heating approximation, namely $dT_s(r, t)/dt = 0$. In this approximation, we neglect the time required to reach the maximum temperature (extremum of the $T_s(t)$ curve) of the nanoparticle and solve the heat diffusion equation for the spatial distribution for that particular temperature. We use here the heat transfer model developed by Goldenberg and Tranter [30.43] for a uniformly heated, homogeneous sphere embedded in an infinite homogeneous medium. Consider a homogeneous sphere of radius r_0 surrounded by an infinite homogeneous medium, with heat produced in the sphere for time $t > 0$ at the constant rate A per unit time per unit volume. Since the surrounding medium is transparent to the chosen wavelength, we can neglect thermally induced changes in the cellular refractive index during the action of a nanosecond laser pulse. Both the sphere and medium are initially at zero temperature. Let the subscript “1” refer to the sphere and “2” to the medium, and

T , μ , and χ denote the temperature, thermal conductivity, and diffusivity, respectively. Then, the heat transfer equations with boundary conditions are

$$\left. \begin{aligned} \frac{1}{\chi_1} \frac{\partial T_1}{\partial t} &= \frac{1}{r^2} \frac{\partial}{\partial r} \left(r^2 \frac{\partial T_1}{\partial r} \right) + \frac{A}{\mu_1}, \\ 0 &\leq r < r_0, \\ \frac{1}{\chi_2} \frac{\partial T_2}{\partial t} &= \frac{1}{r^2} \frac{\partial}{\partial r} \left(r^2 \frac{\partial T_2}{\partial r} \right), \\ r &> r_0, \end{aligned} \right\} t > 0, \quad (30.8)$$

$$T_1 = T_2 = 0, \quad \text{when } t = 0, \quad (30.9)$$

$$\left. \begin{aligned} T_1 &= T_2 \\ \mu_1 \frac{\partial T_1}{\partial r} &= \mu_2 \frac{\partial T_2}{\partial r} \end{aligned} \right\} \text{ for } r = r_0, \quad (30.10)$$

$$T_1 \text{ finite as } r \rightarrow 0 \text{ and } T_2 \text{ finite as } r \rightarrow \infty. \quad (30.11)$$

Using the Laplace transformation for T , defined by

$$\bar{T} = \int_0^\infty e^{-pt} T(t) dt = L[T(t)],$$

Eqs. (30.8–30.11) can be reduced to the stationary heat transfer equations

$$\left. \begin{aligned} \frac{\partial^2}{\partial r^2} (r\overline{T}_1) - r q_1^2 \overline{T}_1 &= -\frac{rA}{\mu_1 p}, \quad 0 \leq r < r_0, \\ \frac{\partial^2}{\partial r^2} (r\overline{T}_2) - r q_2^2 \overline{T}_2 &= 0, \quad r > r_0, \end{aligned} \right\}, \quad (30.12)$$

$$\left. \begin{aligned} \overline{T}_1 &= \overline{T}_2 \\ \mu_1 \frac{\partial \overline{T}_1}{\partial r} &= \mu_2 \frac{\partial \overline{T}_2}{\partial r} \end{aligned} \right\} \text{ for } r = r_0, \quad (30.13)$$

$$\overline{T}_1 \text{ finite as } r \rightarrow 0 \text{ and } \overline{T}_2 \text{ finite as } r \rightarrow \infty, \quad (30.14)$$

where $q_1^2 = p/\chi_1$ and $q_2^2 = p/\chi_2$.

The solution of (30.5–30.7) for the temperature distribution inside the heated sphere is [30.43]

$$\overline{T}_1 = \frac{r_0^2 A}{\mu_1} \left\{ \frac{1}{3} \frac{\mu_1}{\mu_2} + \frac{1}{6} \left(1 - \frac{r^2}{r_0^2} \right) - \frac{2r_0 b}{\pi r} \int_0^\infty \times \frac{\exp(-y^2 t/\gamma_1)}{y^2} \frac{(\sin y - y \cos y) \sin(ry/r_0)}{(c \sin y - y \cos y)^2 + b^2 y^2 \sin^2 y} dy \right\}, \quad (30.15)$$

where

$$b = \frac{\mu_2}{\mu_1} \sqrt{\frac{\chi_1}{\chi_2}}, \quad c = 1 - \frac{\mu_2}{\mu_1} \quad \text{and} \quad \gamma_1 = \frac{r_0^2}{\chi_1}. \quad (30.16)$$

The temperature at the center of the sphere is

$$(\overline{T}_1)_{r=0} = \frac{r_0^2 A}{\mu_1} \left\{ \frac{1}{3} \frac{\mu_1}{\mu_2} + \frac{1}{6} - \frac{2b}{\pi} \int_0^\infty \frac{\exp(-y^2 t/\gamma_1)}{y} \times \frac{(\sin y - y \cos y) \sin(ry/r_0)}{(c \sin y - y \cos y)^2 + b^2 y^2 \sin^2 y} dy \right\}, \quad (30.17)$$

and the temperature outside the sphere is

$$\overline{T}_2 = \frac{r_0^3 A}{r \mu_1} \times \left\{ \frac{1}{3} \frac{\mu_1}{\mu_2} - \frac{2}{\pi} \int_0^\infty \frac{\exp(-y^2 t/\gamma_1)}{y^3} \times \frac{(\sin y - y \cos y) [by \sin y \cos \sigma y - (c \sin y - y \cos y) \sin \sigma y]}{(c \sin y - y \cos y)^2 + b^2 y^2 \sin^2 y} dy \right\}, \quad (30.18)$$

with b , c , and γ_1 as in (30.16) and

$$\sigma = \left(\frac{r}{r_0} - 1 \right) \sqrt{\frac{\chi_1}{\chi_2}}. \quad (30.19)$$

The heat source is characterized here by a constant rate A per unit time per unit volume as

$$A = \frac{E_{\text{abs}}}{\tau_{\text{rel}} V} = \frac{K_{\text{abs}} \varepsilon_L S}{\tau_{\text{rel}} V}, \quad (30.20)$$

where E_{abs} is the energy absorbed by the nanoparticle, ε_L is the laser pulse energy density, K_{abs} is the absorption efficiency of the nanoparticle at the given wavelength of laser radiation, S and V are the area and volume of the absorbing center, and τ_{rel} is the thermal relaxation time in the biological medium. By using spherical symmetry for the absorbing center of radius r_0 , we can reduce (30.20) to

$$A = \frac{3K_{\text{abs}} \varepsilon_L}{\tau_{\text{rel}} r_0}. \quad (30.21)$$

The model described above can be used for simulating the spatial distribution of the temperature for a single or many heat sources in a cell volume.

30.5.2 Laser Heating of a Single Nanoparticle in Biomedica

Let us first calculate the laser heating of single gold nanoparticles with radii $r_0 = 30\text{--}35\text{ nm}$ in water and surrounding blood biomedica when the incident laser pulse has an energy density of $E = 5\text{ J/cm}^2$ and pulse duration of $\tau_L = 8\text{ ns}$. The laser flux is chosen at the level of 5 J/cm^2 to provide cell lethality during a single laser pulse shot, being comparable to the laser fluence currently used in clinical treatments of pigmented skin lesions. The results of these simulations are presented in Figs. 30.11 and 30.12. Figure 30.11 illustrates the spatial behavior of the temperature inside 30 and 35 nm gold particles heated and cooled in the surrounding water and blood media. Figure 30.12 shows the spatial distribution of the temperature outside these nanoparticles.

The events that take place after absorption of the laser pulse energy by small particles depend on the size of the locally heated region and duration of laser exposure. Long pulses that exceed the thermal relaxation time in biological tissue, $\tau_r = l^2/4\chi_t$ (where χ_t is the thermal diffusivity of the biological tissue, and l is the minimum size of the locally heated region), cause heating of both the particle and the surrounding media. If the size of the locally heated region l is chosen to be equal to the size of the laser focal spot, which is about $1\text{ }\mu\text{m}$, the thermal relaxation time for water is $1.75\text{ }\mu\text{s}$ and for blood is $1.56\text{ }\mu\text{s}$, which is much longer than the laser pulse duration ($\approx 10\text{ ns}$) used in our research. For ultrashort laser pulses when $\tau_L \ll \tau_r$, the absorbed energy can be thermally confined within the target, causing rapid heating of the absorber itself. The extreme temperature rise in the absorber can induce ex-

plosive vaporization of the nanoparticle, as described in the final section of this chapter.

Internal Temperature Distribution in a Single Nanoparticle

The integration of (30.15–30.17) gives the temperature distribution inside the heated nanoparticle surrounded by the biomed. Our numerical simulations of the internal 30 nm gold particle's temperature distribution heated by a 5 J/cm^2 laser pulse of 8 ns width in the surrounding water and blood media show that the particle reaches its maximum temperature $T_{\text{max}} \approx 5789.5 \text{ K}$ in

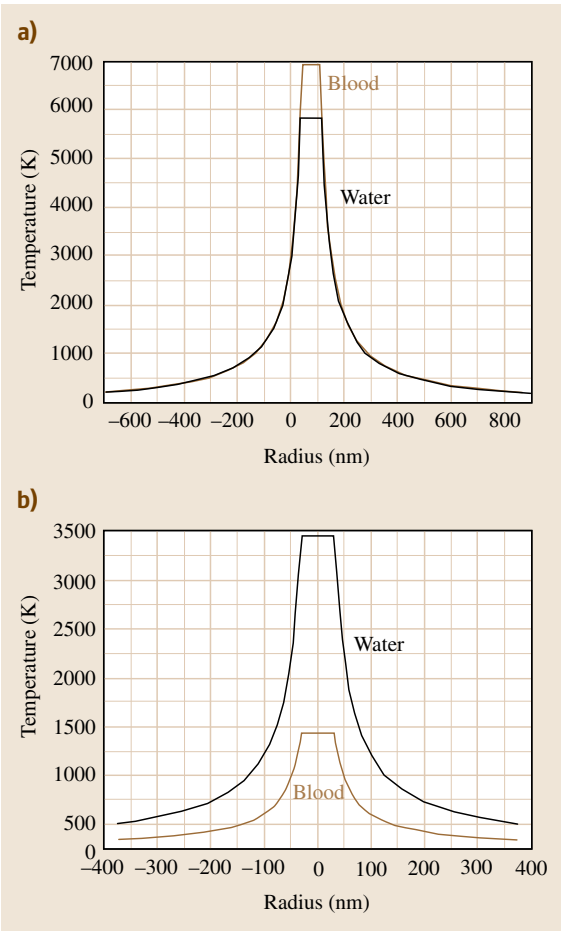

Fig. 30.12a,b Spatial distribution of the temperature outside the 30 nm gold particle (a) in surrounding water and blood media irradiated by a single laser pulse of energy density 5 J/cm^2 and duration 8 ns and (b) in a blood medium irradiated by a single laser pulse of energy density 2.5 J/cm^2 (upper curve) and 1 J/cm^2 (lower curve)

water and $T_{\text{max}} = 6870 \text{ K}$ in blood at the center of the sphere. Then we observe a small decrease of the inside temperature by 6 K to the particle's boundaries, establishing the stationary surface temperature of 5783.3 K in water and 6863.6 K in blood (Fig. 30.11). Since the temperature variation inside the nanoparticle occurs over a small range of 6 K, the internal particle's temperature can be assumed to be constant (Fig. 30.11b). Thus, the quasistationary and homogeneous approach can be applied to modeling the laser heating and evaporation of the nanoparticles in the biological media.

Outside Temperature Distribution Around a Single Nanoparticle

As follows from Fig. 30.12, there is a significant heat loss from the surface of a nanoparticle to the surrounding medium, suggesting that even lower-energy pulses are enough to achieve true and large thermal damage of the biological surroundings. If the temperature of the surrounding medium exceeds some thermal thresholds, secondary phenomena of cell killing effects may develop, such as photothermal ablation, sound generation, bubble formation, and so on. For most cancer cell killing effects, the threshold temperature is about 150 °C (423 K). Calculations show that, at this level of the threshold temperature, the damage area produced by a heated 30 nm gold particle in blood has a size of $\approx 1 \mu\text{m}$ in diameter, which exceeds by 16 times the size of the nanoparticle (Fig. 30.12a). Thus, under chosen conditions, the damage area produced by one 30 nm particle heated by a single laser pulse of 5 J/cm^2 is comparable to the size of the laser focal spot.

To find the lowest energy level of the laser pulse required to achieve thermal thresholds for cell death, we have conducted calculations of the temperature spatial distribution of gold nanoparticles irradiated by different laser fluxes. The results of these simulations are illustrated in Fig. 30.12b. As follows from these calculations, a single 8 ns laser pulse of energy density 2.5 J/cm^2 provides heating of the 30 nm gold particle in the surrounding blood up to the boiling point of gold, $\approx 3400 \text{ K}$. The melting point of gold $\approx 1400 \text{ K}$ is reached for a lower energy pulse density of 1 J/cm^2 for 8 ns laser pulse duration. Decreasing the energy density of the incident single laser pulse leads to a smaller damage volume around the nanoparticle. Using the threshold temperature of 423 K for cell death, we can

determine the size of cell damage produced by the heated 30 nm gold particle. For the 8 ns single laser pulse with energy density of 2.5 J/cm^2 , the damage volume around the nanoparticle has $0.5 \mu\text{m}$ diameter, which is smaller than but still comparable to the focal spot of the incident laser pulse. In the case of a 1 J/cm^2 single laser pulse, the damage area is 180 nm in diameter, which is only thrice the diameter of the nanoparticle. Thus, for experimental realization of selective nanophotothermolysis of cancer cells by a single 30 nm gold particle, we recommend use of a laser pulse with energy density 2.5 J/cm^2 for 8 ns width.

30.5.3 Bone Tissue Ablation by Plasmonic Nanoparticles

Both thermal and optical properties affect the behavior of the thermal field. The thermal properties of the material govern how easily a material can dissipate heat to the surrounding medium, while the optical properties govern how much heat is generated when exposed to an energy source. In these simulations we wish to examine the photothermal effect of a strongly absorbing nanoparticle in hard tissue for applications to medical procedures. For this reason, the material properties of bone and various nanoparticles are listed in Tables 30.8–30.10.

The optical properties of nanoparticles can be much more varied, however, as the absorption efficiency of the particles is affected by the material, size, and geometry of the nanoparticle. To achieve sufficient heating with pulses of lower energy densities, it is important to find absorption efficiency peaks. These peaks occur due to the plasmon resonance of the nanoparticle at that particular wavelength. To determine the ab-

Fig. 30.13 Absorption efficiency for 5 nm aminothiophenol-conjugated gold nanoparticles (4atp-AuNP) and folate-aminothiophenol-conjugated gold nanoparticles (F-4atp-AuNP). The values are calculated with Mie theory using complex index of refraction data for gold from *Shakeri-Zadeh et al.* [30.47]

sorption characteristics of spherical particles in various biomedica, generalized Lorenz–Mie diffraction theory is used (Sect. 30.2), which takes into account the plasmon-resonance absorption effect. Using the complex indices of refraction for the medium and particle (which depend on the wavelength as well as particle size), the the-

ory allows us to determine the absorption efficiency of spherical particles at any wavelength within the bounds of the refractive index values provided. The results of these calculations for the absorption efficiency of AuNP, AgNP, and CuNP are shown in Figs. 30.13 and 30.14 and are listed in Tables 30.1 and 30.2.

Reduction in the size of the spherical nanoparticles lowers the absorption efficiency, as seen when comparing 30 to 5 nm AuNP, where K_{abs} loses an entire order of magnitude. Moving into the IR and

Fig. 30.14 Absorption efficiency for 30 nm-diameter gold, silver, and copper nanoparticles (AuNP, AgNP, CuNP) surrounded by water medium. These values are calculated with Mie theory using complex index of refraction data from *Johnson and Christy* [30.48]

longer wavelengths, the absorption efficiency decreases continuously and without any noticeable peaks upon which to capitalize. This means that larger energy densities would be required to heat the nanospheres to the critical temperature. Thus, utilization of silica-gold nanoshells and/or gold nanorods, which absorb IR wavelengths much better than solid nanospheres, is recommended for selective nanothermolysis of bone tissue when working in the longer-wavelength range of the spectrum.

The choices of nanoparticle material, size, and shape used in the model are listed in Tables 30.11 and 30.12 along with the choice of wavelength and corresponding absorption efficiency for that wavelength. The energy densities were chosen to bring the nanoparticle to the melting temperature of hydroxyapatite (1843 K) [30.48] as it is the main constituent of bone tissues. This was considered an appropriate choice for the ablation temperature, as *Fried et al.* showed thermal ab-

lation and expulsion of molten drops in the temperature range of 1473–2273 K [30.49].

The temperature distribution is mainly dependent upon two factors: the thermal conductivities, which affect the slopes of the curves, and the absorption efficiency, which affects the maximum temperature difference reached. In the case of noble-metal nanopar-

Fig. 30.17 Heat profiles for a 30 nm-diameter AgNP (solid curve) heated by a $\lambda = 394$ nm pulse, and a 30 nm-diameter AuNP (dotted curve) heated by $\lambda = 520$ nm. Both pulses have equivalent energy densities, and both spheres are within an infinite medium with steady-state temperature 300 K ►

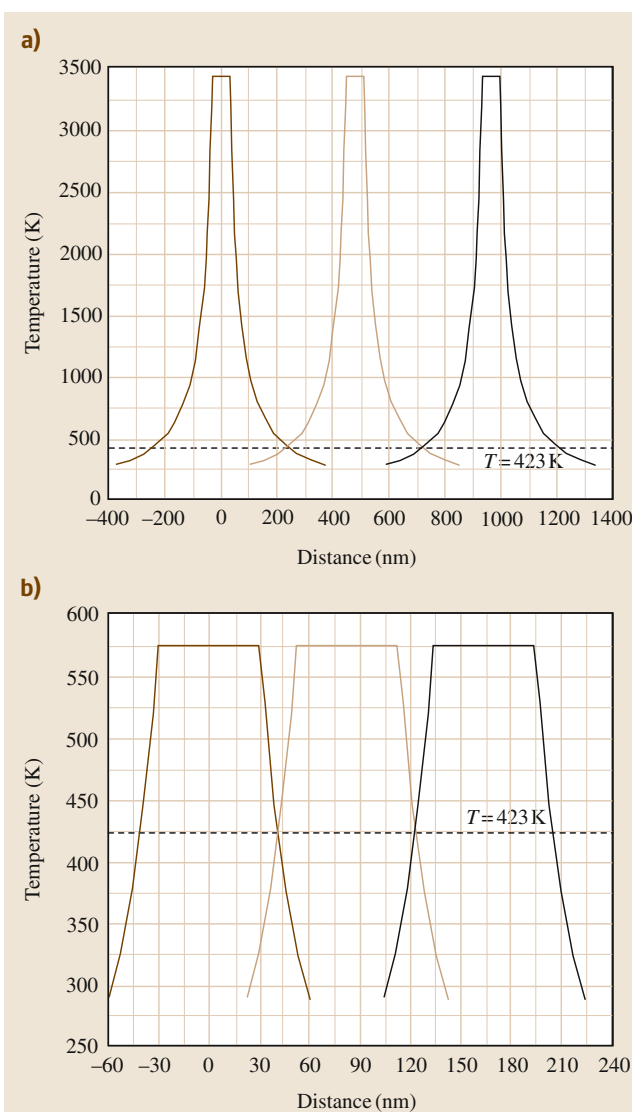

Fig. 30.18a,b Spatial distribution of the temperature fields produced in the blood medium **(a)** by many heat sources irradiated by a single laser pulse with energy density of 2.5 J/cm^2 and pulse duration 8 ns, and **(b)** inside a cluster consisting of 30 nm gold particles irradiated by a 8 ns single laser pulse of energy density 0.42 J/cm^2

ticles, the thermal conductivities of the metals are more than two orders of magnitude greater than that of bone. This leads to an essentially homogeneous temperature distribution within the nanoparticle, with an exponential cooling outside the particle as shown in Figs. 30.15–30.17.

In Fig. 30.17, it is clear that temperature is essentially the same within the nanoparticle radius, with significant cooling outside the radius. Closer inspection shows that the temperature distribution on the plateau varies slightly from the hottest point at the center, to the coolest temperature at the nanoparticle edge. For AgNP this is a variance from 628.1 to 627.8 K, and for AuNP it varies from 349.6 to 349.5 K. Both show less than 0.1% variance from the maximum temperature, and thus the plateau regions can be considered homogeneously heated.

Outside the nanoparticle, the temperatures drop relatively rapidly. In Figs. 30.15 and 30.16 for example, hard-tissue temperatures at the edge of the nanoparticle are at the hydroxyapatite melting temperature (1843 K) and maintain a temperature above 1473 K at a distance 1.05 times the radius of the nanoparticle (i.e., a 31.5 nm-diameter area is heated to this level by the 30 nm nanoparticle). This temperature is the lower bound (1473–2273 K) shown by Fried et al. to produce hydroxyapatite ablation and expulsion of molten drops. The temperature for delayed thermal necrosis of osteocytes (320 K) is maintained for all the tissue up to 75 times the radius, making the cell damage area on the same order of magnitude as the focal spot size.

Thus, we have discussed the method of selective nanophotothermolysis for application to bone tissue cancers. Our simulations for three-dimensional (3-D) thermal fields of plasmonic nanoparticles surrounded by bone medium have shown that alterations to the particle size, particle shape, and material all have effects on the magnitude of the maximum temperature reached in the particle; For example, in the UV and visible ranges of the spectrum, silver and gold solid spherical nanoparticles exhibit a strong plasmonic effect in laser heating of nanoparticles. For longer wavelengths in the transparency window of most biotissues, we recommend utilization of silica–gold nanoshells and/or gold nanorods for selective nanothermolysis of the bone tissue. Additionally, heat loss from the surface of a nanoparticle to the surrounding medium is observed, creating a large thermal damage area in the bone tissue up to 75 times the nanoparticle radius.

30.5.4 Temperature Simulations for Many Heat Sources

The model of (30.15–30.21) can be used for simulations of the spatial distribution of the temperature produced by many heat sources. Figure 30.18a illustrates the temperature fields around closely located nanoparticles in

the surrounding blood medium irradiated by a single laser pulse with energy density of 2.5 J/cm^2 and pulse duration of 8 ns. As follows from these calculations, to provide the threshold temperature 423 K between the particles everywhere in the cell volume (i.e., thermal damage in the cell), the interparticle distance l (i.e., between the centers of neighboring nanoparticles) should not exceed $l \leq 480 \text{ nm}$.

This criterion can be reached by varying l and the energy density of the incident laser pulse. To find the optimal distance l , where the minimal temperature between the nanoparticles is equal to 423 K, we have conducted calculations of the interparticle temperature distribution for different values of the laser energy density. Results of these simulations, presented in Fig. 30.19, show that an optimum l does not exist in the framework of the thermal calculations: l linearly increases with the energy density of the incident laser pulse. The interparticle distance l sets the lower limit for the nanoparticle concentration n required for cell death (i.e., the number of particles per unit volume) as

$$n = \left(\frac{1}{l^3} \right). \quad (30.22)$$

Let us estimate n and the absolute number N of nanoparticles to provide the high-temperature distribution inside the cancer cell volume. For $l = 480 \text{ nm}$, the concentration of $n = 9.0 \times 10^{12} \text{ cm}^{-3}$ is homogeneously distributed throughout the cell volume. N can be found as $N = nV_{\text{cell}}$, where V_{cell} is the cell volume. In the case of the $10 \mu\text{m}$ -diameter cells of the MDA-MB-231 breast cancer line, the number of 30 nm gold particles needed to provide the threshold temperature everywhere

Fig. 30.19 Interparticle distance for different values of the laser energy density

in the cell volume (thermal damage) is $N \approx 4710$. This is a relatively large number of particles per cell, requiring a long incubation time to collect them in the cell or cell membrane. As shown in our experiments [30.12], during this incubation time, the nanoparticles collide with each other, stick together, and form nanoparticle clusters. The temperature distribution inside a cluster is expected to be significantly higher than the threshold temperature 423 K, since the particles in the cluster are compacted much closer to each other. The spatial distribution of the temperature field inside and outside the cluster formed by 30 nm particles conjugated with antibodies is shown in Fig. 30.18.

30.6 New Dynamic Modes in Selective Plasmonic Nanotherapy

30.6.1 Nanocluster Aggregation Mode

Under certain delivery and particle-accumulation conditions, nanoparticles can form clusters in the cancer cell volume or cell membrane surface, as shown in Fig. 30.20. A cluster is a group of closely located nanoparticles (10–30 nm each) separated by the thickness of antibodies with total cluster size of 200–400 nm, which depends on the radii of the nanoparticles and duration of incubation time. This is the time required to collect the appropriate number of nanoparticles in the cell or cell membrane. The presence of nanoclusters

may provide further synergistic enhancement of selective nanophotothermolysis due to:

- Increase of the nanocluster's average local absorption
- Red-shifting of absorption to the near-IR range (window of transparency of most biotissues [30.26]) that may be achieved with conventional gold solid nanospheres, which are simpler to prepare, stable, and nontoxic, and cheaper compared with nanoparticles with special design (e.g., rods, shells, etc.)

Fig. 30.20 Principle of the nanocluster aggregation mode in selective nanophotothermal therapy of cancer

- Better heating efficiency achieved
- Decrease in threshold energy for bubble formation and cell damage.

In this section, we describe theoretically the damage of abnormal cells produced by nanoclusters and then compare this with the single-particle case. Two basic mechanisms of killing of cancer cells in the cluster aggregation mode (CAM) corresponding to a nanosecond laser pulse duration are studied here: thermal damage of abnormal cells by a laser-heated cluster, and bubble generation and their overlapping around the nanoparticles/nanocluster, as shown in Fig. 30.20.

Temperature Distribution Inside the Nanocluster

Our experiments [30.12] show that the distance between the centers of neighboring particles in a cluster is 80 nm, i. e., 20 nm between the surfaces of 30 nm particles. The interparticle distance in the cluster cannot be less than 20 nm, since the particles are covered by antibodies with thickness of about 10 nm. The model described in Sect. 30.4 is used to calculate the temperature distribution inside the cluster consisting of separate gold nanoparticles with radius $r_0 = 30$ nm in the surrounding blood medium irradiated by a single laser pulse of energy density $E = 2.5 \text{ J/cm}^2$ and pulse duration $\tau_L = 8$ ns. As follows from these calculations, the 2.5 J/cm^2 single laser pulse provides an extremely high minimal temperature of 2574 K inside the cluster (minimal temperature between the nanoparticles). The surface temperature of the nanoheaters is 3432 K. So, at the same energy level of the incident laser radiation used for laser heating of the single nanoparticle, the minimal temperature inside the cluster exceeds by six times the threshold temperature for cell killing. Thus, the aggregation of the nanoparticles in clusters gives us a unique possibility to dramatically decrease the inci-

dent laser pulse energy with the same efficiency of cell death.

To find the lowest energy level of the incident single laser pulse, we have conducted calculations of the spatial distribution of the temperature inside a cluster consisting of 30 nm gold particles for different laser fluxes. The size of the cluster is chosen to be smaller than that of the laser focal spot. The results of these simulations for the lowest energy providing the threshold temperature of not less than 423 K inside the cluster (between nanoparticles) are illustrated in Fig. 30.18b. As follows from these calculations, an 8 ns single laser pulse with energy density of 0.42 J/cm^2 is enough to heat the 30 nm gold particles inside the cluster up to 577 K and to reach the minimal temperature of 432 K in the cluster volume. There is evidence that specific properties of gold nanoparticles may be the reason for the remarkably low melting temperature (573 K) [30.50]. Thus, clusters aggregated from small nanoparticles can provide thermal damage of cancer cells at the significantly low energy level of 0.42 J/cm^2 of the incident single laser pulse.

Temperature Distribution Outside the Nanocluster

We assume that the cluster is aggregated from 30 nm gold particles with 20 nm interparticle distances, homogeneously compacted in a cylinder of length 380 nm. The cluster is located along the r -axis and surrounded by blood. It is irradiated by a single laser pulse of energy density 1 J/cm^2 and pulse duration of 8 ns at full-width at half-maximum (FWHM). Results of the simulations for the spatial distribution of the temperature field inside and outside the cluster in the surrounding blood medium are displayed in Fig. 30.21a. As follows from these calculations, the temperature inside the cluster oscillates in the range of 1374–1056 K along its length. So, the cluster heated by a single laser pulse of energy

density 1 J/cm^2 has a high inside temperature which exceeds by thrice the threshold temperature for cell death. The outside temperature distribution shows us that the cluster provides a large thermal damage area of $\approx 0.5 \mu\text{m}$ within the cell volume at the threshold temperature level of 423 K . To reach the same thermal damage area with a single nanoparticle, a laser pulse with energy density 2.5 times higher than for the cluster case is required.

We note that, since the cluster is treated here as a discrete medium (each particle considered separately), the results obtained above for the cluster temperature and thermal damage area have their lowest values. The upper limit for these values can be found for a homogeneous (continuous) distribution of the medium in the cluster. To keep our notations here the same, we label such a continuously distributed medium as a homogeneous cluster. There are two reasons in support of the homogeneous distribution in the cluster.

The first is the optical area. The size of nanoparticles in a cluster is much smaller than the wavelength of the laser radiation, $r_0 \ll \lambda$. As shown in [30.1], according to the Lorenz–Mie scattering theory, the cross-section of absorption exceeds by four times the geometric cross-section of the gold nanoparticle, $\sigma_{\text{abs}} > \sigma_0$. Hence, cross-sections of absorption of each nanoparticle are overlapping in the cluster. Because of this, the light does not distinguish the separate nanoparticles inside the cluster, and the laser energy is distributed homogeneously among the particles.

The second reason is the heat transfer frame. Since the temperature variation inside the nanocluster occurs over a relatively small temperature range of 318 K (45°C), we can assume that the internal cluster temperature is homogeneous and constant. This means that, from a thermal calculations point of view, the cluster can be treated as homogeneous (continuous) gold particles with the same size.

Let us evaluate the damage area produced by continuous gold clusters in the blood medium. The temperature distribution for gold particles of radius 190 nm (cluster diameter 380 nm) in blood irradiated by a single laser pulse of energy density 1 J/cm^2 is illustrated in Fig. 30.21b. As follows from these simulations, the upper limit of temperature inside the homogeneous cluster is 2384 K , and the thermal damage area is $2.13 \mu\text{m}$ in diameter at the threshold temperature level of 423 K . Thus, the 380 nm cluster provides a huge thermal damage area with minimum size of $0.5 \mu\text{m}$ (for a discrete cluster) up to a maximal size of $2 \mu\text{m}$ (for a homogeneous cluster) in a cell vol-

Fig. 30.21a,b One-dimensional distribution of the temperature field inside and outside a discrete cluster (a) and continuous cluster (b) consisting of 30 nm gold particles in the surrounding blood medium irradiated by a single laser pulse of energy density 1 J/cm^2

ume irradiated by a single laser pulse of energy density 1 J/cm^2 .

On the basis of our theoretical modeling, we can conclude that the aggregation of nanoparticles in a cluster mode of nanophotothermolysis raises the efficiency of cancer cell treatment due to the large damage area at

Fig. 30.22 Two-dimensional distribution of the temperature inside and outside a 30 nm gold nanoparticle in surrounding water and blood media irradiated by a single laser pulse of energy density 0.33 J/cm^2 and duration 8 ns

relatively low energy density of the incident single laser pulse. This conclusion is supported by the following results:

- The same laser energy density used for heating a single nanoparticle to the minimal temperature for thermal cell damage provides a temperature six times greater inside the cluster.
- Clusters can produce thermal damage of cancer cells at a significantly lower energy density level of 0.42 J/cm^2 of the incident single laser pulse in comparison with a single particle.
- Clusters provides a larger thermal damage area with minimal size of $0.5 \mu\text{m}$ (for the discrete cluster case) up to maximal size of $2 \mu\text{m}$ (for a continuous cluster) in a cell volume irradiated by a single laser pulse of energy density 1 J/cm^2 and duration of 8 ns. To reach the same thermal damage area of $0.5 \mu\text{m}$ by a single nanoparticle, a laser pulse with energy density 2.5 times higher than for the cluster case is required.

We should note that the damage area is estimated here by using the threshold temperature required for the initiation of cell killing effects, i. e., thermal damage. However, the actual damage area is expected to be significantly larger since the damage can occur on the cellular level, for example, due to bubble

formation around the nano-absorbers and its expansion in the cell volume. Section 30.5.2 is devoted to the investigation of the microbubble dynamics around nanoparticles/nanoclusters in biological media.

30.6.2 Microbubble Overlapping Mode

As shown in Sect. 30.5.1, significant heat conduction away from a heated nanoparticle requires timescales of the order of microseconds ($1.75 \mu\text{s}$ for water and $1.56 \mu\text{s}$ for blood). Because of this, for nanosecond laser pulses, most of the pulse energy remains localized at the absorbing nanoparticles/cluster, whose temperature rises high enough to cause vaporization of the immediate surrounding medium. This creates a bubble that then expands outward from the nanoparticle. We now investigate the bubble dynamics resulting from laser pulses with duration of 8 ns at FWHM.

Experiments [30.12] show that it is enough to heat the strongly absorbing nanoparticles above the boiling temperature of water only, or above the critical temperature of the phase transition in water, to generate bubbles around the particles. So, for a relatively low laser flux, the nanoparticle will be surrounded by a rapidly expanding layer of vapor. Let us calculate the threshold energy density of laser pulse deposited into the nanoparticle which is required to raise its surface temperature to the level of the critical temperature for bubble generation.

An experimental nucleation temperature of $T_{\text{thr}} = 150^\circ\text{C}$ (423 K) for heterogeneous bubble generation on the melanosome's surface was determined by Kelly [30.51]. Our calculations (Fig. 30.22) show that a threshold energy density of 0.33 J/cm^2 for the single 8 ns laser pulse is required to reach a surface temperature of 450 K for the 30 nm gold nanoparticles in blood medium. Thus, the bubble mode of photothermolysis can provide a larger damage area at the relatively low optical flux of 0.33 J/cm^2 ($\tau_L = 8 \text{ ns}$) due to the rapidly expanding nanobubbles around the nanoparticles.

Spherical Bubble Dynamics

Consider a spherical bubble of radius $R(t)$ (where t is time) in an infinite domain of liquid whose temperature and pressure far from the bubble are T_∞ and $p_\infty(t)$, respectively. We will assume that the liquid density ρ_L and dynamic viscosity η_L are constant and uniform. It will also be assumed that the contents of the bubble are homogeneous, and that the temperature $T(t)$ and pressure $p(t)$ within the bubble are always uniform. The radius of the bubble will be one of the primary

results of the analysis. In the absence of mass transport across the boundary (evaporation or condensation) and with the above assumptions, the bubble dynamics can be described by the generalized Rayleigh–Plesset equation [30.52]

$$\frac{p_V(T_\infty) - p_\infty(t)}{\rho_L} + \frac{p_V(T) - p_\infty(T_\infty)}{\rho_L} + \frac{p_G}{\rho_L} = R \frac{d^2 R}{dt^2} + \frac{3}{2} \left(\frac{dR}{dt} \right)^2 + \frac{4\eta_L}{\rho_L R} \frac{dR}{dt} + \frac{2S}{\rho_L R}, \quad (30.23)$$

where $p_V(T)$ is the saturated vapor density, and p_G is the partial pressure of the contaminant gas contained in the bubble. The first term on the left side of this equation is the instantaneous tension, or driving term, determined by the conditions far from the bubble. We refer to the second as the thermal term. It will be assumed here that the behavior of the gas in the bubble is polytropic, so that

$$p_G = p_{G_0} \left(\frac{r_0}{R} \right)^{3k}, \quad (30.24)$$

where p_{G_0} is the partial pressure of the contaminant gas contained in the bubble at some reference size $R = r_0$, with k as approximately constant. Clearly, $k = 1$ implies a constant bubble temperature, and $k = \gamma$ would model adiabatic behavior, where γ is the ratio of the specific heat of the vapor at constant pressure to the specific heat at constant volume.

Equation (30.23) can be readily integrated numerically to find $R(t)$ and the rate of bubble growth $v = dR/dt$ given the input $p_\infty(t)$, the temperature T_∞ , and the other constants. Initial conditions are also required and, in the context of cavitating flows, it is appropriate to assume that a nanobubble of radius $R = r_0$ is in equilibrium at $t = 0$ in the fluid at a pressure $p_\infty(0)$, so that

$$p_{G_0} = p_\infty(0) - p_V(T_\infty) + \frac{2S}{r_0} \quad (30.25)$$

and $(dR/dt)_{t=0} = 0$.

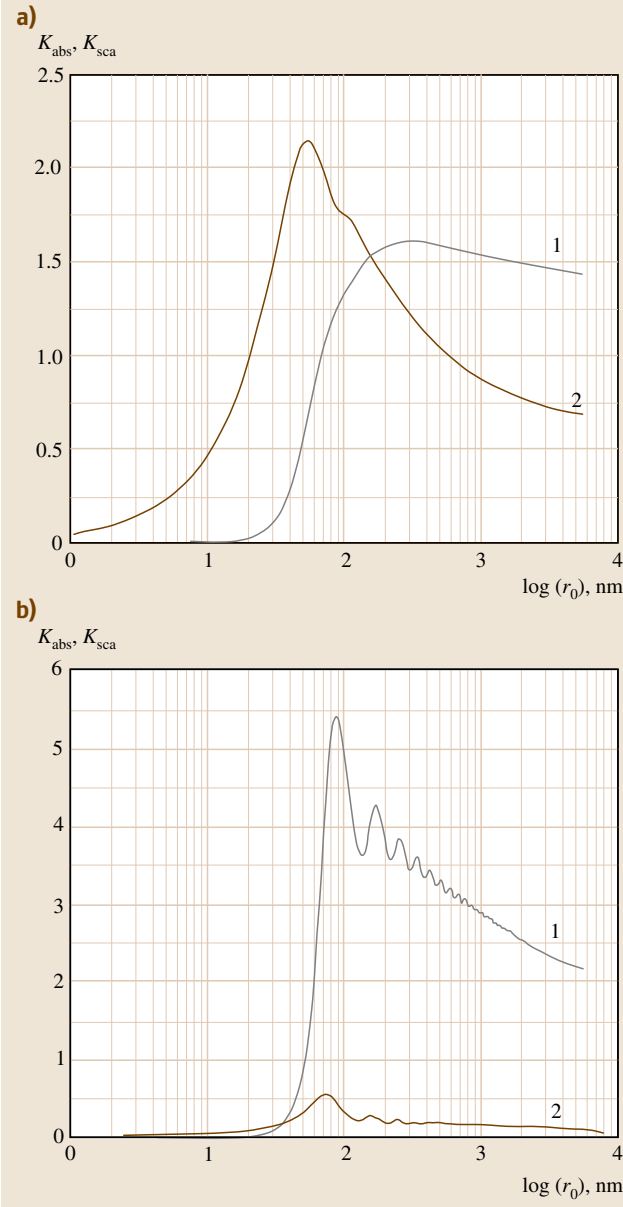

Overlapping Microbubbles

As discussed above, under certain delivery and particle-accumulation conditions, the particles can locate on the membrane surface very close to each other, as shown in Fig. 30.20. In this mode, we can expect the optical, thermal, acoustic, and bubble formation phenomena initiated by laser radiation around each particle to overlap and create some synergistic effects [30.12]; For example, the characteristic radii for

these overlapping effects can be defined by an optical radius $R_{\text{opt}} = (\sigma_{\text{abs}}/\pi)^{1/2}$, thermal diffusion length $R_T = (kt)^{1/2}$, sound transfer distance $R_{\text{ac}} = c_s t$, and microbubble radius $R_{\text{bubble}} = v_b t$, where σ_{abs} is the cross-section of absorption, k is the heat diffusion coefficient, c_s is the speed of sound, and v_b is the bubble growth velocity. Since for a certain range of gold nanoparticle sizes the optical radius can exceed the geometrical particle radius r_0 at the given wavelength of laser radiation, a plasmon–plasmon resonance at $R_{\text{opt}} > L$ (where L is the distance between particles) can be achieved. This resonance leads not only to the known *red-shifting* of maximum absorption [30.53], but also increases the integrated absorption coefficient of the particle cluster. The overlapping thermal fields at $R_T > L$ (during or after the laser pulse t_p) lead to a dramatic increase in thermal and accompanying effects (e.g., to sudden appearance of different nonlinear effects such as phase transitions). The interaction of acoustic waves at $R_{\text{ac}} > L/2$ significantly changes the local refractive index, which might be crucial for diagnostic purposes. Finally, the interaction of growing bubbles (initially of nanoscale sizes) at $R_{\text{bubble}} > L/2$ leads to a substantial increase in the average bubble size, with a decrease in the bubble-formation threshold (which, for single nanoparticles, is relatively high), and probably an increase in the bubble growth velocity. All of these phenomena are crucial when changing the distance between nanoparticles, and they are important for both highly sensitive diagnostics and efficient therapy.

We focus here on therapeutic application of this technology. Indeed, laser-induced overheating effects around nanoparticles may create many therapeutic actions through the microbubble formation phenomena, accompanied by acoustic and cavitation effects, mechanical stress, and laser-induced hydrodynamic pressure arising from the rapid bubble expansion and collapse. In this section, we discuss a dynamic mode for selective cancer treatment by laser-activated nanoheaters, involving the situation where the bubbles are overlapping inside the cell volume. The bubble overlapping mode (BOM) may dramatically increase the efficiency of the cancer treatment by laser-heated nanoparticles as a result of the large damage range.

Since bubbles do not all appear simultaneously, there are few possibilities for bubbles overlapping. The bubbles can overlap at different nucleation times and spreading velocities, or simultaneously with the same spreading velocity when they reach each other midway between neighboring gold particles. In our calculations, we choose stronger criteria than overlapping at

midpoints. Effective overlapping with large damage of tumor cells can be achieved if each bubble reaches the neighboring nanoparticles themselves, not just the midpoints between nanoparticles.

Condition for Concentration of Nanoparticles

The criteria for BOM introduced above impose a requirement on the interparticle distance L , the distance

Fig. 30.23a,b Dependences of the scattering K_{sca} (curve 1) and absorption K_{abs} (curve 2) coefficients at laser wavelength of $\lambda = 450$ nm on the size r_0 of gold particles in water medium ($\tilde{m} = 1.122 - 1.416i$) (a) and (b) for the case $\lambda = 633$ nm ($\tilde{m} = 0.1126 - 2.5754i$) ◀

between two neighboring nanoparticles. Since the bubble must reach the neighboring particles during the growing time τ_{growth} , the integration of the Rayleigh–Plesset equation (30.23) [30.52] for bubble dynamics at the nucleation temperature T_{nuc} gives the requirement for the interparticle distance L as

$$L \leq \sqrt{\frac{2}{3} \frac{P_{\text{sat}}(T_{\text{nuc}}) - P_{\infty}}{\rho(T_{\infty})}} \tau_{\text{growth}}, \quad (30.26)$$

where $P_{\text{sat}}(T_{\text{nuc}})$ is the saturated vapor pressure at the nucleation temperature, P_{∞} is the ambient pressure, and $\rho(T_{\infty})$ is the water density. This sets the lower limit to that required for the BOM concentration of nanoparticles, the number of particles per unit volume, as

$$n = (1/L^3). \quad (30.27)$$

Let us now estimate the interparticle distance, the nanoparticle concentration, and their absolute number collected in a tumor cell to provide the BOM by laser-activated nanoheaters. The interparticle distance L calculated by (30.26) for the experimentally measured nucleation temperature of $T_{\text{nuc}} = 150^\circ\text{C}$ is

$$L \approx 15.8 \tau_{\text{growth}}. \quad (30.28)$$

The bubble growing time τ_{growth} is limited by the bubble nucleation time t_{nuc} and bubble lifetime τ_{bubble} , i. e., $t_{\text{nuc}} \leq \tau_{\text{growth}} < \tau_{\text{bubble}}$. In our experiments [30.12], the nucleation time of the bubbles around isolated gold nanoparticles in aqueous suspension and irradiated by nanosecond laser pulses is $t_{\text{nuc}} \approx 100$ ns. The bubble lifetime depends on the laser energy and ranges from 100 ns to 2 μs . In the overwhelming majority of experiments, including ours, the bubble lifetime is in the range $\tau_{\text{bubble}} = 200\text{--}400$ ns. So, we can conclude that the bubble growing time is close to the nucleation time, i. e., $\tau_{\text{growth}} \sim t_{\text{nuc}}$. Then, from the rate equation (30.28), we can estimate the distance between nanoparticles (microbubble radius) required for the BOM as $L = R_{\text{bubble}} \approx 1.6 \mu\text{m}$, which corresponds to the results of our experiments. Thus, (30.27) gives the lower limit of the concentration of nanoparticles to provide the BOM as $n \approx 2.44 \times 10^{11} \text{ cm}^{-3}$. The absolute number of particles homogeneously distributed inside a tumor cell

Table 30.13 Physical properties of blood at 1 atm pressure used in the simulations

Property	Notation used in the model	Value	Units
Density	ρ_L	998.2	kg/m ³

for this mode can be found as $N = nV_{\text{cell}}$, where V_{cell} is the cell volume. For the case of the breast cancer line MDA-MB-231 of 15 μm size, the number of gold nanoparticles providing **BOM** is $N \approx 430$.

Condition on Nanoparticle Sizes

The optimal range of nanoparticle sizes for effective laser initiation of **BOM** in tumor cells is governed by the nanoparticle optics described in [30.1]. The optical characteristics of spherical nanoparticles dispersed in a biological medium at a given radiation wavelength λ can be calculated on the basis of Lorenz–Mie diffraction theory in the single scattering approximation discussed in Sect. 30.2. The Mie formalism requires the use of two dimensionless input parameters, $\rho = 2\pi r_0/\lambda$ and $\delta = \rho\tilde{m}$, where \tilde{m} is the relative value of the complex refractive index of the nanoparticles in the surrounding medium at the wavelength λ . Computer calculations of the dependences of the absorption K_{abs} and scattering K_{sca} coefficients at the given laser wavelength on the size of gold nanoparticles in aqueous suspension are plotted in Fig. 30.23. Figure 30.23a shows results for gold particles in water heated by laser radiation of wavelength $\lambda = 450$ nm ($\tilde{m} = 1.122\text{--}1.416i$), and Fig. 30.23b is for the case of wavelength $\lambda = 633$ nm ($\tilde{m} = 0.1126\text{--}2.5754i$). It is evident from Fig. 30.23a that the absorption coefficient K_{abs} has a strong maximum at the radius of 50 nm for the gold particle at the given wavelength (for 532 nm wavelength, the maximum radius is 30 nm).

The width of the absorption maximum at the level $K_{\text{abs}} \geq 1$ corresponds to the particle radii range of $r_0 = 20\text{--}600$ nm. This means that, in this size range, the absorption cross-section of gold particles at the given wavelength $\lambda = 450$ nm exceeds the particle geometric cross-section. Light scattering at $\lambda = 450$ nm by gold nanoparticles in aqueous suspension becomes apparent for particle radii larger than 50 nm. For particles of radii $r_0 \geq 150$ nm, the scattering of laser radiation predominates over the absorption, and the

considered suspension containing the nanoparticles becomes a strongly scattering medium at the given wavelength.

For the particle radius range $r_0 = 1\text{--}50$ nm, the absorption coefficient K_{abs} is considerably greater than the scattering coefficient K_{sca} ; i.e., the efficiency of laser heating of nanoparticles in this size range is high. Thus, the optimal range of nanoparticle sizes for effective laser initiation of **BOM** in tumor cells is 1–50 nm. The maximal effect of laser heating of gold particles can be achieved for particles of radii 20–50 nm, where $K_{\text{abs}} \geq 1$ and $K_{\text{sca}} < 1$.

Figure 30.23b demonstrates the $K_{\text{sca}}(r_0)$ and $K_{\text{abs}}(r_0)$ curves for the wavelength of $\lambda = 633$ nm. We observe very weak absorption and strong scattering of the light at this wavelength by the gold nanoparticles. The absorption slightly predominates over the scattering for a small range of nanoparticle radii when $r_0 \leq 35$ nm. It follows that laser light with wavelength $\lambda = 633$ nm can be recommended for diagnostic purposes only. However, creation of nanoclusters on a cell surface may lead to shifting the absorption maximum to the near-IR range [30.53], which can also be used for therapeutic purposes.

Thus, the proposed theoretical model for the nanoparticle optics along with bubble dynamics allows us to find the following conditions for **BOM** realization:

- The maximal effect of laser heating of gold nanoparticles over the wavelength range $\lambda = 450\text{--}550$ nm can be achieved for particle radii of 20–50 nm.
- The optimal nanoparticle concentration is $n \approx 2.44 \times 10^{11} \text{ cm}^{-3}$, which corresponds to an absolute number of nanoparticles in a breast cancer cell volume of 430 (88 on the cell surface).
- The bubble radius providing **BOM** is $R_{\text{bubble}} \approx 1.6 \mu\text{m}$.

These theoretical predictions of the **BOM** conditions have been confirmed by our experimental re-

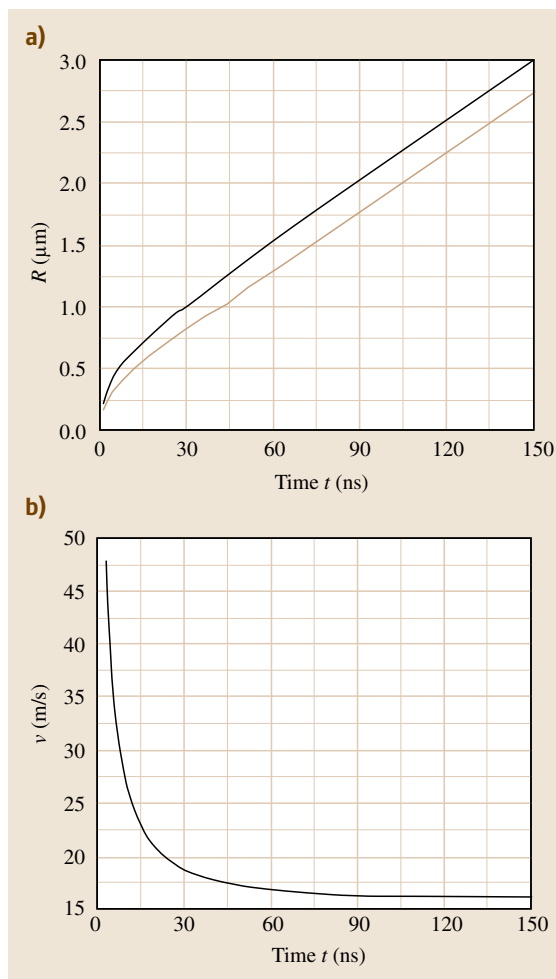

Fig. 30.24 (a) Bubble expansion around a 30 nm gold particle in blood irradiated by a laser pulse with energy density $E = 0.33 \text{ J/cm}^2$ and pulse duration $\tau_L = 8 \text{ ns}$ at constant bubble temperature (*upper curve*) and under adiabatic conditions (*lower curve*). (b) Bubble expansion rate, $v(t) = dR/dt$

sults [30.12], which include the study of nanocluster-related phenomena as discussed in Sect. 30.5.1 and below.

Microbubble Generation Around Nanoclusters

The model described above has been used to calculate the bubble growth in time around 30 nm gold particles and homogeneous clusters with radius of 190 nm surrounded by blood biomedium when the incident laser pulse has energy density of $E = 0.33 \text{ J/cm}^2$ and pulse

Fig. 30.25 Adiabatic expansion of the bubble produced by a single 30 nm particle (*lower curve*) and 190 nm continuous cluster (*upper curve*) irradiated by a laser pulse with energy density $E = 0.33 \text{ J/cm}^2$ and pulse duration $\tau_L = 8 \text{ ns}$

duration of $\tau_L = 8 \text{ ns}$. The physical properties of blood used in the calculations are listed in Table 30.13. The results of the simulations are presented in Figs. 30.24 and 30.25. Figure 30.24 illustrates the time behavior of the radius and its rate for the bubble generated around the 30 nm particles heated and cooled in blood. Figure 30.25 demonstrates the difference in the time dynamics of bubble growth caused by the single 30 nm particle and 190 nm homogeneous cluster.

Calculations are performed for both cases at constant bubble temperature ($k = 1$) and for adiabatic conditions ($k = \gamma = 4/3$). Under such conditions, the time dependence of the bubble radius $R(t)$ is a better fit to our experimental results [30.12]. As follows from our calculations, the adiabatic expansion of the bubble provides a final radius of $3.5 \mu\text{m}$ for the bubble lifetime 200 ns, which agrees well with our experimental observations in [30.12].

The general feature of the simulation results is linear and smooth growth of the bubbles' radius with time when the bubbles' lifetime exceeds 30 ns. The time dynamics of the temperature, as calculated in [30.1] for 30 nm nanoparticles heated by a 8 ns laser pulse, show that the total time for one cycle (heating of the nanoparticles from an initial temperature 300 K to maximum temperature, and then cooling back to the initial temperature) is about 30 ns. Thus, linear growth of the bubble radius with time after 30 ns can be explained by the ab-

sence of an active heat source in the medium. This result is confirmed also by the rate dynamics $v(t) = dR/dt$ for the bubble radius shown in Fig. 30.24b. In the time range 0–30 ns, the curves of both $R(t)$ and $v(t)$ have strong nonlinearity due to active heat transfer from the nanoparticle to the surrounding medium. During the first several nanoseconds, the bubble rapidly expands with a high velocity of 40 m/s. Then, the expansion rate drops exponentially and reaches a constant saturation value of 16 m/s for $t > 30$ ns. Since there is no heating source in the system after 30 ns, the microbubble expands uniformly and linearly at a constant rate.

It is important to compare the bubble expansion rate with the thermal conduction rate in the surrounding medium. Using the thermal properties of blood given in Table 30.13 and the size of the locally heated region $l \approx 1 \mu\text{m}$ as a focal spot of the laser radiation, we find that the approximate speed for heat conduction is

$$v_{\text{thermal}} \approx \frac{\mu_0}{\rho c l} \approx 0.15 \text{ m/s}, \quad (30.29)$$

which is more than two orders of magnitude less than the bubble expansion rate. Here, ρ , c , and μ_0 are, respectively, the density, specific heat, and thermal conductivity of the surrounding medium. So, during a laser pulse of $\tau_L = 8$ ns, thermal damage occurs over a negligible distance from the nanoparticle in comparison with the bubble damage. Thus, bubble expansion occurs on a time scale much shorter than heat loss, which justifies the use of an adiabatic treatment during the expansion. The thermal relaxation time is 1.75 μs for water and 1.56 μs for blood, which is much longer than the bubble lifetime of about 200 ns. This means that, for cell damage by bubble expansion, it is sufficient to heat only the nanoparticles up to the critical threshold temperature for bubble generation (423 K) without having to heat the surrounding cellular medium. Therefore, the relatively low optical flux of 0.33 J/cm^2 ($\tau_L = 8$ ns) is enough for effective cell killing.

Similar bubble expansion dynamics is observed for the bubble produced by a homogeneous cluster, as illustrated in Fig. 30.25. The cluster's curve has both linear and nonlinear parts with notably higher expansion rate of more than 90 m/s in the first 4 ns. During adiabatic expansion of the bubble produced by a homogeneous cluster in blood, the saturated expansion rate is 17 m/s, and the final radius reaches $\approx 5.5 \mu\text{m}$ for bubble lifetime of 200 ns. According to our calculations, the heated 380 nm cluster is able to produce one large bubble in the cell volume, whose damage area is comparable to the

size of a cancer cell (10–15 μm in diameter). Thus, the formation of just one large bubble around one large nanocluster aggregated in the cell volume is good enough for cancer cell killing.

In conclusion, the bubble mode of photothermalysis decreases the threshold optical flux to 0.33 J/cm^2 ($\tau_L = 8$ ns) for cancer cell killing and dramatically increases the damage area due to rapid expanding microbubbles around the nanoparticles and cluster:

- The expansion of the bubble has a strong nonlinearity in the time range 0–30 ns due to active heat transfer from nanoparticles to the surrounding medium. During the first several nanoseconds, the bubble produced around a 30 nm particle rapidly expands with a high velocity of 40 m/s. Then, the expansion rate drops exponentially and reaches a constant saturation value of 16 m/s for $t > 30$ ns. Since there is no heating source in the system after 30 ns, the microbubble expands uniformly and linearly at a constant rate.
- The adiabatic expansion of the bubble produced around a single 30 nm particle reaches a final radius of 3.5 μm for bubble lifetime of 200 ns.
- The speed for heat conduction in the cellular medium ($v_{\text{thermal}} = 0.15 \text{ m/s}$) is more than two orders of magnitude less than the bubble expansion rate ($v_{\text{saturated}} = 16 \text{ m/s}$), so that, during a laser pulse of $\tau_L = 8$ ns, thermal damage occurs over a negligible distance from the nanoparticle in comparison with the bubble damage.
- A heated 380 nm cluster is able to produce a single large bubble within the cell volume, whose damage area is comparable to the size of a cancer cell (10–15 μm in diameter).

30.6.3 Laser-Induced Thermal Explosion Mode – Nanobombs

In this section, we discuss a new mechanism for selective laser killing of abnormal cells by laser thermal explosion of single nanoparticles – nanobombs – delivered to the cells. Thermal explosion of the nanoparticles is realized for ultrashort laser pulses when the heat is generated within the strongly absorbing target more rapidly than the heat can diffuse away. Laser-induced rapid explosive evaporation of gold nanoparticles (GNs) enables the generation of stress transients, shock waves, and high local pressure. A schematic picture of these complex physical effects is provided in Figs. 30.26 and 30.27. There are two main physical mechanisms

Fig. 30.26 Principle of the thermal explosion mode of nanoparticles – nanobombs – in selective nanophotothermolysis of cancer

Fig. 30.27 Laser-induced thermal explosion of a gold nanoparticle

that could lead to the laser-induced explosion of GNs: the *thermal explosion mode* through electron–phonon excitation–relaxation, and the *Coulomb explosion mode* through multiphoton ionization.

Thermal Explosion Mode

Under the action of ultrashort laser pulses in the spectral range of the surface plasmon resonances (for a solid spherical GN, the maximum absorption is ≈ 520 nm), GN atoms are excited to upper electronic states owing to the absorption of many photons. Through rapid (picosecond time scale) relaxation, GN atoms decay to their ground state with effective electron–phonon conversion of the absorbed photon energy into thermal energy. Depending on the GN temperature T , the following scenarios, individually or in combination, can occur:

1. $T < T_{LV}$, where T_{LV} is the liquid vaporization temperature (water in many cases), ≈ 150 – 350 °C [30.54]. This is thermal expansion of a single GN

and surrounding thin liquid layer, which is accompanied by the generation of linear acoustic waves, known as the *classic photoacoustic effect*.

2. $T_{LV} \leq T < T_{GNM}$, where T_{GNM} is the GN melting point, ≈ 1063 °C [30.55]. This is bubble formation with expansion and collapse, which is accompanied by the production of acoustic and shock waves [30.56,57].
3. $T_{GNM} \leq T < T_{GNB}$, where T_{GNB} is the GN boiling point of ≈ 2710 °C [30.55], with GN melting.
4. $T \geq T_{GNB}$, which is GN boiling with the formation of gold vapor around liquid gold drops.

The photothermal process of scenario 3, and especially scenario 4, may lead to GN fragmentation into smaller parts – nanobullets – and to the thermal explosion of a GN into single atoms.

Coulomb Explosion Mode

For ultrashort laser pulses (e.g., femtosecond time scale) comparable to the time scale of electron–electron

interactions and shorter than the electron–phonon interaction time, a nonphotothermal mechanism of GN explosion can occur through multiphoton ionization when the absorbed photon energy is transferred directly to the electrons, leading to their ejection due to the Coulomb explosion mechanism [30.58, 59]. High GN plasmon-resonance absorption may facilitate this effect due to thermionic electron emission.

Time Scale Approximations

The goal of this theoretical modeling is to estimate the threshold laser energy density E_{expl} required for realization of the thermal explosion mode of GNs, and to compare the calculated data with available experimental results. This mode is realized through rapid overheating of a strongly absorbing target during a short laser pulse when the influence of heat diffusion is minimal. Let us first estimate the time scale for thermal relaxation due to heat diffusion from the surface of the nanoparticle.

In the vicinity of $\text{GN} \leq 5R$, where R is the nanoparticle's radius, the thermal relaxation time for a spherical GN can be estimated as $\tau_T = R^2/6.75k$, where k is the thermal diffusivity [30.1]. For $R = 50, 100$, and 200 nm, estimates of τ_T (for water, $k = 1.44 \times 10^{-3} \text{ cm}^2/\text{s}$) are approximately 2.6, 10, and 41 ns, respectively. For a laser pulse duration $t_p \leq \tau_T$, heat is generated within the GN more rapidly than it can be diffused away, so that we can neglect heat losses from the surface of the GN due to heat diffusion into the surrounding medium. This condition for smaller GNs is valid with picosecond and femtosecond laser pulses.

Threshold Intensity for Laser-Induced Thermal Explosion

Consider a nanoparticle selectively delivered to a targeted site (e.g., cancer cell) to be irradiated by a laser of intensity I . The power of the absorbed electromagnetic field is $P = \sigma_{\text{abs}} I$, where σ_{abs} is the GN's cross-section of absorption. If σ_{abs} is large enough, thermal explosion of the GN may occur at certain values of the threshold laser intensity I_{expl} , which is less than the threshold intensity for optical plasma formation in the surrounding medium [30.17, 18]. Under the thermal explosion of GNs, we understand the specific case for which the total energy absorbed by the GN during the time of its inertial retention in vapor state, $\tau_{\text{expl}} = R/u_s$, exceeds the energy required for the GN's complete evaporation, $\rho q V = N_{\text{Au}} q_1 V$. Here, u_s is the sound velocity in Au vapor at the critical temperature $T_{\text{cr}} \sim T_{\text{GNB}}$; ρ is the volume density of GN; N_{Au} is the number of Au atoms per unit volume; q and q_1 are the particle's specific heat

of evaporation per unit mass and per particle, respectively; and V is the GN's volume. We have a laser pulse duration of $\tau_L > \tau_{\text{expl}} = R/u_s$ (≈ 1 ps for $R \approx 10$ nm), where τ_{expl} is an explosive evaporation time.

To compute I_{expl} , we can use the model described in [30.1]. According to that model, the threshold intensity of the laser radiation for thermal explosion of the spherical GN can be expressed as

$$I_{\text{expl}}(R) \approx \frac{4\rho T_{\text{cr}} q u_s}{3K_{\text{abs}}(R)}, \quad (30.30)$$

where K_{abs} is the nanoparticle absorption efficiency. Thus, the solid nanoparticle in a relatively strong laser field with intensity $I \geq I_{\text{expl}}$ during the short time $\tau_{\text{expl}} \approx R/u_s$ transforms into a gas (vapor) sphere of radius $\approx R$, which has high temperature $T \sim T_{\text{GNB}}$ and high pressure $P_{\text{vap}} \gg P_{\infty}$, where P_{∞} is the ambient pressure.

We assume here that thermal explosion of a GN is accompanied by the generation of shock waves that expand with a supersonic velocity $u_s = R/\tau_{\text{expl}} = I_{\text{expl}}/4\Delta H \approx 10^5 \text{ cm/s}$. Here, $\Delta H = \Delta H_{300-\text{vap}} + \Delta H_{\text{vap}}$, where $\Delta H_{300-\text{vap}}$ is the enthalpy change per unit volume for heating the GN from the ambient temperature to the vaporization temperature, and ΔH_{vap} is the vaporization enthalpy per unit volume. The shock waves could be waves of high acoustic or/and water vapor pressure, which spread out over long distances around an epicenter of explosion and produce irreparable mechanical cell damage [30.60–67]. It should be noted that the pressure produced by vaporization of a GN itself (e.g., $\approx 10^{-2} \text{ atm}$ [30.68]) is less than the water vapor pressure around the hot GNs. Indeed, the number of atoms vaporized per unit of time and per unit of particle surface is given by [30.69]

$$\frac{dN_{\text{vap}}}{dt} = u_s N_{\text{Au}} = \frac{I_{\text{expl}}}{4\Delta H} N_{\text{Au}}. \quad (30.31)$$

For example, the atomic density of bulk gold is $5.9 \times 10^{22} \text{ cm}^{-3}$, while each GN contains approximately 10^9 atoms, leading to an average atom density of 10^{17} cm^{-3} . Higher gold vapor pressure can only be reached on the front end of the explosion, where explosion products are localized in a thin layer.

Cell Damage Effects

The therapeutic effect of laser-induced explosion of GNs for cancer treatments can be achieved due to one or several phenomena, such as protein inactivation (e.g., through denaturation or coagulation) around hot GNs [30.61], bubble formation [30.12], generation of

Fig. 30.28 Schematic time scale for shock wave and conventional bubble formation using the thermal explosion mode

acoustic and shock waves [30.62–67], and interaction with GN fragments and atoms. An important damage-related factor is not only the temperature but also the vapor pressure produced by both water and gold vapors, accompanied by the cavitations and shock waves, with local pressure up to gigapascals [30.62–67]. The damage of specific cellular structures (e.g., plasmatic membranes, nuclei, cytoskeletons, and organelles) in the laser explosion mode depends on GN parameters (composition, size, and shape), their number and location, laser parameters (wavelength, fluence, pulse duration, and number of pulses), and properties of the surrounding media (e.g., amount of water).

The time required to destroy an abnormal cell of size d by supersonic expansion of shock waves can be roughly estimated as $\tau_{sw} \approx d/u_s$. In the case of 15 μm -diameter cancer cells [30.12, 17, 18], this is $\tau_{sw} \approx 15$ ns, which is comparable to the lifetime of sound/pressure shock waves in an aqueous medium. We can estimate the lower level of the threshold energy density of a laser pulse required for thermal explosion of the GN using $E_{\text{expl}}(R) \approx I_{\text{expl}}(R) \times \tau_{\text{expl}}$, where the threshold intensity I_{expl} depends on the absorption efficiency of the nanoparticle. For the particular lasers used in the experiments [30.12, 17, 18] ($\lambda = 532$ nm, $\tau_L = 8$ –10 ns), the threshold energy density for thermal explosion of a solid gold nanosphere of size $R = 35$ nm (absorption efficiency of $K_{\text{abs}} = 4.02$) is $E_{\text{expl}} = 38.5$ mJ/cm².

This density strongly depends on the types of nanoparticles (e.g., gold solid nanospheres, nanoshells, and nanorods). For example, gold nanorods have a near-IR resonance absorption efficiency of approximately 14 for an effective radius of 11.43 nm [30.26]. Due to the higher plasmon-resonance absorption efficiency of nanorods, the threshold energy density can be reduced by using gold nanorods to $E_{\text{expl}} = 25$ mJ/cm². It is important to note that the estimated threshold energy densities for thermal explosion of GNs at the given wavelength $\lambda = 532$ nm are 2.5–4 times less than the laser fluence of 100 mJ/cm² established as the safety standard for medical lasers [30.70].

The estimated values for E_{expl} are in good agreement with some available experimental results. Indeed, for spherical GNs with average size of 45 nm irradiated with second-harmonic Nd:YAG laser pulses (532 nm for 7 ns), the laser fluence threshold for changing the GN shape and its fragmentation associated with GN melting and boiling phenomena are 16 and 30 mJ/cm², respectively [30.55]. The more intense GN fragmentation to small fragments of mainly 5–10 nm in size has been observed for laser fluences in the range 30–140 mJ/cm² and higher [30.55]. For a 30 ps pulse, 25 nm GN fragmentation has been observed at 23 mJ/cm², with a slight effect on changing the GN shape, even at 2–5 mJ/cm² [30.28].

Thus, thermal explosion around GNs may make a significant contribution to cell damage alone or together with conventional water vapor bubble formation in nanophotothermolysis, which is characterized by a higher laser fluence range of 50–500 mJ/cm² [30.1]. As previously mentioned, conventional bubble formation usually starts at the end of a nanosecond laser pulse, while the thermal explosion time scale is from 1 ps to a few ns [30.17, 18]. A schematic time scale for shock wave and conventional bubble formation in the thermal explosion mode is shown in Fig. 30.28. Thus, shock waves appear earlier than bubbles induced by the explosive vaporization of GNs in a liquid environment.

The laser-induced explosion effect can explain the experimental results [30.7, 16] with notable cancer damage with 1.4 nm GNs inside viruses on a cell membrane with picosecond laser pulses (30 ps, 50–100 mJ/cm²) when the probability of classic water bubble formation is very low. We believe that the explosion mode may be essential in selective nanophotothermolysis of DNA, and this mode is definitely becoming dominant in the absence of a sufficient amount of water around GNs. This mode can be combined with a bubble overlapping

mode [30.12] as described above, where the explosion of a few closely located GNs in a gold nanoparticle cluster (GNC) can produce one large bubble with enhanced killing efficiency. The explosion of GNs on smaller particles or single gold atoms during a laser pulse may provide the condition for interaction of the pulse with its atoms, leading to their ionization and plasma formation. However, these effects should appear at relatively high laser fluences that are not safe for normal cells [30.57].

Thus, we have considered a new mechanism for selective laser killing of abnormal cells by laser thermal explosion of single nanoparticles (nanobombs) delivered to the cells. Thermal explosion is realized when heat is generated within a strongly absorbing target more rapidly than the heat can diffuse away. On the basis of simple energy balance, it is shown that the threshold energy density of a single laser pulse required

for the thermal explosion of a solid gold nanosphere is approximately 40 mJ/cm^2 . The nanoparticle's explosion threshold energy density can be reduced further (to 11 mJ/cm^2) by using large nanorods (and probably nanoshells) and many other advanced GNs whose optical plasmon resonance lies in the near-IR region, where the biological tissue transmissivity is the highest. Additionally, the effective therapeutic effect for cancer cell killing is achieved due to nonlinear phenomena that accompany the thermal explosion of the nanoparticles, such as the generation of GN explosion products with high kinetic energy (nanobullets), as well as strong shock waves with supersonic expansion in the cell volume or production of optical plasma. It is important that most of these phenomena can explain some published experimental results whose interpretation was performed without taking into account this effect.

Carbon Nano

31. Carbon Nanotube Membrane Filters

Anchal Srivastava, Saurabh Srivastava, Kaushik Kalaga

This chapter provides an overview of different filtration processes (Sect. 31.1) and the mechanism of nanofiltration (Sect. 31.2). In the following sections, we focus on nanofiltration based on carbon nanotube membranes. A brief introduction to carbon nanotubes and their structure and properties is given, with an emphasis on the different kinds of synthesis of membranes; their function in nanofiltration in gas–vapor transport, liquid transport, and some other filtration-like techniques for filtration of bacteria and viruses is also discussed

in detail (Sect. 31.3). Finally, an outlook of future research is proposed.

Membrane technology is a widely explored process for separation and filtration of many chemicals, both domestically and commercially. Historically in India, domestic filtration techniques were based on conventional methods using cloth membranes. Different cloth materials were used for filtration of drinking water and separation of various kinds of colloidal solutions. This provided a relatively efficient and inexpensive means for achieving otherwise difficult separations. Starting in the late 1960s, membrane processes gradually found their way into industrial applications to serve as viable alternatives to more traditional processes such as distillation, evaporation or extraction. Membrane and module sales in 1998 were estimated at more than US \$ 4.4 billion worldwide, shared by different applications as shown in Fig. 31.1. According to data from 1996, about 45% of these sales were in the USA and 29% in Europe and the Middle East. The market in Asia and South America is also growing fast. The quest for efficient filtration membranes continued, based on the main driving force of accomplishing separation. Many such membrane processes can be distinguished. Pressure-driven membrane processes such as reverse osmosis (RO), nanofiltration (NF), ultrafiltration (UF), and microfiltration (MF) are emerging as key components of water purification systems throughout the world. The

majority of the operating cost of membrane systems is associated with the high pressure needed to remove dissolved contaminants (e.g., monovalent ions and small organic molecules). RO and NF are very effective for removing dissolved ions and organic solutes. However, high pressures (100–1000 psi) are required to operate RO and NF membranes. Conversely, UF and MF membranes require much lower pressure (5–60 psi).

Such methods are presently an established part of several industrial processes. Applications of membrane technology include the use of RO and NF for desalination and water purification, electrodialysis (ED) in a chlorine caustic cell, hemodialysis for artificial kidneys, UF in the food industry for protein separation from milk whey and apple juice concentration, pervaporation (PV) for dehydration of ethanol, controlled release of drugs, genetic engineering, etc. [31.1–5]. An overview of the driving forces and the related membrane separation processes is presented in Table 31.1.

Vacuum-driven hollow membranes are also available, commercially known as ZeeWeed membrane. The microfilter, consisting of 0.085 μm pores, operates under a small suction created within the hollow fibers by a permeate pump. The treated water passes through the membrane, enters the hollow fibers, and is pumped out for distribution by the permeate pump. Air flow is intro-

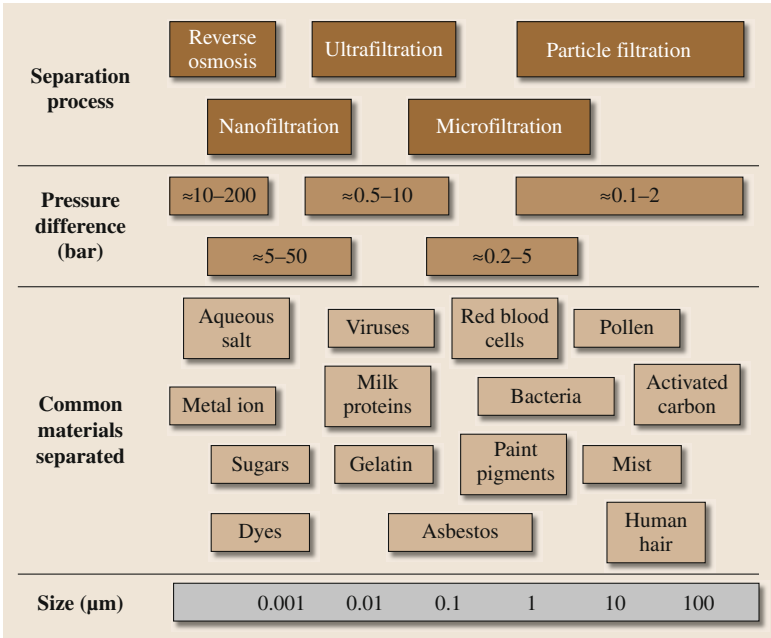

Fig. 31.1 Flowchart showing different filtration applications

Table 31.1 Driving forces and their related membrane separation processes

Driving force	Membrane process
• Pressure difference	Microfiltration, ultrafiltration, nanofiltration, reverse osmosis or hyperfiltration
• Chemical potential difference	Pervaporation, pertraction, dialysis, gas separation, vapor permeation, liquid membranes
• Electrical potential difference	Electrodialysis, membrane electrophoresis, membrane electrolysis

duced at the bottom of the membrane module to create turbulence which scrubs and cleans the outside of the membrane fibers, allowing them to function at high flux rate. This air will also oxidize iron and other, organic compounds, generating better quality water than provided by microfiltration alone.

Access to hygienic water has emerged as one of the most serious problems around the world in the 21st century. Nanotechnology has great potential for providing efficient and environmentally acceptable solutions for improving water quality and for increasing the amount of potable water available. Nanomaterials have a number of key physicochemical properties

that make them particularly attractive as separation media for water purification. On a mass basis, they have much larger surface areas than bulk materials. Thus, they are ideal building blocks for developing high-capacity sorbents with the ability to be functionalized to enhance their affinity and selectivity. Nanomaterials can serve as high-capacity and recyclable ligands for cations, anions, radionuclides, and organic compounds. They provide extraordinary opportunities for developing more efficient water-purification catalysts and redox-active media due to their large surface areas and their size- and shape-dependent optical and electronic properties.

31.1 Types of Filtration

Water treatment processes employ several types of membranes. These include microfiltration, ultrafiltration, reverse osmosis, and nanofiltration membranes:

1. Microfiltration (MF) is characterized by a membrane pore size between 0.05 and 2 μm and operating pressures below 2 bar. MF is primarily

used to separate particles and bacteria from other smaller solutes.

2. Ultrafiltration (UF) is characterized by a membrane pore size between 2 nm and 0.05 μm and operating pressures between 1 and 10 bar. UF is used to separate colloids such as proteins from small molecules such as sugars and salts.
3. Nanofiltration (NF) is characterized by a membrane pore size between 0.5 and 2 nm and operating pressures between 5 and 40 bar. NF is used to achieve separation between sugars, other organic molecules, and multivalent salts on the one hand from monovalent salts and water on the other. Nanofiltration, however, does not remove dissolved compounds.

In recent times, research in the application of nanofiltration techniques has been extended from separation of aqueous solutions to separation of organic solvents to homogeneous catalysis, separation of ionic liquids, food processing, etc. [31.6, 7]. In the literature, two main terms are used to denote this process, viz. organic solvent nanofiltration (OSN) and solvent resistant nanofiltration (SRNF). Two types of membranes are most commonly used: cellulose acetate based and polyamide composites. Membrane configurations typically include spiral wound and hollow fiber. Operational conditions and useful life vary depending on the type of membrane

Fig. 31.2 Principle of reverse osmosis

selected, the quality of the feedwater, and the process operating parameters.

4. Reverse osmosis (RO) or hyperfiltration is a physical separation process in which properly pretreated source water is delivered at moderate pressures against a semipermeable membrane. In reverse osmosis, the two solutions are separated by a semipermeable membrane, but pressure is applied to reverse the natural flow of the water as shown in Fig. 31.2. This forces the water to move from the more concentrated solution to the weaker. Thus, the contaminants end up on one side of the semipermeable membrane while the pure water is on the other side. The mechanism of solvent transport in RO is similar to that of NF [31.8].

31.2 Mechanisms of Filtration

The basic mechanism of filtration at such a small scale is governed by the Donnan effect of charge balance [31.9, 10]. When different ions diffuse through a membrane, the speed of diffusion varies from ion to ion. Sometimes, a variety of ions are slowed down and others are sped up in order to maintain charge neutrality. This effect becomes more prominent with very small pore sizes and the charge associated with the membranes. Rejection of divalent anions is higher than for monovalent anions because of the charge effect. Because the membrane must still maintain chemical equilibrium on both sides, rejection of monovalent anions will actually decrease as the concentration of divalent anions is increased in a multicomponent feed solution. In some cases this phenomenon can be so pronounced that negative rejection of monovalent anions occurs. Such charge accumulation on the feed end of the membrane leads to concentration polar-

ization. A schematic of this mechanism is shown in Fig. 31.3.

Another proposed mechanism is dielectric exclusion, which generally does not play a role in ultrafiltration or microfiltration but which is of major importance in electrodialysis [31.11, 12]. Due to the charge of the membrane and the dipole moment of water, water molecules will show a polarization in the pore. This polarization results in a decrease of the dielectric constant inside the pore, thereby making it less favorable for a charged solute to enter. However, even in the situation in which the dielectric constant inside the pore is equal to that of water, a change in the electrostatic free energy of the ion occurs when the ion is transferred from the bulk into the pore. This also results in exclusion. The relative importance of these two mechanisms in NF is still a point of debate in the scientific community. Most of the literature on NF

Fig. 31.3 Donnan mechanism of charge balance in nanofiltration

reports the Donnan effect as the distribution mechanism [31.13–15].

Various models have been proposed for the transport of solvent through membranes. These include the Kedem and Katchalsky model, Spiegler and Kedem model, solution-diffusion model, and solution-diffusion imperfection model. Transport of the solvent is accomplished through the free volume between the segments of the polymer of which the membrane is constituted. The operating pressures in RO are generally between 10 and 100 bar, and this technique is mainly used to remove water. Currently, more than 90% of the RO market is in the production of municipal drinking water and ultrapure industrial water. The remaining 10% is used in important separation processes in various applications.

On the basis of their composition and physical nature across the cross-section of the membrane,

membranes are also classified as either isotropic or anisotropic. There are two main types of anisotropic membranes: phase-separation membranes and thin-film composite membranes. Anisotropic phase-separation membranes are often called Loeb–Sourirajan membranes, referring to the people who are credited with initially developing them. These phase-separation membranes are homogeneous in chemical composition but not in structure. Loeb–Sourirajan membranes often consist of a rather dense layer of polymer on the surface of an increasingly porous layer. Thin-film composite membranes are both chemically and structurally heterogeneous [31.16]. The most commonly used materials for RO are cellulose acetate, polyamide, and thin-film composites, prepared by interfacial polymerization on the surface of a porous support [31.17–20].

31.3 Carbon Nanotube Membrane Filters

Carbon nanotubes (CNT) are an allotrope of carbon with tubular structure having diameter on the nanometer scale. Carbon atoms in nanotubes are covalently bonded to each other to form hexagonal rings, as in the case of a monolayer of graphite. They exhibit extraordinary strength and unique electrical properties, and are efficient thermal conductors. The chemical bonding of nanotubes is composed entirely of sp^2 bonds, which are stronger than the sp^3 bonds found in diamonds and provide nanotubes with their unique strength. CNTs have attracted considerable interest since their discovery. They have been well investigated in order to exploit their superior properties and multifarious applications owing to their novel properties. CNTs have been ex-

tensively used for Li-ion secondary batteries [31.21–25], nanofiltration [31.26–28], hydrogen storage in fuel cells [31.29–32], and supercapacitors [31.33–36]. End/sidewall-localized COOH and NH_2 groups generated by oxidation of CNTs have been exploited for covalent attachment of biomolecular probes [31.37–41], polymers [31.37, 42–44], and metallic particles [31.45–48].

Recently, molecular transport through CNTs and the interstices between vertically aligned CNTs has attracted much attention due to its outstanding mass transport properties. CNTs serve as a suitable membrane that shows an enhanced transport rate of water, by almost four to five orders of magnitude as compared

with other porous materials of similar size, also being very close to that of biological membrane channels such as aquaporin-1 [31.49]. A typical schematic view of this novel phenomenon is shown in Fig. 31.4, where the inner diameter is 7 nm. Molecular dynamics simulation studies predict extremely fast liquid and gas mass transportation through the inner core, as was also experimentally verified [31.50, 51]. Thus, CNT membranes, serving as a technological alternative to the existing reverse osmosis process for desalination, are of great interest [31.52, 53].

For more macroscopic measurements, the flow velocity of a liquid v through a porous membrane can be predicted using the Hagen–Poiseuille equation and is given by

$$v = \frac{\varepsilon_p \mu r^2 \Delta p}{8 \mu \tau L}, \quad (31.1)$$

where ε_p is the relative porosity, r is the pore radius, p is the applied pressure, μ is the dynamic viscosity, τ is the tortuosity, and L is the pore length. The basic assumptions behind this equation are laminar flow and no slip at the boundary layer (i.e., the velocity of the fluid at the CNT wall is zero). Pressure-driven flow measurements for liquid hexane, decane, water, ethanol, and isopropyl alcohol in CNT membrane were reported by Majumder et al. [31.49] based on (31.1), with flow velocity for these liquids of $(5.6, 0.67, 26.1 \pm 17.2, 4.5, 1.12) \times 10^{-2}$ m/s; the enhancement factors obtained for the mentioned liquids were $(1.09, 3.9, 6 \pm 1.6, 3.2, 1.4) \times 10^4$, respectively, calculated as

$$\begin{aligned} &\text{Enhancement factor} \\ &= \frac{\text{Experimentally observed flow velocity}}{\text{Hagen–Poiseuille flow velocity}}. \end{aligned}$$

In addition, there is considerable interest in integrating nanoporous membranes into microfluidic devices, thus enhancing the multiple functionality of such devices [31.54–56].

31.3.1 Structure and Properties of CNTs

A few key studies have explored the structure of carbon nanotubes using high-resolution microscopy techniques, confirming that the nanotubes are cylindrical in structure based on the hexagonal lattice of carbon atoms that forms crystalline graphite. Three types of nanotubes are possible, called armchair, zigzag, and chi-

Fig. 31.4 Water molecules passing quickly through the inner core of a carbon nanotube

ral nanotubes, depending on how the two-dimensional graphene sheet is rolled up.

These different types are most easily explained in terms of the unit cell of the carbon nanotube, i.e., the smallest group of atoms that defines its structure (Fig. 31.5). The so-called chiral vector of the nanotube, C_h , is defined by $C_h = na_1 + ma_2$, where a_1 and a_2 are unit vectors in the two-dimensional hexagonal lattice, and n and m are integers. Another important parameter is the chiral angle, which is the angle between C_h and a_1 .

When the graphene sheet is rolled up to form the cylindrical part of the nanotube, the ends of the chiral vector meet each other. The chiral vector thus forms the circumference of the nanotube's circular cross-section, and different values of n and m lead to different nanotube structures. Armchair nanotubes are formed when $n = m$ and the chiral angle is 30° . Zigzag nanotubes are formed when either n or m is zero and the chiral angle is 0° . All other nanotubes, with chiral angle intermediate between 0 and 30° , are known as chiral nanotubes.

The parameters of nanotubes are determined by their diameter and chiral angle, both of which depend on n and m . The diameter d_t is simply the length of the chiral vector divided by π , and we find that $d_t = (\sqrt{3}/\pi)a_{C-C}(m^2 + mn + n^2)^{1/2}$, where a_{C-C} is the distance between neighboring carbon atoms in the flat sheet. In turn, the chiral angle is given by $\tan^{-1}(\sqrt{3}n/2m + n)$.

Multi-walled (MW) CNTs are nanotubes with more than one wall, and their diameters are of the order of

Fig. 31.5 The chiral vector is defined on the honeycomb lattice of carbon atoms by the unit vectors a_1 and a_2 with respect to the zigzag axis. Along the zigzag axis $\theta = 0^\circ$, and along the armchair axis $\theta = 30^\circ$. Possible vectors are specified by pairs of integers (n, m)

a few tens of nanometers. There are two models which can be used to describe the structures of multi-walled nanotubes. In the Russian doll model, sheets of graphite are arranged in concentric cylinders. In the parchment model, a single sheet of graphite is rolled up around itself, resembling a scroll of parchment or a rolled-up newspaper. The interlayer distance in multi-walled nanotubes is close to the distance between the graphene layers in graphite, approximately 3.4 \AA .

CNTs exhibit a wide range of mechanical, optical, and electronic properties. Carbon nanotubes are the strongest and stiffest materials yet discovered in terms of tensile strength and elastic modulus, respectively. This strength results from the covalent sp^2 bonds formed between the individual carbon atoms. In the year 2000, a multi-walled carbon nanotube was tested to have a tensile strength of 63 GPa. Under excessive tensile strain, the tubes will undergo plastic deformation. This deformation begins at strains of approximately 5% and can increase. Geometrical considerations suggest that carbon nanotubes should be much softer in the radial direction than along the tube axis. Indeed, transmission electron microscope (TEM)

observations of radial elasticity suggest that even the van der Waals forces can deform two adjacent nanotubes [31.57,58].

Owing to their unique structure consisting of sp^2 hybridized carbon, CNTs exhibit excellent electrical conductivity along their axial direction. Their conductivity is significantly low along the radial direction. For a given (n, m) nanotube, if $n = m$, the nanotube is metallic, and if $n - m$ is a multiple of 3, then the nanotube is semiconducting with a very small bandgap; otherwise, the nanotube is a moderate semiconductor. Multi-walled carbon nanotubes with interconnected inner shells show superconductivity with a relatively high transition temperature $T_c = 12 \text{ K}$.

CNTs are good thermal conductors along the axis of the tube and are equally good insulators along the lateral direction to the tube axis. The type of conduction most commonly exhibited by CNTs is known as *ballistic conduction*. A single-walled carbon nanotubes (SWCNTs) has a room-temperature thermal conductivity along its axis of about $3500 \text{ W m}^{-1} \text{ K}^{-1}$ as compared with $385 \text{ W m}^{-1} \text{ K}^{-1}$ for copper, which is the most widely used conductor [31.59–61].

31.3.2 Types of CNT Membranes in Nanofiltration

Primarily, there are five approaches to the synthesis of membranes based on CNTs:

1. Deposition of carbonaceous materials inside preexisting ordered porous membranes, such as anodized alumina, also known as template-assisted open-ended CNT membranes [31.62, 63].
2. Membranes based on the interstices between nanotubes in a vertical array of CNTs, subsequently referred to as aligned-array outer-wall CNT membranes [31.64].
3. Vertically aligned open-ended CNTs surrounded by an inert polymer or ceramic matrix, or open-ended CNT/polymer composite membranes [31.65, 66].
4. Membranes composed of nanotubes in the form of a thin mat, also known as buckypaper membranes [31.67–69].
5. Multistacked membranes of aligned CNT bundles.

Template-Assisted Open-Ended CNT Membranes

In this approach, a preexisting ordered porous ceramic membrane (alumina) acts as a template for deposition of carbonaceous materials, usually using chemical vapor deposition (CVD) [31.62, 64–66, 70] at high temperatures, forming pores with reduced dimensions. Ceramic membrane-based templates fabricated by electrochemical anodization of metal films have very low porosity (< 10%), are mechanically very brittle, are often irreproducible (usually having less than 5 nm pore size), and have controllable pore size distribution. These membranes have great potential for application in size-based separation [31.71] and as catalytic membrane reactors [31.72], which upon further modification by carbonaceous materials leads to many possibilities. A schematic representation of carbon nanotubes grown inside an anodized alumina template and a scanning electron micrograph of partially dissolution of the template are shown in Fig. 31.6a,b.

The synthesis and characterization of template-synthesized membranes have been pioneered by Martin's group at the University of Florida. A typical schematic and scanning electron microscopy (SEM) image of a template-synthesized CNT membrane is shown in Fig. 31.6. The carbonaceous materials deposited inside the alumina template by CVD of ethylene can reduce the pore size from ≈ 300 to 200 nm, but further reduction was not observed [31.62]. Since the faster ki-

Fig. 31.6 (a) Schematic representation of carbon nanotubes grown inside an anodized alumina template; and (b) scanning electron micrograph of partial dissolution of the template

netics of this deposition procedure is less controllable for obtaining smaller pore dimension, Martin's later work was dedicated to the use of more well-controlled solution-based electroless deposition techniques for steric separation of small molecules [31.73]. In this context, *Alsyouri* et al. [31.70], used trimethyl ammonium and water for CVD deposition, resulting in a reduction of the porosity of ≈ 20 nm templates and not their pore size.

CNT membranes synthesized by this method also contain amorphous or partially graphitized CNTs and are chemically different from membranes based on highly ordered graphitic CNTs. They can, however, be graphitized by heat treatment at higher temperature ($> 2000^\circ\text{C}$) [31.74].

In this regard, it is valuable to point readers to the fabrication of finely controllable, well-branched, and crystallized CNT architectures by *Ajayan* and coworkers [31.75] using this template approach. These have smaller pore dimensions at one end and larger pore structure at the other end, similar to the asymmetric membranes usually used for filtration purposes.

The excellent mass transport properties of these novel nanoscale architectures are of much interest in water vapor/oxygen [31.70] and electroosmotic transport [31.62]. A major advantage of the template synthesis approach is that the modular components of thin-film deposition, electrochemical treatment, and CVD can be integrated into microfluidic device fabrication platforms. However, other approaches using as-formed graphitic CNTs seem to be more realistic for producing CNT membranes for large-scale applications.

Partition of water vapor from air by a membrane was carried out using the apparatus shown in Fig. 31.7 [31.70]. CVD-modified Anopore membranes were carefully fixed in a stainless-steel permeation cell. A $100\text{ cm}^3/\text{min}$ mixture of dry air and wet air was established on the upstream side of the sample. Dry

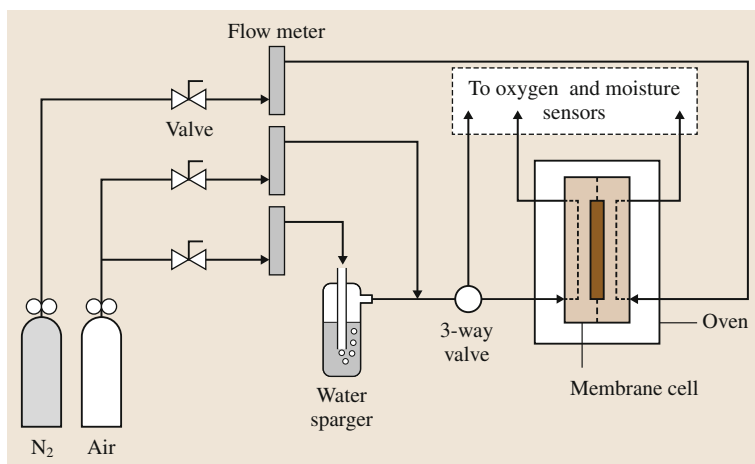

Fig. 31.7 Water vapor separation system

nitrogen from a cylinder was passed at a flow rate of $75 \text{ cm}^3/\text{min}$ in cross-flow fashion over the downstream side of the sample. Different upstream humidity was acquired by changing the flow rate of dry air and wet air, with the total flow rate kept at about $100 \text{ cm}^3/\text{min}$. The temperature was kept at about 25°C . The relative humidity and oxygen content of the streams were respectively detected by a humidity and oxygen sensors. The occurrence of each species was calculated from the permeation flux of that species divided by its trans-membrane partial pressure. Then, the water to oxygen separation factor was obtained from the ratio of water to oxygen molar fraction in the outlet of downstream and that in the outlet of the upstream.

In another example of electroosmotic flow (EOF) across a carbon nanotube membrane (CNM), the membrane separates two electrolyte solutions and an electrode in each solution passes a constant ionic current through the nanotubes [31.62]. EOF was investigated by measuring the flux of a probe molecule (phenol) across the CNM. The as-synthesized CNMs have anionic surface charge, and EOF is in the direction of cation migration across the membrane.

Membranes Formed from Aligned Arrays of CNTs

In the past two decades, production of controlled nanostructure composed of aligned CNTs has become a subject of interest due to its interesting anisotropic properties. Aligned arrays of CNTs can be used as membranes, where transport occurs largely through the interstices between the CNTs, as shown in Figure 31.8a,b. The CNTs in this membrane structure are held together by van der Waals interactions, and the pore size of the membrane is usually in

the range of $40\text{--}100 \text{ nm}$ – suitable for ultrafiltration applications.

The earliest report of aligned MWCNT films was by *deHeer* et al. in 1995 [31.76], using the arc evaporation process. Subsequently, other methods, such as CVD, a scalable and industrially viable process, became popular [31.77]. Aligned MWCNTs were also grown on nickel-coated glass substrates by plasma-enhanced hot-filament CVD from a mixture of acetylene and ammonia below 666°C [31.78], but considerable bamboo-type structures limit their flowthrough applicability. Efforts have also been focused on ideal and mass production of MWCNT arrays from a continuous source of ferrocene and xylene at $\approx 650^\circ\text{C}$ [31.79].

CNTs have several unique properties, including high electrical conductivity and elasticity, which have been exploited in creating stimuli-responsive membranes. An account of such demonstrations and how this effect might influence some technologies is presented in this section.

Researchers have demonstrated that superhydrophobic CNT arrays can be rendered hydrophilic by application of an electric potential. These membranes are analogous to dense outer-wall membranes, but are superhydrophobic; water transport through the CNT arrays can be controlled by the application of an electrical bias to the membrane [31.80].

Although this potential-dependent wicking behavior through the CNT membrane is analogous to the well-known phenomenon of electrowetting, the ability to control water transport through a membrane structure by an external stimulus can be useful in applications where controlled transport of water droplets is necessary, for example, in lab-on-chip devices.

In this context, it is worthwhile to discuss the fabrication of freestanding monolithic uniform macroscopic hollow cylinders having radially aligned carbon nanotube walls, with diameters and lengths up to several centimeters, by *Srivastava et al.* [31.64]. The aligned nanotubes that form the uniform nanoporous, cylindrical membrane walls are synthesized from sprayed ferrocene-derived iron catalyst particles; the nanotubes grow in radial directions on the walls of removable silica tube templates. They have been used as filters to demonstrate their utility in two important settings: the elimination of multiple components of heavy hydrocarbons from petroleum – a crucial step in postdistillation of crude oil – with a single-step filtering process, and the filtration of bacterial contaminants such as *Escherichia coli* or the nanometer-sized poliovirus (≈ 25 nm) from water. A major advantage of using nanotube filters over conventional membrane filters lies in the fact that they can be cleaned repeatedly after each filtration process to regain their full filtering efficiency. A simple process of ultrasonication and autoclaving ($\approx 121^\circ\text{C}$ for 30 min) was found to be sufficient for cleaning these filters. While conventional membranes are not reusable due to strong bacterial adsorption over the membrane surface, this organized nanotube architecture is reusable and can be operated at temperature of $\approx 400^\circ\text{C}$, which is several times higher than the highest operating temperatures of conventional polymer membrane filters ($\approx 52^\circ\text{C}$). The process of filtration is shown in Fig. 31.9a,b.

Open-Ended CNT/Polymer Composite Membranes

Membranes composed of open-ended CNTs have recently aroused much interest. In this approach, a composite film is synthesized from an aligned array of CNTs and a space-filling polymer [31.65] or ceramic matrix [31.66], with the openings at the ends of the CNTs formed by a plasma oxidation process. These open-ended CNT channels acts as the canal for molecular

Fig. 31.8 (a) Schematic representation of aligned CNTs membrane. (b) SEM image indicating aligned array of dense nanotubes. Transport occurs primarily through the interstices between nanotubes; moreover, transport through the inner core of the open nanotubes may also occur

transport. A schematic and SEM image of a typical nanotube membrane fabricated by such a process is shown in Fig. 31.10a,b. The choice of a suitable polymer is important: among the various polymers, polystyrene is largely explored due to its high wettability with CNTs, resulting in a dense MWCNT array ($\approx 10^{10}$ tubes/cm²).

The CNT/polymer film grown over the quartz substrate is removed by a hydrofluoric acid (HF) etch. The vertically oriented CNTs in the polymer matrix often have a graphitic end cap (with a larger concentration of defects and being easily oxidized compared with the side-walls) or a catalyst metal particle sealing the graphitic interiors, which are etched away using mild plasma oxidation without degrading the mechanical structure of the CNTs [31.81, 82].

This plasma oxidation process is advantageous for the membrane fabrication process, since it removes excess polymer by oxidative trimming to make the membrane electrically conducting. Moreover, it also removes amorphous carbon and iron impurities by HCl treatment. Additionally this plasma oxidation process introduces functional groups (mainly $-\text{COOH}$) at the CNT tips, making these membranes suitable for chemical and biological applications.

Fig. 31.11 (a) Schematic of the permeation cell. The feed solution contains 5 mM $[\text{Ru}(\text{bipy})_3]^{2+}$ and 5 mM MV^{2+} , the permeate volume is 1.3 ml, and the exposed membrane area is 0.3 cm^2 . (b) The probe molecules have similar charge but different sizes and shapes. $[\text{Ru}(\text{bipy})_3]^{2+}$ is a spherical molecule of about 11 \AA diameter, and MV^{2+} is a cylindrical molecule of 5 \AA equivalent spherical diameter (10 \AA long, 3 \AA diameter)

The CNT membrane structure after the plasma oxidation process shows a pore size distribution of $\approx (6 \pm 2) \text{ nm}$, which is consistent with TEM observations of the inner core of $\approx 7 \text{ nm}$.

In similar work, aligned CNTs (with $< 2 \text{ nm}$ diameter) were grown on a Si chip patterned with metal catalyst using a CVD process. The surrounding space between the nanotubes was filled up with a ceramic material (Si_3N_4). Standard etching procedures created openings on the Si chip, and the excess Si_3N_4 and catalyst nanoparticles were removed by Ar-ion milling. Eventually, the CNTs were uncapped by reactive-ion etching [31.66]. The common feature of these two works is that they are based on standard lithography.

More traditional inorganic membrane fabrication research has focused on making robust and cost-efficient CNT membranes, avoiding the use of lithographic tools. In this approach, aligned CNT arrays are grown over macroporous alumina supports and the interstitial space between the CNTs is filled by poly(styrene); however, the viscosity of the polymer is high enough to inhibit its entry into the macroporous alumina support. Mechanical polishing and acid treatment are adopted to remove the polymer overlayer and to open up the CNTs [31.83].

In sum, the fabrication of open-ended CNT membranes is complex, but it offers tighter control over pore

size as the transport occurs through the inner cores of the CNTs.

These membranes have been employed mainly in nanoparticle partition and small-molecule separation. Plasma oxidation during the membrane fabrication process establishes carboxylic acid groups on the CNTs' tips that can be modified using carbodiimide-mediated coupling between the carboxylic acid and available amine groups of the functional molecule. Transport through the membrane of two differently sized but equally charged molecules (ruthenium bipyridine and methyl viologen) was quantified in a U-tube permeation cell by UV-Vis spectroscopy [31.84]. The process is depicted in Fig. 31.11a,b.

Owing to their high electrical conductivity, these CNT membranes are used in controlled molecular transport in an effort to mimic the complex functionality of biological voltage-gated membrane channels in an artificial system. In simplified terms, biologists have shown that molecules attached to the walls and entrances of CNT membranes can be actuated electrostatically, thereby selectively occluding the pores and altering the transport of molecules through the pores [31.85].

The CNTs are conductors inside an insulating matrix, allowing for concentration of the electric field at the tips of the CNTs for voltage gating or use as an elec-

trode. In these experiments, the electrically conducting CNT membrane is used as the electrode in a three-electrode electrochemical cell, as shown in Fig. 31.12. To make the aligned CNT membrane an optimal platform for ion channel mimetics, it is essential to increase the functional density of tethered molecules only at the entrances to the CNT cores.

Voltage-gated membrane channels, in which large macromolecules were tethered to the conducting pores of CNTs that can be actuated to selectively occlude the pores. This results in voltage-controlled transport, mimicking biological membranes, for transdermal drug delivery-type applications.

Buckypaper Membrane

CNTs are recognized to have strong affinity to aggregate due to van der Waals interactions, and it is these van der Waals interactions which also hold the CNTs together into cohesive CNT sheets, also known as buckypaper (BP). These have been demonstrated to have various potential applications, e.g., as hydrogen storage materials [31.86], anode materials in lithium-ion batteries [31.87], actuators [31.88], sensors [31.89], and artificial muscles [31.90].

Buckypaper sheets are fabricated by continuous filtration of CNTs suspension in tetrahydrofuran (THF) using a microfiltration setup under high vacuum. A polytetrafluoroethylene (PTFE) membrane is used for the filtration process. After the completion of filtration, the sample is dried in a vacuum oven, and then a thin sheet of buckypaper mat is carefully removed. The process of synthesis of buckypaper membrane,

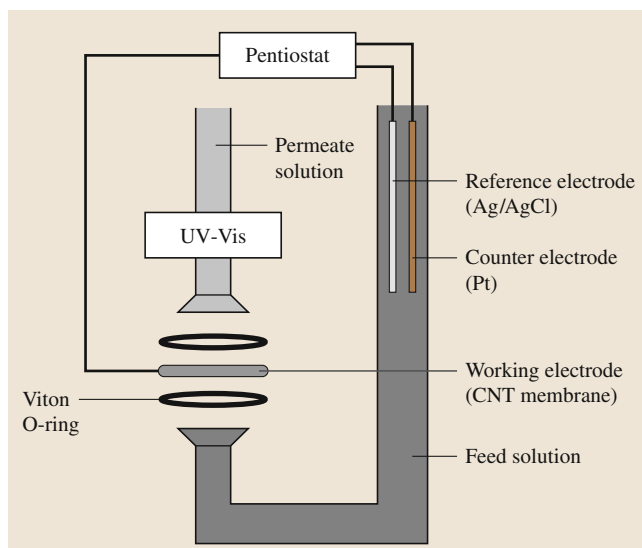

Fig. 31.12 Schematic of the experimental setup for measuring transport through membranes as a function of applied voltage. Note that the CNT membrane placed between the fed and permeate solution is the working electrode. The permeate volume is 0.8 ml, and the exposed membrane area is 0.3 cm^2

an SEM image, and the schematic are shown in Fig. 31.13a–c.

Longer, narrower (fewer walled), and purer nanotubes typically lead to stronger buckypaper with higher tensile strength. With increasing MWCNTs diameter, the attractive van der Waals forces between CNTs become less efficient, leading to buckypaper with lower

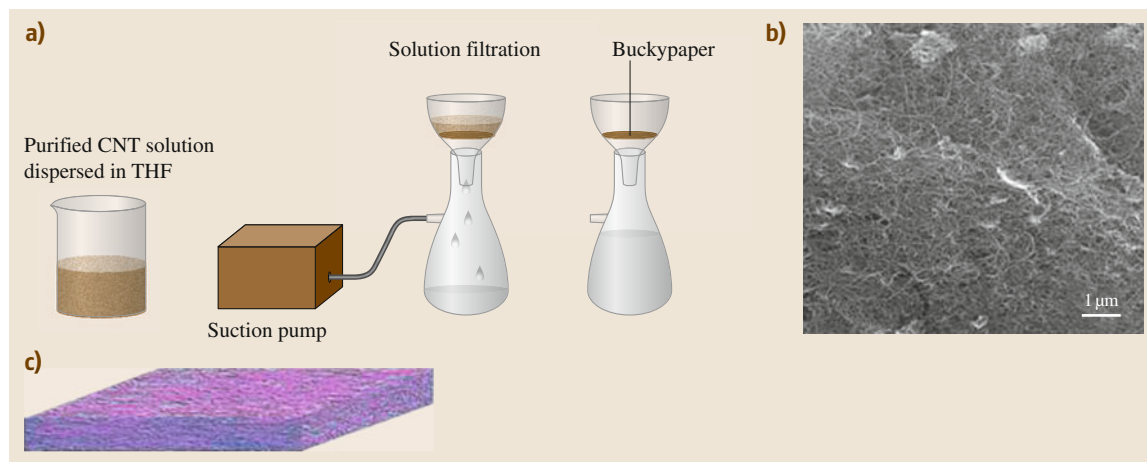

Fig. 31.13 (a) Synthesis of buckypaper membrane. (b) SEM image of fabricated buckypaper composed of randomly oriented CNTs. (c) Schematic representation of buckypaper

Fig. 31.14 Process of direct contact membrane distillation

tensile strength and reduced cohesiveness. Generally, these are more vulnerable to breakage, so different approaches to strengthen the BPs, such as electron irradiation [31.91], chemical treatment [31.92], polymer intercalation [31.93], and graphitization [31.51], have been theoretically and experimentally investigated, with some positive results.

Recently, a newer technique has been employed, where BPs were infused with polycarbonate (PC) by means of vacuum-aided solution infiltration. This procedure is capable of treating large-size BPs and is readily scalable for mass production [31.94]. A schematic of a buckypaper mat formation and a typical SEM micrograph are shown in Fig. 31.13a,b, where a mat is formed due to the entangled CNTs (Fig. 31.13c). This CNT carpet is so dense that vacuum-assisted filtration can be used to separate desired filtrates.

Buckypapers offer incredible porosity and high specific surface area in a three-dimensional (3-D) network, making them suitable for water purification by a process called direct contact membrane distillation. This technique is an alternative to reverse osmosis and other desalination techniques, particularly when the concentration of solutes is high. As illustrated in Fig. 31.14, the buckypaper is used as a highly hydrophobic membrane to separate a feed of hot sea or salty water from a permeate of cold fresh water. While liquid cannot cross the air gap formed by the membrane, water vapor is able to pass through the pores from the hot feed to the cold permeate, driven by the difference in partial vapor pressure. This vapor then condenses on the permeate side, creating fresh water.

Multistacked Membranes of Aligned CNT Bundles

This process is very similar to that reported by *Andrews et al.* [31.79], where MWCNT arrays are fabricated from a continuous source of ferrocene and xylene using CVD, wherein instead of a single bundle, multistacked bundles can be grown. In this process, a single bundle of

aligned CNTs is first grown for a few minutes, then the process is stopped. A successive layer is again grown over this, following the same process. In this way, a membrane composed of the desired number of aligned CNT stacks can be grown. The advantage of this process lies in the fact that, by changing the concentration of ferrocene and by controlling the flow rate of xylene-ferrocene solution, one can tune the density and length of the nanotubes. Therefore, one can produce a desired number of stacks with different density and preferred length of carbon nanotubes during the growth process.

There is also a possibility of sandwiching another thin layer of hydrophilic/hydrophobic materials between the CNT stack to provide desired functionality and specificity to the membrane in filtration processes. A schematic of the growth process and a typical SEM micrograph are shown in Fig. 31.15a,b. A 20 μm -thick membrane formed from 25 stacks of well-aligned CNT bundles has been fabricated. For high-quality filtration, the length of the column is an important parameter. Because of the nanochannels, the column length is reduced and therefore the size of the device is reduced significantly. Nanochannels made up of stacked CNTs will thus provide an advantage for filtering different kinds of pollutants. Another advantage is that, by changing the numbers of stacks, the filtration rate as well as the kind of filtration are modified.

CNT membranes can be widely applied for many potential commercial applications. Extensive research is being conducted in this area, trying to make efficient use of the extraordinary properties of CNTs. There have been attempts to develop functionalized CNT membranes for mass transport, sensors, chemical, and biochemical applications. CNT membranes can be functionalized with various functional groups such as carboxylic acids [31.95], amines, enzymes, and polyelectrolytes containing charged amino and carboxyl groups to achieve separation of ions by electrostatic adsorption [31.96] or proteins by affinity-based separation [31.97].

Experimental results indicate that liquid-phase treatments tend to introduce carboxylic acid groups, whereas gas-phase treatments introduce less oxidized entities such as hydroxyl and carbonyl groups [31.98].

Water plasma treatment for opening CNTs is most likely to introduce carboxyl groups on the tips of the CNT membrane, because the high reactivity of the plasma precludes its entrance deep into the pores, limiting the functionalization to the surface [31.99].

A model of the functionalization of a cylindrical membrane with carboxyl and amino functional groups

Fig. 31.15 (a) Schematic representation of the formation of multistacked CNT membrane. (b) SEM image shows 25 layers, each 20 μm thick, composed of aligned CNT arrays

is shown in Fig. 31.16b,c. Figure 31.16d presents the nanocomposite structure of this cylindrical membrane and polymer for use in numerous applications. Polymers can also be used as a filler material between the layer. Figure 31.16a shows an SEM image of a fabricated cylindrical membrane.

The concept of membrane reactors, which combine reaction and separation to increase efficiency based on the laws of mass action, is well established [31.100]. The development of electrochemical membrane reactors has been hindered by the lack of electrical conductivity of the membrane materials used to date. As discussed above, the high electrical conductivity and chemical inertness of dense array

outer-wall CNT membranes make them a candidate for simultaneous electrochemical reaction and separation, particularly for destruction of hazardous organic compounds [31.101].

The concept of a cross-flow electrochemical membrane reactor based on cylindrically shaped dense array CNT membranes [31.64] with both an open and closed channel is shown in Fig. 31.16e,f.

The organic pollutants containing phenol are fed through the opening of this membrane, using sulfuric acid as the background electrolyte.

Under a constant potential difference between the membrane (anode) and a metallic cathode, the phenol-containing organic pollutants are electrochemically

oxidized to less toxic compounds such as carbon dioxide, water, and aliphatic compounds such as oxalic acid, which permeate through the wall of the mem-

Fig. 31.17 (a) Photo of the filtration device, constant-pressure pump, and pressure-driven filtration setup. (b) Experimental results of dextran filtration studies. The black data points show the constant pressure across the membrane; the brown data points show the amount of filtrate increasing with time ◀

brane [31.102]. Electrochemical oxidation inside this membrane reactor aims at the mineralization of the contaminants to carbon dioxide, water, and inorganics, or, at least, their transformation into harmless products.

The rate of the filtration process can be further improved by applying a constant pressure along the cylindrical membrane using a constant-pressure pump as shown in Fig. 31.17a. The remaining solution comes out of the membrane from the other end and can be fed again to improve the quality of the filtrate.

The result of dextran (molecular weight 25–35 kDa) filtration studies by applying a constant pressure across a cylindrical CNT membrane is shown in Fig. 31.17b, where the black data points are obtained by continuous monitoring of the pressure difference across the two ends of the membrane during the filtration study, showing that its mechanical strength is high enough to withstand the pressure. The constant-pressure curve shows there is no breakage or distortion in the membrane at this pressure. The other graph shown by brown data points is obtained by measuring the quantity of dextran filtrate against time, showing that the amount of filtrate increases with time, exhibiting linear behavior.

31.4 Future Research Perspectives

In this chapter we have observed that a variety of CNT membranes find different applications in nanofiltration. Research interest in these CNT membranes arose due to their fast mass transport and electrochemical actuation-driven transport and because they represent substitute materials for traditional membranes in the field of membrane technology. These filters may be tailored to specific needs by controlling the

nanotube density in the walls and the surface character by chemical functionalization. There are many opportunities for use of these CNT membranes in nanoscale fluidic interconnect-based microfluidic platforms. This wide range of properties, not obvious with traditional membrane materials, is why CNT-based membranes represent a new frontier in membrane science.

32. Nanomaterial Toxicity, Hazards, and Safety

Zuzanna A. Lewicka, Vicki L. Colvin

Manufactured nanoparticles of different chemical compositions are now widely commercially applied. They are found in places as diverse as food packaging and automotive bumpers, where their special nanoscale properties help to lower cost while improving performance. Given these widespread applications, the unintended effects of manufactured nanomaterials on workers, consumers, and the environment have become a focal point for international research. Initially, the human health effects of nanoscale materials were of most interest, but more recently identification of nanoscale particles in wastewater sludge has turned attention towards their environmental impacts. Though the topic of nanomaterial safety has received substantial attention in the literature, many basic questions about nanoparticle transport, fate, and toxicology remain unanswered. A central challenge for researchers has been the definitive characterization of particular manufactured nanomaterials, particularly in commercial products that have significant human or environmental exposure. Careful determination of the physical size, surface chemistry, internal structure, and intermediate stability of manufactured nanomaterials helps investigators compare results, as well as link unwanted biological outcomes to particular material features. This chapter provides an overview of the current exposure and toxicity studies of manufactured (e.g., engineered) nanomaterials. A special emphasis in this chapter is the practice used for nanomaterial characterization as it relates to their biological and environmental properties.

Nanotechnology has been defined by the American Society for Testing and Materials (ASTM) as [32.1]

A term referring to a wide range of technologies that measure, manipulate, or incorporate

materials and/or features with at least one dimension between approximately 1 and 100 nm. Such applications exploit the properties, distinct from bulkmacroscopic systems, of nanoscale components.

32.1 Engineered Nanomaterials – General Overview

Nanoscale materials (or nanomaterials) have been described as any material having one or more dimension between approximately 1 and 100 nm [32.1, 4]. These materials can be naturally occurring (e.g., volcanic ash), incidentally produced (e.g., diesel exhaust particles) or intentionally manufactured (e.g., carbon nanotubes). Of most relevance to this work is the latter class – manmade (engineered or manufactured) nanoscale materials designed with specific properties (e.g., mechanical, optical, electrical, and/or magnetic) that differ from those of bulk materials. Nanomaterials can exist in various shapes: nanoplates, nanorods, nanotubes or nanoparticles, as presented in Fig. 32.1. According to the British Standards Institution (BSI), nanoplates are objects which have a nanoscale-order thickness while having two other external dimensions significantly larger, nanorods have two similar external dimensions on the nanoscale and the third dimension significantly larger, nanotubes are hollow nanorods, while nanoparticles are defined as particles with all three dimensions within the nanoscale [32.4].

Nanoscale materials are often lighter, stronger, and more reactive than bulk materials and can be applied in industries as diverse as medicine and aerospace [32.2, 5]. One size-dependent property that often motivates incorporation of nanoscale materials is the surface area. As the size of a material decreases, the ratio of surface molecules or atoms to total molecules or

atoms increases exponentially [32.6]. Greater surface area means a larger fraction of material is available for chemical reactions, a fact that generally increases nanomaterial overall reactivity as compared with bulk materials (Fig. 32.2) [32.3]. This translates into improved physical, chemical, and biological properties which can be incorporated into many improved applications. Other size-dependent properties may arise from the confinement of electronic excitations, or the enhanced cooperativity of magnetic spins in solids of low dimensions [32.7, 8].

Given their many unique and size-dependent properties, it is not surprising that nanomaterial use in consumer products is increasing rapidly [32.9, 10]. In 2011, the Project on Emerging Nanotechnologies (PEN) inventory identified over 1300 nanotechnology-based consumer products on the market from over 24 countries, including the USA, China, Canada, and Germany [32.10]. The largest group of products (738 products) was within the health and fitness category, which included cosmetics, clothing, personal-care products, sporting goods, sunscreens, and air and water filters. However, the database has not been updated since March 2011. Therefore, the number of consumer

Fig. 32.1 Schematic representations of various forms of nanomaterials, which include nanoparticles (nanoscale in all three dimensions), nanotubes (nanoscale in two dimensions), and nanoplates (nanoscale in only one dimension); nanoscale refers to a dimension between 1 and 100 nm (after [32.2])

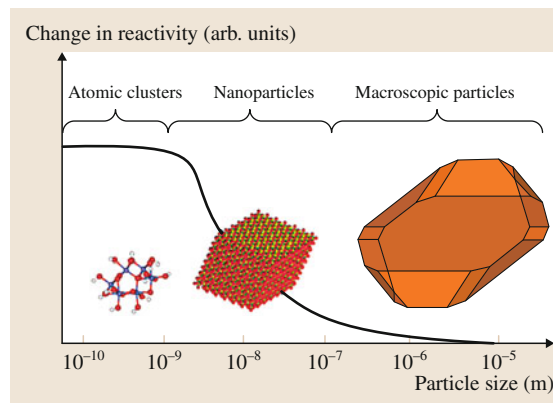

Fig. 32.2 Trend for size-dependent reactivity change of a material as the particle transitions from macroscopic (bulk like) to atomic (after [32.3])

products having engineered nanomaterials as presented in [PEN](#) is only a portion of the nanotechnology-enabled products currently on the market [32.10, 11].

As their use has expanded to include many applications that bring them into contact with people and the environment, significant questions have been raised about their possible biological and environmental interactions [32.13, 14]. As noted by *Simkó* and *Mattsson* [32.15], *A risk can be deduced from exposure data together with the hazard assessment that results after exposure*. As shown in [Fig. 32.3](#), work on hazards has dominated the development of the study of nano-

Fig. 32.4 Percentage of scientific papers addressing the hazard and exposure of carbon-based, metal oxide, metal, and semiconductor nanoparticles between 2001 and 2011 (after [32.12])

material risk, representing 90% of papers published in scientific journals.

Different nanomaterials have been the subject of varying levels of risk-based analysis. These types include carbon-based materials such as fullerenes and carbon nanotubes, metal oxide nanoparticles and rods (iron oxide, cerium oxide, titanium dioxide, silicon dioxide, etc.), metals (gold and silver), as well as semiconductor nanoparticles or so-called quantum dots (typically cadmium sulfide or cadmium selenide) [32.16]. Interestingly, a literature analysis reveals that of these materials the metal oxide and carbon-based systems have been the most examined ([Fig. 32.4](#)).

32.2 Occurrence of Engineered Nanoparticles in the Environment

As the number of consumer products containing engineered nanoscale particles grows, so will the chance of environmental exposure of a wide range of organisms [32.17]; For example, it has been estimated that in the USA, based on the reported market size for sun-care products, approximately 125 tons of nanoscale TiO_2 and ZnO ultraviolet (UV) blocking agents are used (and released) in commercial products every year [32.18]. Nanoscale TiO_2 and ZnO particles are used in sunscreens because they do not scatter visible light like their larger counterparts and appear transparent when applied to the skin [32.19, 20]. Furthermore, *Hendren* et al. estimated upper and lower bounds for the annual production quantities for five classes of engineered nanomaterials in the USA: titanium dioxide (TiO_2), silver (Ag), cerium oxide (CeO_2), carbon nanotubes (CNTs), and fullerenes, which ranged from

7800–38 000 tons/year for TiO_2 , 2.8–20 tons/year for Ag, 35–700 tons/year for CeO_2 , 55–1101 tons/year for CNTs, and 2–80 tons/year for fullerenes [32.21]. These estimates were done based on data from academic publications, professional reports, company websites, production process patents, and personal communication with company representatives. The fact that such information was not readily available reflects the lack of labeling and reporting standards for consumer products that contain nanoscale materials.

Nanoparticles can enter the environment during either their manufacture, use, or disposal; studies of nanoparticle fate and transport have concluded that the natural sinks for nanoparticles generally are soil or water [32.22, 23]. So far, no measurements of engineered nanoparticles in the environment have been able to quantify trace concentrations of these mater-

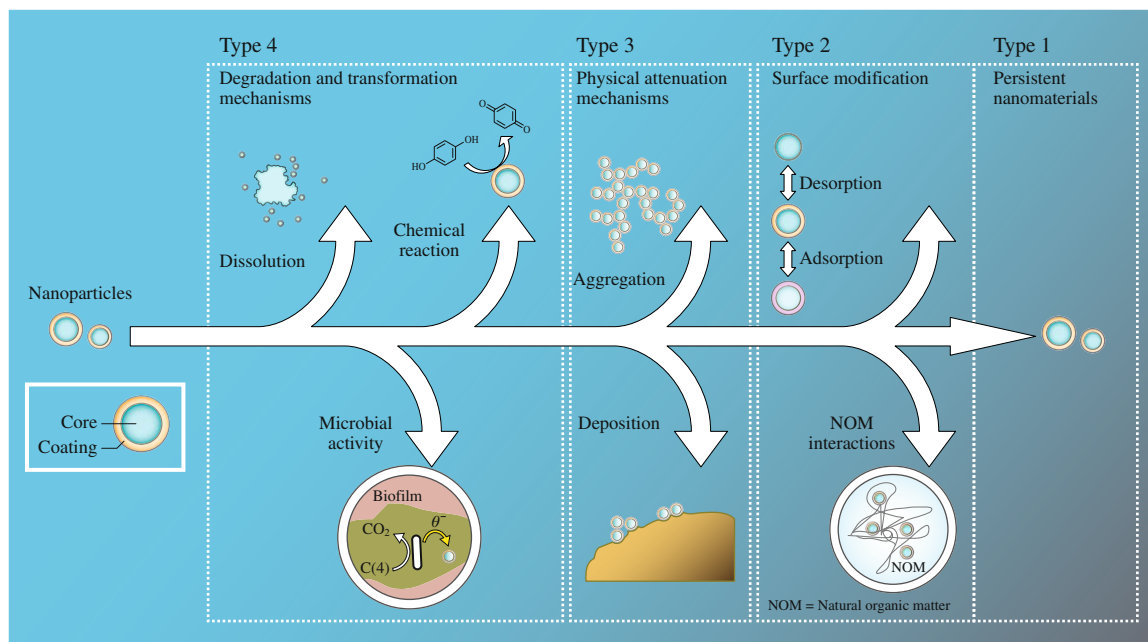

Fig. 32.5 Transformation of nanomaterials as they move through the environment (after [32.28])

ials [32.17]. However, some have found qualitative evidence that nanoscale materials, particularly those from sunscreens, can be detected in the solid waste generated by wastewater treatment plants [32.24]. Due to the lack of quantitative analytical tools for environmental exposures, much of the information about exposure has been derived from relatively coarse-grained environmental exposure models [32.25–27].

To complicate the study of exposure even further, a growing body of research focuses on the fact that nanoparticles can drastically change their behavior and physical characteristics as they move through the environment (Fig. 32.5) [32.28–33].

Changes in physicochemical properties such as surface charge and size can modify environmental fate and transport. As an example, Guzman et al. showed that the mobility of nanoscale materials in aqueous environments is dependent on the size of the nanoparticles. They reported that the point of zero charge

(*pzc*) of TiO_2 nanoparticles changed with their size and that the aggregation state increased as the pH of the solution approached the *pzc* [32.34]. On the other hand, Labille et al. studied the aging and fate of TiO_2 nanoscale particles recommended by the manufacturer (BASF Chemical Company) as sunscreen pigments and discovered that, after contact with water, the TiO_2 nanocomposite dispersed and formed a stable suspension available to microorganisms [32.35]. Lin et al. published a thorough review on the fate and transport of nanoscale materials in the environment, which included aggregation and suspension behaviors with emphasis on the influencing factors, including natural colloids, natural organic matter, pH, and ionic strength [32.36]. The authors concluded that there are still many unknowns regarding the environmental fate, transport, exposure, ecotoxicity, and lifecycle of engineered nanomaterials and that future research should focus more on real environments and experiments in the field.

32.3 Effects of Nanoparticles on Organisms

Once released into the environment, nanomaterials will interact with organisms [32.6, 37–39]. Although nanomaterial toxicity is an active area of research, the major-

ity of the published data focus on mammalian toxicity studies using a range of in vitro and in vivo tests to assess the possible toxic behavior of nanoscale materials

Fig. 32.6 Annual number of articles published in scientific journals by topic: mammalian, aquatic ecosystem, and soil ecosystem toxicity studies (after [32.12])

(Fig. 32.6). On the other hand, study of nanomaterial ecotoxicity, which identifies hazards to the environment in both aquatic and soil ecosystems, is just emerging.

32.3.1 Ecotoxicity of Nanoparticles in Aquatic Ecosystems

In 2004, Oberdorster et al. demonstrated for the first time that 0.5 ppm aqueous carbon-based nanoparticles (uncoated fullerenes, C_{60}) can cause oxidative damage and depletion of glutathione (GSH) in vivo in an aquatic species (juvenile largemouth bass) [32.37]. Since that initial report, researchers have studied how nanomaterials affect other freshwater species and marine organisms including trout, fish, waterflea, bacteria, algae, and other aquatic plants [32.40–44]. Farre et al. presented a review of ecotoxicological data on carbon-based nanomaterials, metal and metal oxide nanoparticles, as well as quantum dots in the aquatic environment [32.40]. The results indicate that nanoparticles may have ecotoxicological effects which depend sensitively on the physicochemical properties. Factors such as the chemical composition, concentration, size, shape, surface coating, charge, as well as mechanical stability can play a central role in whether a given nanomaterial is toxic or benign [32.45–50]. Farre et al. and Kahru and Dubourguier discussed also challenges in nanoeecotoxicological research [32.40, 51]. Both groups agreed that the fate of nanosized materials and in situ investigation of their impact on organisms are of the highest priority for validation of models proposed for environmental risk assessment of nanoparticles. Moreover, physicochemical characteristics of particles before, during, and

after experiments were vital to ensure the progress and comparison of research results. Furthermore, a battery of tests with different organisms is recommended to ensure adequate evaluation of the ecological situation; For example, Kahru and Dubourguier demonstrated that, among organism groups representing the main food-chain levels (bacteria, algae, crustaceans, ciliates, fish, yeasts, and nematodes), algae and crustaceans (daphnids) were the organism groups most sensitive to aquatic exposure of nanoparticles [32.51].

32.3.2 Ecotoxicity of Nanoparticles in Soil Ecosystems

While research on the ecotoxicity of nanoparticles in aquatic ecosystems is not yet complete, it is an extensive dataset compared with the very few studies of nanoparticles in the terrestrial ecosystem (Fig. 32.6). Soil ecosystems are much more complex than aqueous ones. Soils contain a wide variety of colloidal materials, including phyllosilicates, humic acids, iron oxides, and naturally occurring nanosized particles [32.52, 53]. These complexities make it particularly difficult to measure and distinguish between naturally occurring materials and engineered nanoparticles. Moreover, colloidal soil can interact with engineered nanoscale materials and affect their fate, transport, and transformation [32.36, 54]. For this reason, information on the interactions of engineered nanoparticles with soil components is needed to understand the effect of nanoparticles on terrestrial organisms.

Microbes are an important component of the terrestrial ecosystem, yet the antimicrobial activity of nanoparticles largely has been studied with human pathogenic bacteria. There is very little information available on soil microorganisms such as those that promote plant growth (e.g., rhizobacteria, nitrifying and denitrifying bacteria) or those that benefit nutrient cycling in soils [32.55]. Fourteen studies reporting the effects of engineered nanoscale materials on soil microorganisms published between the years 2007 and 2011 were reviewed by Dinesh et al. [32.55]. They summarized that fullerenes did not cause any significant toxicity to soil microorganisms while high concentrations (5000 $\mu\text{g/g}$ soil) of multi-walled carbon nanotubes could significantly suppress the activity and biomass of soil microorganisms. Metal nanoparticles such as Al, Si, Pd, Au, and Cu and metal oxides (TiO_2 and ZnO) impacted soil bacterial communities, with silver nanoparticles being highly toxic to these organisms. It is important to note that the mentioned studies were done

using simplified ecosystems, under controlled conditions, far from the actual soil environment. Real-world studies, using components that reflect the complexity of the existing environment, are vital in order to assess the actual risk of manufactured nanomaterials in this environment.

The interactions between engineered nanoparticles and plants are another important area for study. A review of the toxic effects of engineered nanoparticles on plant growth was completed by Ma et al. [32.56]. They focused on the toxicity of nanoparticles to plant seedlings and cells, as well as analyzing uptake, translocation, and accumulation of nanoparticles by plants and their interactions with plant cells. Most studies of nanoparticles indicated a certain degree of phytotoxicity to seedlings affecting, e.g., root elongation and seed germination; For instance, Canas et al. investigated the effects of the surface properties of single-walled carbon nanotubes on root elongation of six crop species [32.57]. They tested the phytotoxicity of non-functionalized and functionalized carbon nanotubes on cucumber, cabbage, carrot, lettuce, tomato, and onion. Nonfunctionalized nanotubes inhibited root elongation in tomato but enhanced that of onion and cucumber. Functionalized nanotubes inhibited root elongation in lettuce, while cabbage and carrots were not affected by either form of nanotubes. On the other hand, Khodakovskaya and coworkers did not find any toxic effects of multi-walled carbon nanotubes on root elongation of tomato seedlings up to a concentration of 40 mg/l but observed an increase in seed germination [32.58]. Ma et al. concluded that differences in the toxicity of nanoparticles to plants may arise from the changing physicochemical properties of nanoparticles as they are exposed to the exudates of varying plant species.

Recently, studies have also been performed on terrestrial organisms such as the nematode *Caenorhabditis elegans* [32.59, 60]. Wang et al. did not observe a significant difference in toxicity between nano (TiO_2 of 50 nm, ZnO of 20 nm) and bulk materials (> 200 nm), for example. However, as is the case in many studies, there was a significant difference between the particle compositions as a function of size. On the other hand, Roh et al. demonstrated a relationship between the diameter of TiO_2 nanoparticles and their impact on nematodes. Smaller-sized (7 nm) titania had a more negative impact on *C. elegans* fertility and survival than larger-sized zinc oxide (20 nm). These kinds of inconsistencies in the nanotoxicology literature are more the exception than the rule. Peralta-Videa et al. reviewed available literature on the toxicity, fate, and transport

of nanoparticles in terrestrial ecosystems for the years between 2008 and 2010 [32.17].

Most analyses of the data suggest that direct comparison between studies is a challenge because the form of the nanomaterials – their size, shape, degree of agglomeration, and composition – was not appropriately defined [32.61]. Thus, studies of nanoscale titania can reach different conclusions because the specific forms of nanoscale titania examined can be different. Furthermore, there are no specific standardized protocols or certified reference materials for nanomaterial testing, which leads to difficulties in comparing results. Handy et al. reviewed ecotoxicity test methods for conventional chemicals and presented strategies and modifications to these experimental methods and protocols so they can be applied to nanomaterial testing [32.62].

32.3.3 Routes of Human Exposure to Nanoparticles and Their Translocation in the Body

Human toxicity studies of nanoscale materials are far more common in the research literature (Fig. 32.7). These studies usually start with a perspective about the nanomaterial exposure routes, which include inhalation, skin penetration, and ingestion [32.6, 16, 63, 64]. As shown in Fig. 32.7, inhalation studies are the most prevalent, largely because of the existing work on incidental exposure to exhaust particles.

Respiratory Route

Nanoparticle deposition in the body after inhalation and the factors influencing the fate of inhaled nanomaterials are described in the reviews by Yang et al. [32.65] and Bakand et al. [32.66]. Once inhaled, these materials will be carried by diffusional motion from the nose or mouth through the various diameters of airways (trachea, bronchi, bronchioles) to the alveoli [32.64, 67]. As a result, particles of different sizes will have different effects in different parts of the lungs [32.6, 63]. Lipid- or water-soluble particles will be dissolved by mucous or serous lining fluid on the walls of the respiratory tract. These soluble components can interact with proteins or subcellular structures and eventually be transferred to the blood. Finally, metabolic products of these solutes may reach other organs and produce toxic effects [32.63]. In case of insoluble particles smaller than 200 nm, neither tracheal mucociliary transport nor digestion by defense cells such as alveolar macrophages would be able to completely remove these particles. Such small materials may be able to translocate through

Fig. 32.7 Annual number of articles published in scientific journals by human health topic: respiratory, dermal, and gastrointestinal routes of nanoparticle exposure (after [32.12])

the lymphatic pathways into the blood, resulting in systemic exposure of internal organs [32.6, 63, 64].

For example, in vivo studies by *Kreyling et al.* showed that about 1% of iridium particles (15 and 80 nm) inhaled by rats accessed the systemic circulation and deposited material in organs such as liver, spleen, heart, and brain [32.68]. Moreover, 15 nm particles were deposited at a rate far greater than 80 nm particles. Furthermore, translocation of carbon nanoparticles into the brain via the olfactory nerve system has also been reported [32.69]. Metal oxide nanoparticles such as TiO₂ entered the brain through the olfactory bulb, as well. In the presence of TiO₂ particles, the level of malondialdehyde (MDA), which is a marker of oxidative stress, was elevated and ultrastructural changes of neurons in the hippocampus were observed [32.70]. Wang et al. noticed differences in the responses of the central nervous system to anatase TiO₂ particles versus rutile titania, with lower risk potential for the latter. In summary, different types of inhaled nanoparticles can translocate into the liver, brain, and other organs through blood vessels and the central nervous system. This exposure can produce acute and chronic changes within cells and organisms. Fewer data are available about dermal contact and ingestion exposures [32.2, 71].

Dermal Route

Currently, there is widespread use of nanotechnologies in cosmetic products [32.10, 72, 73]. Most relevant for these topically applied products is the potential for nanoparticles to translocate across the skin. Studies of the skin penetration of cosmetic nanoscale materials

have been reviewed by *Nohynek et al.* [32.74, 75]. Researchers found an agreement that such particles can accumulate in hair follicle openings and the stratum corneum but do not reach living cells of the epidermis and dermis. A negligible tendency for penetration into intact and healthy skin, independent of species, has also been reported recently for topically applied nanosized TiO₂, ZnO, and quantum dots [32.76–80].

On the other hand, *Ryman-Rasmussen et al.* reported that spherical quantum dots with diameter 4.6 nm were able to reach the dermis of porcine skin [32.81]. *Baroli et al.* have shown, using human skin pieces, that metallic nanoparticles smaller than 10 nm were able to localize to the epidermal layers [32.82]. *Huand et al.* demonstrated diffusion of 5 nm gold nanoparticles through the stratum corneum of intact mouse skin [32.83]. Other studies performed by *Sonavane et al.* have found that 15, 102, and 198 nm gold nanoparticles penetrated ex vivo rat skin [32.84]. Furthermore, it has been shown that the state of the skin can have a profound effect on its barrier properties; For example, flexed, broken or diseased skin has a greater susceptibility to penetration by nanoparticles [32.78, 80, 85–89].

As noted in prior areas of safety research, these studies are difficult to compare. They differ in methods (for example, tape stripping, scanning or transmission electron microscopy, fluorescent microscopy), type of investigated nanoparticles (elemental composition, size, and shape), and models (e.g., pig, rat, human biopsies). In particular, measuring the penetration of any substance across human skin – whether it is nanoscale or not – is a challenging experiment, and one that is fraught with controversy [32.90–93]. It is not surprising that these unresolved issues in dermal toxicology are reflected in the inconsistent data found in investigations of nanoparticle–skin interactions.

Gastrointestinal Route

Due to the limited number of studies and lack of complete characterization of the nanomaterials studied, there is also no consensus about the behavior of nanomaterials in the gastrointestinal tract [32.2, 94]. Nanomaterials may get into the human body directly via oral ingestion of food, water or drugs that contain nanoscale materials [32.6, 64]. Currently, nanotechnology is mostly used in functional food compounds and delivery systems, food packaging, and food security [32.94, 95]. Food may also be unintentionally contaminated by nanoscale materials through environmental exposure during production [32.94]. Alternatively, exposure to nanoparticles may occur through

hand-to-mouth transfer if products, such as cosmetics, are left on hands [32.64, 96]. Nanoparticles may also be cleaned from the respiratory system through mucociliary transport, where they are swallowed and introduced into the gastrointestinal tract [32.63]. Once in this environment, materials could be eliminated in urine or feces or penetrate the gastrointestinal tract, resulting in translocation to other organs [32.97]; For example, 98% of water-soluble fullerenes when administered orally to rats were cleared in the feces within 48 h, whereas the rest were eliminated via urine [32.98]. On the other hand, studies by *Jani et al.* have shown that rutile TiO₂ particles of nominal size (500 nm), administered orally as a suspension to female rats, were translocated to systemic organs such as the liver and spleen [32.99]. Furthermore, when mice were exposed to nanoscale particles of copper via the gastrointestinal tract, these materials targeted kidney, liver, and spleen, causing heavy injuries to these organs [32.100].

In summary, current in vivo studies indicate that the target organ for nanomaterial exposure depends on the experimental conditions and nanoparticle physicochemical properties. However, a central and still unanswered question is the rate at which nanoparticles are cleared or degraded. A review discussing the interaction of nanoparticles with living systems has been carried out recently by *Lu et al.* [32.101]. One model anticipates that, should nanoparticles find their way into the body, they would be marked with proteins as foreign agents and consumed by phagocytes (immune cells) [32.102]. After delivery to the lymph nodes, they could be biodegraded into biologically safe components if their constituent material is itself nontoxic. Phagocytosis is a basic defense mechanism against exogenous substances. However, if particles are very stable and difficult to metabolize within the body, they could reside in the body for long time periods and unknown health effects may occur.

32.3.4 In Vitro Toxicity of Nanoparticles

In the past few years many investigators have been developing in vitro model systems using both human

and animal cells to simplify the study of the cellular response to nanoparticles [32.103, 104]. While in vitro testing provides a limited view of the responses of only the cell types being tested, it is quick and relatively inexpensive, and allows evaluation of specific mechanisms of action [32.105]. Although nanoparticle-induced cytotoxicity has been reported by several groups, the exact mechanism for toxicity is not well understood [32.106–109]. Nonetheless, studies point to nanoparticle-enhanced generation of reactive oxygen species (ROS) that may result in oxidative stress, inflammation, and consequent damage to proteins, membranes, and DNA [32.110, 111].

Lewinski et al., who reviewed the cytotoxicity of carbon-, metal-, and semiconductor-based nanoparticles, concluded that different data have been published about cytotoxicity due to differences in experimental procedures as well as differing nanoparticle properties [32.106]. Incomplete characterization and lack of protocols and calibration standards in nanoparticle characterization will result in inconsistent and unreliable in vitro toxicity data; For example, in one study, multi-walled carbon nanotubes were reported to be toxic and cause a decrease in mitochondrial membrane potential [32.112], whereas another study reported that these nanotubes were nontoxic [32.113]. Such uncertainties and inconsistencies are likely caused by variations in nanoparticle characteristics and experimental procedures [32.106, 114–116].

Because the physicochemical properties of nanomaterials can influence toxicological endpoints, thorough characterization is vital to this community [32.29, 105, 117, 118]. There is no doubt that nanoscale particles can in some forms be biologically reactive and lead to cell damage; what is less clear is whether these cell culture effects are apparent in animal systems [32.119]. In addition, the risk due to any potentially toxic substance is not only a function of the hazard but also of the chance of exposure. However, lack of exposure data for humans and the environment limits the effective risk assessment of commercially available nanomaterials [32.9, 120].

32.4 Nanoparticle Physicochemical Characteristics of Relevance for Toxicology

The examples provided in human and ecological toxicity studies of engineered nanomaterials highlight that

nanomaterial structure is essential for determining biological outcomes. This broad hypothesis certainly

What does the material look like?

- Particle size/size distribution
- Agglomeration state/aggregation
- Shape

What is the material made of?

- Overall composition (including chemical composition and crystal structure)
- Surface composition
- Purity (including levels of impurities)

What factors affect how a material interacts with its surroundings?

- Surface area
- Surface chemistry including reactivity, hydrophobicity
- Surface charge

Overarching considerations

- *Stability*—how do material properties change with time (dynamic stability), storage, handling, preparation, delivery, etc.? Include solubility, and the rate of material release through dissolution.
- *Context/media*—how do material properties change in different media, i.e. from the bulk material to dispersions to material in various biological matrices? (“as administered” characterization is considered to be particularly important)
- *Where possible, materials should be characterized sufficiently to interpret the response to the amount of material against a range of potentially relevant dose metrics, including mass, surface area and number concentration.*

Fig. 32.8 Recommended minimum physical and chemical parameters for characterizing nanomaterials in toxicology studies (after [32.123])

needs refinement, with a specific focus on which physicochemical properties of nanomaterials are the most important in defining their hazard [32.119, 121, 122].

To date, no specific regulation for nanomaterials at the international level exists. The International Standards Organization (ISO) published nanotechnology terminology in 2008 as an outcome of ISO/TC 229 Nanotechnologies: ISO/TS 27687 *Nanotechnologies – Terminology and definitions for nano-objects – Nanoparticle, nanofiber and nanoplate* [32.124]. This international organization continues its work in developing effective regulation for nanotechnology-related products, including *Guidance on physicochemical characterization of engineered nanoscale materials for toxicologic assessment* (ISO/DTR 13014), but writing new rules takes time; hence it will take some time before new standards are completed [32.124].

A minimum set of parameters that accounts for the most important and identifiable nanomaterial characterization in nanotoxicity studies was discussed and proposed at the Woodrow Wilson International Center for Scholars in Washington, DC in 2008 [32.123]. Although there is some variability across the list of

ideal properties, most authors agree with the minimum characterization set presented in Fig. 32.8 [32.29, 121, 123, 125, 126]. Definitions of nanoparticle characteristics and techniques suitable for their measurements were described in [32.29, 127].

Characterization of nanoscale particles should begin with the study of as-received samples, which are often shipped as dry powders [32.127]. This primary characterization is useful, particularly for ensuring batch similarity, however study of these powders is not sufficient for safety studies. It is vital to investigate the properties of nanomaterials when they are dispersed in the media used for toxicity studies. Some material properties, such as primary particle size and shape, chemical composition, and crystal structure, are the same in both dry and dispersed phases. However, the composition of the fluid in which nanoparticles are dispersed may affect their agglomeration state, surface charge, and reactivity [32.119, 125]. Also, many of these changes can be slow to occur, and thus samples dispersed in fluids may change over a period of time. Ideally, physicochemical studies should be completed at various time points which reflect the times relevant to the biological questions [32.29].

Technique	Information
Scanning electron microscopy (SEM)	Particle size distributions, shape, agglomeration/aggregation state
Transmission electron microscopy (TEM) Atomic force microscopy (AFM)	Particle size distributions, shape, agglomeration/aggregation state, surface texture
Brunauer–Emmett–Teller (BET) surface area analysis	Specific surface area, porosity, average diameter
X-ray diffraction (XRD)	Crystal structure, crystallite size
Energy-dispersive spectroscopy (EDS)	Overall elemental composition
X-ray photoelectron spectroscopy (XPS)	Surface elemental composition
Inductively coupled plasma mass spectrometry (ICP-MS)	Overall elemental composition
Dynamic light scattering (DLS)	Hydrodynamic size, aggregation/agglomeration state, charge on a particle surface

Table 32.1 Common techniques for investigating nanomaterial properties

32.4.1 Characterization Methods

Physicochemical characterization of nanoparticles generally requires advanced instrumentation. Scanning and transmission electron microscopies can produce high-resolution two-dimensional images of nanoparticles [32.128], while atomic force microscopy (AFM) gives information about nanoparticles in three dimensions [32.129, 130]. Another approach to characterization of nanoparticles involves Brunauer–Emmett–Teller (BET) surface area analysis and x-ray diffraction (XRD). The BET method can analyze dry powders and provide the specific surface area of the nanoparticles [32.131], while XRD yields the atomic structure [32.132]. Energy-dispersive x-ray spectroscopy identifies the elemental composition of the sample [32.128], and x-ray photoelectron spectroscopy (XPS) can be employed to determine the chemical composition at the nanoparticle surface [32.133]. Inductively coupled plasma mass spectrometry (ICP-MS) is a type of MS which is capable of detecting nanoparticles in environmental samples [32.134, 135]. Furthermore, measurement of the nanoparticle hydrodynamic size and zeta potential is useful for getting information about the stability of nanoparticle suspensions with respect to time and medium [32.136, 137]. Common techniques capable of investigating nanomaterial properties are summarized in Table 32.1.

32.4.2 Electron and Atomic Force Microscopy

In vitro and in vivo studies, using carbon, metal oxide, and metal nanomaterials, have all noted various size- and surface-dependent toxicity effects [32.106, 138–144]. These parameters are critical determinants

of cellular uptake, distribution through the body, and accumulation in organs.

Direct visualization of nanoparticles by electron or atomic force microscopy allows exact determination of primary particle size and shape. They can also indicate if aggregation or agglomeration is a factor in the sample, an essential issue for safety studies. The agglomeration/aggregation state is likely to differ depending on whether it is determined in powder form or in the experimental media [32.145]; For example, the tendency for airborne nanoparticles to form clusters may limit inhalation exposure to free nanoscale particles, but on the other hand promote locally high concentrations in sediments. Furthermore, depending on the interparticle bond strength, such agglomerates could still undergo deagglomeration once reaching biological fluids. In this case, the primary particles will be of interest for toxicity studies. Therefore, characterization of the size, shape, and agglomeration/aggregation state of nanoparticles in the context of the experimental exposure media (cell culture media, dosing solution, aerosol, etc.) is necessary for informative nanotoxicity studies.

Scanning electron microscopy (SEM) offers the ability to image an area of the order of square millimeters and can be used to observe the formation and arrangement of nanoparticle clusters. However, whether the clusters are formed by nanoparticles in an agglomerated state (weak van der Waals forces between the particles) or aggregated state (strong attractive interactions between the particles) is difficult to establish. Quantitative methods to measure the strength of nanoparticle associations are not routinely available [32.146]. Additionally, it can sometimes be a challenge to fully evaluate aggregated or agglomerated nanomaterials. In the example shown in Fig. 32.9a, some of the individual nanoparticles forming the clusters appear to be visible in higher-magnification SEM

Fig. 32.9a,b Electron microscopy images of TiO_2 nanoparticles coated with SiO_2 : (a) SEM image showing degree of agglomeration/aggregation in the sample and (b) high-magnification TEM image showing surface coating

images. However, given the 20 nm resolution limit of SEM, it is hard to conclude that nanoscale particles are made of one crystallite or several smaller nanoparticles.

Transmission electron microscopy (TEM) analysis provides improved spatial resolution and can, under some circumstances, confirm the presence of nanoscale primary particles in clusters and even measure their size distribution [32.128, 147, 148]. Moreover, high-resolution TEM can reveal a coating layer on nanoparticle surfaces (Fig. 32.9b) [32.149]. Furthermore, TEM of a cryogenically fresh-frozen sample (cryo-TEM) can produce micrographs of what a biological system, e.g., cell, encounters when exposed to nanoparticles [32.150]. Electron microscopy analysis can be time consuming and expensive, but it provides valuable information in toxicological testing regarding the formation of clusters, primary particle size/size distribution, shapes, and surface coating.

Unlike electron microscopies, AFM does not rely on electron beams to create an image. AFM offers three-dimensional visualization of nanoparticles distributed on a flat surface by measuring the small force between a sharp probe, which is supported on a flexible cantilever, and the surface [32.129]. Therefore, unlike electron microscopies, AFM does not require a vacuum environment or special sample preparation. Such versatility makes it very useful for many questions relevant for nanomaterial safety testing, but it lacks the intrinsic structural sensitivity of electron microscopies [32.130]. Nevertheless, with the appropriate protocols, it can provide information about nanoparticle size, shape, surface texture, and roughness [32.129].

32.4.3 Brunauer–Emmett–Teller Analysis and X-Ray Diffraction

Size-dependent toxic effects of nanoparticles have been correlated with the increased surface-to-volume ratio

Fig. 32.10 Adsorption–desorption isotherms of nitrogen measured on TiO_2 nanoparticles with surface area of $261 \text{ m}^2/\text{g}$ that at high relative pressures exhibit a hysteresis loop attributed to the interparticle spaces

of small particles [32.6]. Therefore, the surface area is a physicochemical parameter often considered to be of central importance to nanoparticle toxicity. When the surface area-to-volume ratio increases, there is a greater portion of nanoparticle surface atoms or molecules available to react, and reactivity is generally thought to be a prelude to toxicity [32.127]. This principle has been demonstrated explicitly in several instances where the surface area rather than the particle mass was found to be the best measure of nanomaterial dose [32.151–154]. However, there are also studies that defined the hypothesis of increased toxicity for smaller-surface-area nanoparticles because nanomaterial toxicity depends on several physicochemical parameters that include surface area [32.116, 155].

Brunauer–Emmett–Teller (BET) analysis provides specific surface area (SSA) evaluation of nanoscale materials by nitrogen multilayer adsorption measured as a function of relative pressure. Furthermore, the surface area can be related to primary particle size [32.131]. BET analysis can also be used for an indication about aggregation/agglomeration state; For example, if the primary particles form strong aggregates (due to strong bonds between particles), they have lower surface areas than that calculated from TEM images [32.156, 157]. The aggregation/agglomeration state of nanoparticles can also be determined from adsorption–desorption isotherms of nitrogen measured on nanoparticle surfaces (Fig. 32.10), as well as the pore shape, area, and specific pore volume [32.158–160].

The interior crystal structure also determines the toxicity of nanoscale materials; For example, the two

Fig. 32.11 X-ray diffraction patterns of anatase and rutile TiO_2 nanoparticles

most important polymorphs of titania, rutile and anatase (Fig. 32.11), display different photocatalytic activities, with anatase acting as a stronger photocatalyst than rutile [32.161]. Studies have shown that this chemical activity of anatase TiO_2 translates into an increase in biological activity [32.70, 126]. The crystalline structure of nanoparticles can be identified by x-ray diffraction, which is based on the constructive interference of monochromatic x-rays and a crystalline sample. The crystallite size of nanopowders can be determined from the most intense peaks of the XRD patterns according to the Scherrer equation [32.132].

32.4.4 Overall and Surface Elemental Analysis

Several studies have shown that nanomaterials of similar size but differing chemical composition can have varying biological effects [32.115, 116]; For example, *Lanone* et al. demonstrated that, among 24 nanoparticles of similar shape and size but various elemental composition, copper- and zinc-based nanomaterials had the greatest toxicity to human pulmonary cells [32.116]. Furthermore, in addition to the primary material structure, impurities in nanomaterials may also be responsible for biological effects; For example, *Pulskamp* et al. showed that impurities associated with commercial nanotubes caused toxicity in cells [32.112]. Nanomaterials may be contaminated during the preparation process by more toxic, surface-adsorbed surfactants used, for example, to control the size and shape of the particles [32.162]. Unfortunately, manufacturers are not willing to share the details of their proprietary manufacturing methods; hence, in nanotox-

Fig. 32.12 EDS spectra of TiO_2 nanoscale particles (NPs) coated with alumina plus simethicone and uncoated ZnO particles (after [32.18])

icity studies, researchers need to investigate the purity of nanoparticles independently.

For environmental and health studies, the nanoparticles should be free from reactants used in the synthetic steps. Otherwise, toxic impurities can drastically change the results of the toxicity study; For example, for nickel ferrite particles coated with oleic acid prepared by the polyol method, the cytotoxicity significantly increased when one or two layers of oleic acid were deposited as compared with particles without oleic acid prepared by ball milling [32.163].

Moreover, particle surface coatings intentionally designed to optimize use in applications may end up defining the overall toxicity of the nanomaterial. Studies on a number of commercial formulations of TiO_2 particles indicate that different surface treatments can influence the pulmonary toxicity [32.164]. Surface coatings can render noxious particles nontoxic, while less harmful particles can be made highly toxic; For example, in the case of TiO_2 nanoparticles, silica is often used to block access to the titania surface in a solution environment, and consequently reduce its reactivity [32.165, 166].

The overall chemical composition of nanoparticles can be analyzed by energy-dispersive x-ray spectroscopy (EDS) to evaluate impurities; for more surface-specific information, x-ray photoelectron spectroscopy (XPS) is an ideal tool. EDS is commonly coupled with SEM or TEM, where an electron beam scans the surface of the sample and causes emission of x-rays characteristic of the elements present [32.128]. By analyzing the energy of the x-rays from the elements, qualitative analysis of the sample can be

performed in a few minutes (Fig. 32.12). However, EDS has some limitations; For example, elements lighter than sodium are not detectable, and closely spaced lines may not be resolved due to poor energy resolution of the detector [32.128]. Furthermore, EDS does not provide information about chemical bonding. To obtain such detailed chemical characterization of the nanoparticle surface, XPS is often performed.

XPS uses x-rays of sufficient energy to eject core electrons from the sample's various atoms and then measures the energy of the ejected electrons. In addition to chemical state information, XPS spectra can be quantified to provide additional semiquantitative elemental analysis, offering far greater surface sensitivity than EDS or conventional elemental techniques [32.133]. XPS is among the most common analytical methods used in determining the chemical composition of a nanoscale particle's surface. Alternative surface chemical analysis tools for characterization of nanoparticles have been presented recently by Bear et al. [32.129].

Analyses by EDS and XPS can provide important information in terms of the chemistry of nanoparticles. Unfortunately, in these cases the samples are analyzed under a vacuum, and thus the results are difficult to apply to the complex environments relevant to nanomaterial safety. ICP-MS has been used as a detection method for nanoparticles in environmental materials [32.134, 135]. It offers sensitive and accurate determination of chemical elements in aqueous media as well as biological samples. A common approach for quantification of nanoparticles by ICP-MS is based on the determination of the total elemental concentrations in a nanoparticle suspension after sample digestion by acid. In an ICP-MS system, a high-temperature argon plasma creates elemental ions, which are separated according to their mass-to-charge ratios, enabling identification and quantification of unknown materials. Another common technique for nanoparticle characterization in solution is dynamic light scattering, which determines the hydrodynamic size.

32.4.5 Dynamic Light Scattering (DLS)

Dynamic light scattering (DLS) involves monochromatic light that interacts with particles undergoing Brownian motion in a fluid. The motion is size dependent (e.g., larger particles move more slowly through the fluid), and this causes a shift in the frequency of the scattered light (Doppler shift). Larger particles, which have lower velocities, cause lower frequency shifts, whereas smaller particles that move rapidly through

the fluid cause higher frequency shifts. Therefore, measuring the frequency shift provides the movement of the particles and their hydrodynamic size distribution. Moreover, DLS measurements of nanoparticle hydrodynamic diameter can be used as a method for monitoring the stability of nanoparticle solutions [32.136]. When the stability of the nanoparticles is changing and aggregates/agglomerates form, the DLS spectrum of hydrodynamic diameter increases. DLS can also be used for determining the quality of nanoparticle dispersion by directly measuring the zeta potential, which is a measure of particle interaction. The particles will repel each other and resist the formation of clusters when their zeta potential is large, above +30 mV or below -30 mV [32.137].

Well-characterized hydrodynamic size and zeta potential of nanoparticle dispersions are imperative for toxicological studies. As a result, The International Alliance for NanoEHS (environment, health, safety) Harmonization (IANH) decided to perform round-robin tests on the hydrodynamic size and zeta potential of monodisperse gold, silica, polystyrene, and agglomerated/aggregated ceria nanoparticles [32.167]. Roebben et al. concluded that, for highly uniform nanoparticles, DLS provided an excellent measure of hydrodynamic diameter. Therefore, the IANH DLS test protocol can be applied to the characterization of nearly monodisperse nanoparticle dispersions in ecotoxicity studies. However, polydisperse samples, such as ceria that consisted of nanoparticle aggregates, showed large lab-to-lab variations in measured hydrodynamic diameters. Sonication was a difficult process to standardize, and without this preparation the highly aggregated materials sedimented to the bottom of solution vials, yielding nonuniform solutions for DLS analysis. Methods to produce homogeneous dispersions of nanomaterials should use sonication cautiously and with detailed procedures to ensure reproducibility across laboratories [32.167]. There was also a significant difference between round-robin participants in reported zeta potential data. Therefore, IANH protocols for zeta potential require further improvement to enable accurate and precise measurements.

The surface charge of nanoparticles, which can be approximated by zeta potential measurement, and surface composition are not the only surface chemistry properties that need to be measured for safety research. According to Powers et al. surface chemistry includes also surface energy (or wettability), solubility, catalytic properties, surface adsorption and desorption of molecules from solution, etc., and quantification of

these characteristics can be difficult [32.127]. Powers et al. listed several common methods for analysis of nanoparticle surfaces that included, for example, contact angle and microcalorimetric measurements for surface energy and reactivity.

In summary, currently, the research literature on nanomaterial safety is inconclusive due to the lack of sufficient detail about characterization and the dearth of standardized laboratory methods for characterization. The IANH developed protocols for measuring nanoparticle hydrodynamic diameter and performed round-robin experiments to ensure that the protocols are reproducible. This one example needs to be replicated

and expanded to more critical physiochemical parameters. With such standard tools, it would be possible to integrate the vast amount of safety data to provide a correlation of nanoparticle properties to their toxicological effects.

One topic not highlighted yet is the importance of completing characterization studies directly on the most relevant engineered nanomaterials, i.e., those found directly in consumer products [32.31]. In the next section, an overview of the challenges in risk evaluation of sunscreen nanoparticles is presented as a case study for nanomaterial characterization within consumer products.

32.5 Special Case – Sunscreens

In sunscreens, the size-dependent optical properties of TiO_2 and ZnO nanoparticles make them transparent at visible wavelengths; thus, when applied to the skin, they form clear films as opposed to white, cloudy applications. Moreover, both materials have very strong absorbance and scattering at UVB and UVA wavelengths (290–320 and 320–400 nm, respectively), which makes them effective at protecting skin from the ultraviolet radiation present in sunlight [32.20, 168–170]. SEM and TEM images of TiO_2 and ZnO sunscreen particles are presented in Fig. 32.13.

32.5.1 Regulatory Policy as Related to Sunscreens

In the USA, product labeling regulations have specifically addressed the issue of pigment size in the list of sun-care ingredients. Briefly, manufacturers need only list the chemical composition rather than the diameter, form, or crystalline structure of the pigment. Historically, micronized titania and zinc oxide particles have

been used in sunscreens for decades. Because of their large size, they scatter visible light and produce a white and chalky appearance when applied. When manufacturers began to shrink the particle size of these inorganic pigments, the US Food and Drug Administration (FDA) reviewed their requirements for labeling of personal care product ingredients. They ruled in 1999 that *micronized* titania and zinc oxide was an appropriate terminology for sunscreen pigments and that it was not necessary to specify whether pigments were truly nanoscale [32.171]. As a result, consumers do not know from the label when the products they are using contain nanoscale materials.

32.5.2 Photocatalytic Activity of TiO_2 and ZnO Nanoscale Particles

While the label may not convey the particle size of sunscreen pigments, this does not mean that such information is irrelevant. One specific area of concern has been the native photocatalytic activity of sunscreen pigments. While they are effective at absorbing ultraviolet light, some forms of both titania and zinc oxide are also effective at transforming their photoexcitations into surface-reactive species that generate highly oxidizing products. As a result, in addition to sun-care products, nanoscale TiO_2 is also of interest in the ultraviolet-mediated oxidation of organic pollutants and wastewater contaminants [32.172–176]. These applications rely on the ability of TiO_2 nanoparticles to form reactive oxygen species (ROS) such as hydroxyl (OH^\bullet), superoxide ($\text{O}_2^{\bullet-}$), and hydroperoxy (HOO^\bullet) radicals and hydrogen peroxide (H_2O_2) when excited with UV light [32.177–180].

Fig. 32.13a,b TEM images of (a) TiO_2 and (b) ZnO sunscreen nanoparticles (after [32.18])

Critical for these remediation examples is the observation that the generation of ROS by certain forms of nanoscale titania is catalytic: a single particle of titania can generate many hundreds of ROS species under constant ultraviolet illumination [32.108]. While less studied, nanoscale ZnO materials can also catalyze the photooxidation of organic species in water, and may be more efficient photocatalysts than TiO₂ [32.181–188]. However, since zinc oxide is more soluble than titania, the lifetime of these materials is more limited than titania for some applications. However, since zinc oxide is more soluble than titania, the lifetime of these materials is more limited than titania for some applications.

32.5.3 Health Effects of Nanoscale Titania and Zinc Oxide

Reactive oxygen species are generally acutely toxic to living systems because they rapidly react with many cell components (e.g., DNA, proteins, and lipids) and lead to cell damage [32.189–191]. In light of their potential as photocatalytic materials, it is not surprising that toxicology studies have shown that TiO₂ and ZnO nanoparticles have an adverse effect on cellular function when illuminated by UV light. Some studies have shown that TiO₂ nanoparticles are toxic only in the presence of UV light [32.192, 193], while other studies have shown that in the presence of UV irradiation the toxicity is higher than in the dark [32.194–198]. ZnO nanoparticles have also shown photocatalytic effect on cells [32.197, 199–201].

Whether these acute cell effects are relevant to a product applied to skin depends in part on whether the particles translocate across the dermis; studies of TiO₂ and ZnO pigments appear to indicate that, for healthy and intact skin, these nanoscale materials do not penetrate the dermis but can end up in hair follicles, sweat glands, or skin folds [32.74, 75, 202–205]. However, at the seaside, where sunscreens are more likely to be used, the action of sun, water, and sand can irritate or even harm the skin by hydration, infrared (IR) irradiation, peeling or inflammation, consequently enhancing its permeability [32.206]. Furthermore, recent studies demonstrated that the state of skin can have significant effects on its barrier performance [32.78, 80, 85–89]. Therefore, there is still uncertainty regarding skin penetration of sunscreen zinc oxide and titanium dioxide nanoparticles under a variety of real-life conditions. Moreover, to fully assess the toxicological impact of sunscreen nanoparticles, future studies will need to focus on the potential for ROS generation by TiO₂ and

ZnO nanoparticles lodged in hair follicles [32.204]. In addition to the potential photocatalytic effect on cells, ZnO and TiO₂ nanoparticles may cause loss of the ultraviolet protection efficacy of sunscreens, due to the enhanced photooxidative degradation of organic sunscreen components [32.165].

Also important in understanding the connection between chemical and biological reactivity are the physicochemical characteristics such as particle size and surface area, crystal structure, surface chemistry, and particle aggregation/agglomeration tendency; For example, photochemical reactivity is quite sensitive to the phase composition of TiO₂, with rutile materials being orders of magnitude less chemically reactive than equivalently sized anatase systems. This trend in chemical reactivity parallels the results of acute in vitro cell toxicology studies, which find anatase to be more toxic than rutile for a range of diameters [32.126]. Additionally, the chemical reactivity of nanoscale oxides can be reduced by modifying their surface with inert inorganic materials such as silica (SiO₂) or alumina (Al₂O₃), and/or by doping with manganese or vanadium [32.165, 207–211]. Due to the great variety of different nanoparticle forms of TiO₂ and ZnO that exhibit different chemical behaviors, it is difficult to generalize the potential ROS generation capacity of inorganic pigments used in sunscreens [32.212].

32.5.4 Materials Derived from Consumer Products and Their Photochemical Behavior

FDA regulations do not require that labels provide information about the diameter, form or photoactivity of inorganic sunscreen ingredients [32.171]; therefore, consumers and researchers have little information about what people are exposed to. Compared with studies of model titania and zinc oxide pigments, there has been comparatively little systematic study of the properties of pigments derived directly from commercial products.

Hidaka et al. showed that ZnO pigments extracted from sunscreen products commercially available in Japan, when illuminated by UV, caused DNA plasmid strand breaks via the generation of ROS [32.199]. The same pigments were also photoactive toward degradation of phenol. A similar effect of rapid photodegradation of methylene blue dye by sunscreen-isolated zinc oxide pigments (uncoated, dimethicone coated, and mixtures of ZnO and TiO₂ particles) was presented by Rampaul et al. [32.209]. In the area of the poten-

tial hazard of sunscreen pigments, ZnO has been less studied than TiO₂ [32.213]. Titania is a more commonly used photocatalyst than ZnO, and as a result there has been more concern regarding this material. DNA damage induced by TiO₂ nanoparticles extracted from sunscreens was first noted in 1997 by *Dunford et al.* [32.214]. Then, *Rampaul et al.* found that some TiO₂ particles isolated from sunscreens caused significant cellular damage to cultured human skin and other animal epithelium cells [32.209]. Recently, *Buchalska et al.* tested the photoreactivity of TiO₂ sunscreen components toward degradation of azur B and oxidation of α -terpinene and showed high efficiency of singlet oxygen formation [32.215].

These studies largely relied on *pure* pigments; it is possible that the other constituents in sunscreens may modify or augment the nanoparticle effects. Full sunscreen, including TiO₂ pigments, has also been tested toward the formation of oxygen- and carbon-centered radicals using spin-trap electron paramagnetic resonance (EPR) spectroscopy by *Brezova et al.* They concluded that some sunscreens generated ROS [32.178]. These observations were confirmed by *Barker and Branch*, who showed that sunscreens containing titanium dioxide and zinc oxide nanoparticles were the primary cause of the rapid corrosion of paint surfaces on steel roofing via the production of reactive oxygen species [32.216]. Furthermore, *Lewicka and Colvin*, who evaluated the photochemical properties of whole sunscreen emulsions that contained nanoscale components and the inorganic particles derived from these sunscreens using several assays such as dichlorofluorescein fluorescence, decolorization of Congo red dye, and 5,5-dimethyl-pyrroline *N*-oxide (DMPO) spin-trap electron paramagnetic resonance spectroscopy, showed that samples with nanoscale ZnO materials were more

photoactive than the samples that contained TiO₂ nanoparticles [32.217].

32.5.5 Physicochemical Characteristics of Sunscreen Nanoscale Materials

A central challenge in assessing the risk of inorganic pigments used in sunscreens has been the great diversity of material types present: both titania and zinc oxide are used, often with different sizes and forms, with different surface coatings and possibly distinct crystal structures [32.18]. Recently, *Lewicka et al.* characterized the inorganic pigments derived from nine commercial products purchased in the USA [32.18]. Nanoscale pigments were apparent in evaporated sunscreen residues from all items that listed TiO₂ or ZnO as active ingredients, and these materials could be isolated further for analysis via water or alcohol washes. Their dimensions, shape, phase, and elemental composition were determined using a suite of methods including TEM, SEM, XRD, EDS, and inductively coupled plasma optical emission spectroscopy. Wurtzite zinc oxide pigments were rod-like in shape with short axes under 40 nm and longer dimension ranging from tens to hundreds of nanometers. TiO₂ materials were generally rutile and exhibited needle-like or near-spherical shapes; they were consistently smaller than the zinc oxide materials, with average length of 25 nm and widths ranging from 7 to 16 nm. The physical and chemical features of pigments derived from commercial sunscreens were notably similar to two commercial sources of TiO₂ and ZnO nanoparticle powders obtained from EMD and BASF [32.18]. Therefore, in some cases, these pure materials may serve as surrogates for ongoing research evaluating the transport, fate, and toxicology of these widely applied engineered nanomaterials.

32.6 Conclusions

Adequate characterization of manufactured nanomaterials in toxicity, ecotoxicity, and exposure studies is central to clear definition and management of their risks. Diameter, shape, aggregation state, and surface area are some of the basic parameters that should be measured, ideally on the most relevant samples in media that reflect the biological or environmental questions of interest. Typically, such characterization should utilize a variety of techniques that provide complementary information about nanoparticles before *in vitro*

or *in vivo* testing. Moreover, standardized tests and protocols for nanoparticle characterization need to be established for accurate assessment of their physicochemical properties. Ultimately, such data could be held in a public-access *nanoparticle safety database*, which in addition to listing the material composition (e.g., ZnO) could also include its characteristics (e.g., size, shape) and the results of toxicity tests. Then, by asking a specific question (e.g., “How hazardous are ZnO nanoparticles of a certain size and form?”),

the database would provide the result of an experiment that was done on the safety of this specific material [32.11]. Even though characterization of nanomaterials can be complicated, time consuming, and

expensive, it is vital in order to define exactly what manufacturers, consumers, and the environment are exposed to during the production, application, and release of nanomaterials.

Acknowledgements

A.2 Graphene – Properties and Characterization

by Aravind Vijayaraghavan

The author would like to acknowledge L. Song for his support in preparing this chapter.

A.3 Fullerenes and Beyond: Complexity, Morphology, and Functionality in Closed Carbon Nanostructures

by Humberto Terrones

I acknowledge the École Polytechnique de Louvain of the Catholic University of Louvain for support as visiting professor and the Center for Nanophase Materials Sciences at Oak Ridge National Laboratory for support as invited scientist.

A.8 Nanodiamonds

by Olga A. Shenderova, Suzanne A. Ciftan Hens

Gary McGuire, International Technology Center is acknowledged for his valuable comments.

B.9 Noble Metal Nanoparticles

by Theruvakkattil S. Sreepasad, Thalappil Pradeep

We thank our coworkers who have contributed to several aspects of our work presented here. Thanks are also due to the Department of Science and Technology, Govt. of India and the Indian Institute of Technology Madras, for constant support for all the research activities presented here.

C.16 Compound Crystals

by Roi Levi, Maya Bar-Sadan, Reshef Tenne

This work was supported by ERC grant INTIF 226639, the Israel Science Foundation, the G. Schmidt Minerva Center for Supramolecular Chemistry, the Irving and Cherna Moskowitz Center for Nano and Bio-Nano imaging, and the Harold Perlman Foundation. Reshef Tenne holds the Drake Family Chair in Nanotechnology and is the director of the Helen and Martin Kimmel Center for Nanoscale Science.

C.18 Glasses on the Nanoscale

by Hellmut Eckert, Sidney J.L. Ribeiro, Silvia H. Santagneli, Marcelo Nalin, Gael Poirier, Younès Messaddeq

Authors acknowledge funding from Brazilian agencies FAPESP, CNPq and CAPES. This chapter summarizes previously published contributions from numerous co-workers, doctoral students and postdoctoral associates. Concerning the NMR part, H. Eckert expresses special thanks to former PhD students H. Deters, C.C. De Araujo, S. Elbers, J.D. Epping, D. Larink, S. Puls, S. Santagneli, M.T. Rinke, and U. Voigt. Scientific contributions made by previous postdoctoral workers J.C.C. Chan and L. Zhang are also most gratefully acknowledged. The same holds for lanthanide containing transparent glass ceramics and S.J.L. Ribeiro thanks L.A. Bueno, A.S. Gouveia-Neto, M. Mortier, V. Briois, M. Poulain, G.F. Sá, M.A.P. Silva, J.P. Donoso, C.J. Magon, L.F.C. Oliveira, I. Kosacki and A. Monteil. H. Eckert's work is supported by the Wissenschaftsministerium Nordrhein-Westfalen and by the Deutsche Forschungsgemeinschaft.

E.21 Nanoporous Metals

by Yi Ding, Zhonghua Zhang

The authors gratefully acknowledge financial support by the National Science Foundation of China (20928003, 90923011, 50971079, 50831003) and the Independent Innovation Foundation of Shandong University (IIFSDU). Y. Ding is a Tai-Shan Scholar supported by the Shandong Natural Science Fund for Distinguished Young Scholars.

F.26 Nanocomposites as Bone Implant Material

by Vinod Kumar, Bipul Tripathi, Anchal Srivastava, Preeti S. Saxena

The authors are thankful to Prof. P.M. Ajayan and Dr. Robert Vajtai, Rice University, for their valuable suggestions. P.S. Saxena acknowledges the CAS program in the Zoology Department and Anchal Srivastava acknowledges the CAS program in the Physics Department, Banaras Hindu University (BHU) funded by the University Grants Commission (UGC).

G.28 Nanostructured Materials for Energy-Related Applications

by Arava L.M. Reddy, Sundara Ramaprabhu

The authors acknowledge the Indian Institute of Technology, Madras, India. The Defence Research and De-

velopment Organization (DRDO) India, Department of Science and Technology (DST) India, Ministry of Non-conventional Energy Sources (MNES) India, and Ministry of Human Resource Development (MHRD) India are gratefully acknowledged for their financial support.

About the Authors

Maya Bar-Sadan

Chapter C.16

Ben-Gurion University
Department of Chemistry
Be'er Sheva, Israel
barsadan@bgu.ac.il

Dr. Maya Bar-Sadan is an Assistant Professor in the chemistry department of Ben-Gurion University. She received her PhD in 2007 from the Weizmann Institute of Science where she specialized in characterizing closed-cage structures to the atomic level by high resolution electron microscopy. Dr. Bar-Sadan is currently interested in studying functional interfaces in nanomaterials and their properties by atomic-resolution HRTEM.

Giovanni Barcaro

Italian National Research Council
Institute for the Physical and Chemical
Processes
Pisa, Italy
barcaro@ipcf.cnr.it; giobarc@gmail.com

Chapter B.11

Giovanni Barcaro got a degree in Materials Science in 2003 and received his PhD in Chemistry from the University of Pisa, Italy, in 2007. The aim of Dr. Barcaro's research has mainly been centred on the theoretical/computational structural characterization of pure and bimetallic metal nanoclusters, both in the gas-phase and absorbed on oxide supports.

Paolo Bettotti

University of Trento
Department of Physics, Nanoscience
Laboratory
Povo, Italy
bettotti@science.unitn.it

Chapter E.24

Paolo Bettotti received his MS in Materials Science at the University of Padova and his PhD in Physics at the University of Trento. He is currently working in the development of optical sensors and analytical tools using both integrated silicon photonic devices and nanoporous materials.

Alfredo Caro

Chapter B.11

Los Alamos National Laboratory
Materials Science and Technology Division
Los Alamos, NM, USA
caro@lanl.gov

Alfredo Caro received his PhD from the Swiss Federal Institute of Technology at Lausanne in 1981. He worked at the Atomic Center at Bariloche, Argentina, at the Paul Scherrer Institute in Switzerland, and at the Lawrence Livermore and Los Alamos National Laboratories in the US. He works now on computational materials science, focused on the thermodynamic aspects of multicomponent.

Eunhyea Chung

Chapter G.29

Korea Institute of Science and Technology
(KIST)
Center for Water Resource Cycle
Seoul, Korea
echung@kist.re.kr

Eunhyea Chung received her MS degree in Civil, Urban, and Geosystem Engineering at Seoul National University, Korea and her PhD in Environmental Engineering from the Georgia Institute of Technology. Her research activities include the estimation of colloidal particle and surface interactions in natural or engineered environments through theoretical and experimental approaches using scanning probe microscope or the neutron diffraction technique, and their applications.

Suzanne A. Ciftan Hens

ITC/International Technology Center
Raleigh, NC, USA
shens@itc-inc.org

Chapter A.8

Suzanne Hens received her PhD degree in Chemistry from UNC Chapel Hill. Her work at the International Technology Center (ITC) has encompassed the areas of nanoparticles and microelectronic applications. She has focused on the biological, chemical, and colloidal stability of nanodiamonds, synthesis of nanodiamond conjugates for commercial sales, as well as the design of highly conductive thermal interface materials used in microelectronic applications.

Vicki L. Colvin

Rice University
Office of Research, Chemistry
Houston, TX, USA
colvin@rice.edu

Chapter G.32

Vicki Colvin is Vice Provost of Research and Kenneth S. Pitzer-Schlumberger Professor of Chemistry at Rice University, Houston, USA. She earned her PhD in Chemistry from the University of California at Berkeley in 1994. The focus of her research is the unique behavior of nanoparticles in complex systems such as cells, organisms and the environment and problems related to water purification as well as targeted cell death.

Rodolfo Cruz-Silva

Shinshu University
Research Center for Exotic Nanocarbons
Nagano, Japan
rcruzsilva@shinshu-u.ac.jp

Chapter A.6

Rodolfo Cruz-Silva graduated in Chemical Engineering from Coahuila State University, Mexico, and received his PhD in Polymer Science from the Applied Chemistry Research Center, in Saltillo, Mexico. His research interests are in polymer/carbon nanocomposites and chemistry of nanocarbons. He is currently Associate Professor at the Research Center for Exotic Nanocarbons, at Shinshu University, in Nagano, Japan.

Pratap Kumar Deheri

ShayoNano Singapore Pte Ltd.
Singapore
dehe0001@e.ntu.edu.sg

Chapter B.12

Pratap Kumar Deheri is a PhD student from the School of Materials Science and Engineering, Nanyang Technological University (NTU), Singapore, where he does research in the chemical synthesis of magnetic nanomaterials. He is working as a Research Assistant in ShayoNano Singapore Pte. Ltd., a nanomaterials synthesis based company.

Libo Deng

University of Manchester
School of Materials
Manchester, UK
libo.deng@manchester.ac.uk

Chapter D.19

Libo Deng was educated in China and earned his PhD with work on carbon nanotube composites from the University of Manchester, UK. He presently does post-doctoral studies on the manufacture of carbon fibers by the pyrolysis and graphitization of cellulose fibers. His recent interest is in the behavior of double-walled carbon nanotubes and graphene.

Yi Ding

Shandong University
School of Chemistry and Chemical
Engineering
Jinan, China
yding@sdu.edu.cn

Chapter E.21

Yi Ding received his PhD in Materials Science and Engineering from Johns Hopkins University, Baltimore in 2005. He then joined the faculty of Shandong University as a Tai-Shan Scholar and full Professor in Chemistry and Materials Science and Engineering. His research focuses on design and processing of functional nanostructures such as de-alloyed nanoporous metals for advanced energy technology applications.

Huanli Dong

Chinese Academy of Sciences
Institute of Chemistry,
Key Laboratory of Organic Solids
Beijing, China
dhl522@iccas.ac.cn

Chapter F.25

Huanli Dong received her PhD degree in Physical Chemistry from the Institute of Chemistry, Chinese Academy of Sciences in 2009 after she got her MS degree in Inorganic Chemistry from Fujian Institute of Research on the Structure of Materials, Chinese Academy of Sciences in 2006. Her researches are presently focusing on the self-assembling of molecular materials and the application of molecular materials in optoelectronic devices. She is an Associate Professor of the Institute of Chemistry, Chinese Academy of Sciences.

**Mildred S. Dresselhaus**

Chapter A.7

Massachusetts Institute of Technology
Physics; Electrical Engineering
Cambridge, MA, USA
millie@mgm.mit.edu

Mildred Dresselhaus received her PhD from the University of Chicago in 1958. After two years as an NSF postdoctoral fellow at Cornell, Dresselhaus took permanent positions at MIT, first at Lincoln Labs in 1960 and then as part of the MIT faculty, as Professor of Electrical Engineering in 1967 and in 1983 in the Physics Department. She is known for her contributions to carbon nanoscience.

Dimple P. Dutta

Chapter C.13

Bhabha Atomic Research Centre
Chemistry Division
Mumbai, India
dimpled@barc.gov.in

Dr. Dutta joined Bhabha Atomic Research Centre in 1996 after completing her MSc from Indian Institute of Technology, Kanpur. She did her PhD at Mumbai University and Postdoctoral research from Ruprecht-Karls University Heidelberg, Germany. She has been selected for Young Associate of Maharashtra Academy of Sciences, India in 2008. She is a member of Member of National Academy of Sciences India (NASI), 2011. Her current research interests include synthesis, property evaluation of inorganic phosphor nanomaterials for white light generation, magnetic and multiferroic materials.

Hellmut Eckert

Chapter C.18

University of Sao Paulo
Department of Physics
Sao Carlos, SP, Brazil
eckert@ifsc.usp.br

Professor Eckert obtained his doctoral degree in Physical Chemistry in 1982 from the Westfälische Wilhelms Universität (WWU) Münster. He was a Professor of Chemistry at UC Santa Barbara (1987–1996), before he accepted a Chair in Physical Chemistry at the WWU Münster. He has published some 400 papers on solid state NMR technique development and applications in Materials Science, with a particular focus on glasses. In 2011 he became a faculty member of the Instituto de Física de Sao Carlos, IFSC/USP.

**Morinobu Endo**

Chapter A.7

Shinshu University
Research Centre for Exotic Nanocarbons
Nagano, Japan
endo@endomoribu.shinshu-u.ac.jp

Morinobu Endo studied Electrical Engineering at Shinshu University, Japan and obtained his PhD from the University of Orleans, France in 1975. In his PhD he had developed the synthesis method of carbon nanotubes and showed that it is a tubular structure for the first time. He is a CEO of the Institute of Carbon Science and Technology and is a Distinguished Professor of the Research Centre for Exotic Nanocarbons at Shinshu University. His current interests are in science and technology of nanocarbons such as carbon nanotubes, and the development of high-performance energy storage devices.

**Adam W. Feinberg**

Chapter F.27

Carnegie Mellon University
Department of Biomedical Engineering
Pittsburgh, PA, USA
feinberg@andrew.cmu.edu

Professor Feinberg graduated with a BS in Materials Science and Engineering from Cornell University in 1999 and with a PhD in Biomedical Engineering from the University of Florida in 2004. He holds a joint appointment in the Departments of Biomedical Engineering and Materials Science and Engineering at Carnegie Mellon University and is developing biomimetic fabrication strategies that use extracellular matrix proteins to engineer 2-D and 3-D nanofiber scaffolds. Prof. Feinberg has been awarded the NIH Director's New Innovator Award and holds 10 US patents and patent applications.

Alessandro Fortunelli

IPCF Consiglio Nazionale delle Ricerche (CNR)
Pisa, Italy
alessandro.fortunelli@cnr.it

**Chapter B.11**

Alessandro Fortunelli is Senior Researcher at CNR-IPCF which he joined in 1984 after obtaining his degree in Chemistry at Scuola Normale Superiore. He coordinated two European projects, is taking part to others, including COST Action on “Nanoalloys”, and is Visiting Associate at Caltech, Pasadena. His research interests focus on structural, optical, catalytic and magnetic properties of nanoalloys and ultrathin oxide-on-metal films. He is author of roughly 150 articles in peer-reviewed journals.

Yogeeswaran Ganesan

Intel Corporation
Hillsboro, OR, USA
yogiganesan@gmail.com

**Chapter A.4**

Yogeeswaran Ganesan obtained in PhD in Materials Science from Rice University (2011), where he worked on the in situ mechanical characterization of carbon nanotubes and carbon nanotube reinforced composites with Professor Jun Lou. He is currently employed as a lithography engineer at Intel Corp., Hillsboro, USA.

Wei Gao

Los Alamos National Laboratory
Center for Integrated Nanotechnology
Los Alamos, NM, USA
wei.gaofanyi@gmail.com

**Chapter C.15**

Dr. Wei Gao received her MA (2009) and PhD (2012) in Chemistry from Rice University, Houston, USA. Her research interests include synthesis of carbon nanomaterials and their composites, and their applications in water purification, energy storage and conversion technologies. Currently, she is working on a carbon-based solar cell project at Los Alamos National Laboratory.

Thomas F. George

University of Missouri–St. Louis
Office of the Chancellor, Center for Nanoscience
St. Louis, MO, USA
tfgorge@umsl.edu

**Chapter G.30**

Thomas F. George is Chancellor and professor of chemistry and physics at the University of Missouri – St. Louis. He is an active researcher in chemistry and physics, specializing in chemical/materials/laser physics and nanoscience, including nanomedicine. His work has led to 735 papers, 5 authored and 18 edited books. He has been recognized worldwide, such as being awarded the Marlow Medal by the Royal Society of Chemistry in Great Britain and the Medal of Honor by Gulf University for Science and Technology in Kuwait.

Lei Gong

University of Manchester
School of Materials
Manchester, UK
lei.gong@stud.manchester.ac.uk

**Chapter D.19**

Lei Gong was educated in China and got an MSc from the University of Sheffield and his PhD upon graphene composites from the University of Manchester. He has published a number of papers on graphene-based composites in high-impact journals and a major review in the mechanics of graphene-based composites.

Takuya Hayashi

Shinshu University
Department of Electrical and Electronic Engineering
Nagano, Japan
hayashi@endomoribu.shinshu-u.ac.jp

**Chapter A.7**

Takuya Hayashi received a PhD in 1999 from University of Tokyo, Japan. He is an Associate Professor of Shinshu University and he has published about 150 papers in international journals. His research interests are structural analysis and property measurements of carbon nanomaterials using high-resolution transmission electron microscopy, in-situ physical property measurement of nanostructured carbon materials and simulation of carbon nanomaterial formation, and its property prediction.

**Wenping Hu**

Chapter F.25

Key Laboratory of Organic Solids
Institute of Chemistry,
Chinese Academy of Sciences
Beijing, China
huwp@iccas.ac.cn

Wenping Hu received his PhD in 1999. Then he joined Osaka University and Stuttgart University as a research fellow of the Japan Society for the Promotion of Sciences and Alexander von Humboldt Research Fellowship, respectively. In 2003 he worked at Nippon Telephone and Telegraph, and then returned to the Institute of Chemistry, Chinese Academy of Sciences. He focuses on molecular electronics and has more than 180 refereed publications. He is now a Professor of the Institute of Chemistry, Chinese Academy of Sciences.

**Erik H. H  roz**

Chapter A.4

Rice University
Electrical and Computer Engineering
Houston, TX, USA
enano@rice.edu

Erik H  roz is a PhD student in Electrical Engineering with final exams in Spring 2013 from Rice University. At Rice he already earned a BA in Chemistry and a MS in Electrical Engineering. His doctoral work, under the supervision of Professors Junichiro Kono, Robert Hauge and Frank Tittel, has been on carbon nanotube colloid and separation chemistry as well as armchair carbon nanotube photophysics.

Quentin Jallerat

Chapter F.27

Carnegie Mellon University
Biomedical Engineering
Pittsburgh, PA, USA
qjallerat@andrew.cmu.edu

Quentin Jallerat received a BS from Ecole Centrale Paris, France and a MS in Biomedical Engineering from Columbia University, New York. He is now a graduate student in the Regenerative Biomaterials and Therapeutics Group at Carnegie Mellon University, Pittsburgh, PA. He is developing new scaffolds that mimic the extracellular matrix of the chick embryonic heart for cardiac tissue engineering.

Heli Jantunen

Chapter D.20

University of Oulu
Department of Electrical Engineering
Oulu, Finland
heli.jantunen@oulu.fi

Heli Jantunen received her Dr. Tech. degree in Microelectronics from the University of Oulu, Finland, in 2001 and is working as Full Professor in Technical Physics in the Microelectronics and Materials Physics Laboratory. Her research interests include novel sensors and RF applications by implementation of advanced functional materials, structures and nanotechnology into multifunctional micromodules and printed electronics devices.

**Song Jin**

Chapter C.17

University of Wisconsin-Madison
Department of Chemistry
Madison, WI, USA
jin@chem.wisc.edu

Song Jin received his BS from Beijing University in 1997 and his PhD from Cornell University, Ithaca, NY, in 2002. He is currently an Associate Professor of Chemistry at the University of Wisconsin-Madison, WI. With interest in chemistry and physics of nanomaterials, Dr. Jin studies the fundamental formation mechanisms of nanomaterials, their novel physical properties and applications in renewable energy such as solar and thermoelectric energy conversion as well as energy storage, nanospintronics, and nanobiotechnology.

**Kaushik Kalaga**

Chapter G.31

Rice University
Department of Mechanical Engineering &
Materials Science
Houston, TX, USA
kalaga.kaushik@gmail.com

Kaushik Kalaga received his B.Tech and M.Tech (Integrated Dual Degree) from Indian Institute of Technology, at Banaras Hindu University, Varanasi. He is currently pursuing his PhD at Rice University, Houston, USA in Mechanical Engineering and Materials Science. He is currently working on carbon nanomaterials and other layered materials for lithium ion battery applications.

Ji-Hee Kim

Rice University
Department of Electrical and Computer
Engineering
Houston, TX, USA
withphys@gmail.com

Chapter A.4

Ji-Hee Kim received her PhD from Chungnam National University, Korea, in 2011 under the supervision of Professor Ki-Ju Yee. Her thesis focused on coherent phonons in graphene and single walled carbon nanotubes by ultrafast spectroscopy. She moved to Rice University as a postdoctoral researcher in Professor Junichiro Kono's group. Her current research focuses on many-body processes of excitons in quantum wells under high magnetic fields.

Yoong A. Kim

Shinshu University
Department of Electrical and Electronic
Engineering
Nagano, Japan
yak@endomoribu.shinshu-u.ac.jp

Chapter A.7

Yoong Ahm Kim received a PhD in Materials Engineering in 2001 from Shinshu University, Japan. He is an Associate Professor at Shinshu University and has published about 160 papers (H-index = 33). His current research areas are carbon nanotube-based transparent conductive films, optical properties of double-walled carbon nanotubes, fabrication of novel nanofibers by electrospinning, biological compatibility of carbon nanotubes, fabrication of high-quality graphenes, application of nanocarbons in energy storage devices, and nanocarbon-based three dimensional scaffolds for growing cells.

Ian A. Kinloch

University of Manchester
School of Materials
Manchester, UK
ian.kinloch@manchester.ac.uk

Chapter D.19

Ian Kinloch studied Physics at Durham University, UK, and undertook his PhD at the University of Cambridge upon the processing characterization and properties of carbon nanotubes. He was awarded a Royal Academy of Engineering/EPSRC Research Fellowship in Carbon Nanotubes in Advanced Engineering Materials at Cambridge and moved to Manchester University in 2006. His research is now concentrated upon the production, processing and applications of nanomaterials and has recently refocused his interests towards graphene.

Imre Kiricsi (deceased)

Chapter E.22

Junichiro Kono

Rice University
Electrical and Computer Engineering &
Physics and Astronomy
Houston, TX, USA
kono@rice.edu

Chapter A.4

Junichiro Kono received his BS and MS degrees in Applied Physics from the University of Tokyo in 1990 and 1992, respectively, and completed his PhD in Physics at the State University of New York at Buffalo in 1995. He was a postdoctoral research associate at the University of California, Santa Barbara (1995–1997) and a W. W. Hansen Experimental Physics Laboratory Fellow at Stanford University 1997–2000. He joined the Department of Electrical and Computer Engineering of Rice University in 2000 and since 2009 he has been a Professor at Rice University. Kono's current research interests include optical studies of low-dimensional systems; spintronics and quantum information processing; nonlinear, ultrafast, and quantum optics in solids; phenomena in ultrahigh magnetic fields; and terahertz phenomena in semiconductors.

Krisztián Kordás

University of Oulu
Department of Electrical Engineering
Oulu, Finland
lapy@ee.oulu.fi

Chapters B.10, D.20

Krisztián Kordás is a Research Professor at the Department of Electrical Engineering, University of Oulu, where he earned his Dr. Tech. degree in Microelectronics in 2002. Between 2004 and 2008 he held an Academy Research Fellow position of the Academy of Finland. His research is focused on nanomaterials synthesis and modification for (photo)catalysis, sensors and electrical components and devices.

Gábor Kozma

University of Szeged
Department of Applied and
Environmental Chemistry
Szeged, Hungary
kozmag@chem.u-szeged.hu

Chapter A.5

Gábor Kozma graduated in Environmental Science from the University of Szeged, Hungary, in 2007. After graduation he started his PhD studies at the Department of Applied and Environmental Chemistry, where he is now working as Assistant Research Fellow. His research interests include mechanochemical synthesis and kinetics, nanocomposites and nanoscaled materials applications in environmental remediation.

Jarmo Kukkola

University of Oulu
Department of Electrical Engineering
Oulu, Finland
jarmo.kukkola@gmail.com

Chapter D.20

Jarmo Kukkola, after receiving his MSc degree in Theoretical Physics from the University of Oulu, Finland (2008), he joined the Micro-electronics and Materials Physics Labs in Oulu, where he is currently a PhD student. His primary research interest are electrical properties of nanostructured materials.

Ákos Kukovecz

University of Szeged
Department of Applied and
Environmental Chemistry
Szeged, Hungary
kakos@chem.u-szeged.hu

Chapters A.5, D.20, E.22

Ákos Kukovecz received his PhD in chemistry from the University of Szeged, Hungary, in 2001 and has done his postdoctoral work at the University of Vienna, Austria. He is now an Associate Professor of Chemistry at Szeged. His current research interests include porous nanocomposites, networks of one-dimensional nanostructures, fluid–nanoparticle interactions, electron microscopy and Raman spectroscopy.

Vinod Kumar

Banaras Hindu University
Department of Zoology
Lanka, Varanasi, India
mail2vinod2@gmail.com

Chapter F.26

Vinod Kumar is a PhD student in the department of Zoology at Banaras Hindu University, India. He received his MSc in Biotechnology from Chhatrapati Shahu Ji Maharaj University (CSJM), Kanpur, India. His current research interests focus on biomedical application of carbon nanomaterials with a special attention to the field of tissue engineering and disease diagnosis.

Zoltán Kónya

University of Szeged
Department of Applied and
Environmental Chemistry
Szeged, Hungary
konya@chem.u-szeged.hu

Chapters A.5, D.20, E.22

Zoltán Kónya received his PhD in Chemistry from the University of Szeged, Hungary (1997). His research interests include inorganic nanostructures, synthesis procedures, spectroscopy and microscopy. Currently he is working on two main fields, one is the synthesis and modifications of new 0-D and 1-D nanostructures for (photo)catalytic applications. The second is the possible environmental applications of nanostructures.

Jaesang Lee

Korea Institute of Science and Technology
(KIST)
Center for Water Resource Cycle
Seoul, Korea
lee39@kist.re.kr

Chapter G.29

Dr. Jaesang Lee is a senior research scientist at the Center for Water Resource Cycle, Korea Institute of Science and Technology. He received his PhD from POSTECH and worked as a postdoctoral researcher at Georgia Institute of Technology and Rice University. His current research interests include environmental photochemistry and photocatalysis, advanced oxidation processes, and environmental fate of nanomaterials.

**Seunghak Lee**

Chapter G.29

Korea Institute of Science and Technology (KIST)
Center for Water Resource Cycle
Seoul, Korea
seunglee@kist.re.kr

Dr. Seunghak Lee received his PhD in Geoenvironmental Engineering from Seoul National University (2005) and worked as a postdoctoral research associate at University of Wisconsin-Madison. His research interests include subsurface remediation technologies, especially, permeable reactive barriers, contaminant transports in the subsurface and hazardous waste landfills. His current research is focused on estimating fate and transport of nanoparticles in the subsurface.

Renat R. Letfullin

Chapter G.30

Rose-Hulman Institute of Technology
Physics and Optical Engineering
Terre Haute, IN, USA
letfullin@rose-hulman.edu

Renat R. Letfullin is Associate Professor of Physics and Optical Engineering Department at the Rose-Hulman Institute of Technology at Terre Haute, IN. He has extensive academic credentials in nanotechnology and specializes in laser physics, wave and quantum optics, biophotonics and nanomedicine. He published over 150 articles and conference proceedings, including 12 book chapters and 10 authored/edited books. He is an Editor for International Journal of Theoretical Physics, Group Theory and Nonlinear Optics.

Roi Levi

Chapter C.16

Weizmann Institute of Science
Department of Materials and Interfaces
Rehovot, Israel
roi.levi@weizmann.ac.il

Roi Levi received his BSc in Chemical Engineering from the Ben-Gurion University, Israel (2006), the MSc degree in Chemistry from the Weizmann Institute of Science and is currently striving for his PhD in Chemistry at the Weizmann Institute of Science, Rehovot. His research interests include electronic and electro-mechanic properties of inorganic nanotubes and functional devices incorporating inorganic nanotubes.

**Zuzanna A. Lewicka**

Chapter G.32

Rice University
Department of Chemistry
Houston, TX, USA
zuzanna@rice.edu

Dr. Zuzanna Lewicka received a PhD from Rice University, Houston, USA, in May 2012 and a Master of Science degree from the University of Technology, Wrocław, Poland, in 2005. Her research has centred upon the characterization of engineered nanomaterials prior to their examination in toxicology and environmental studies, as well as the development of methods to produce nanostructure arrays over large areas.

**Longtu Li**

Chapter C.14

Tsinghua University
Materials Science & Engineering
Beijing, China
llt-dms@mail.tsinghua.edu.cn

Longtu Li is a Professor in the Department of Materials Science and Engineering at Tsinghua University, where he graduated in 1958. He is a member of the Chinese Academic of Engineering and has worked as visiting scholar and visiting Professor at Lehigh University and Penn State University, USA, in 1987 and 1994, respectively. His research fields include piezoelectric, ferroelectric, dielectric, semiconductive, ferrite materials and their applications.

Shaily Mahendra

Chapter G.29

University of California, Los Angeles
Civil and Environmental Engineering
Los Angeles, CA, USA
mahendra@seas.ucla.edu

Dr. Shaily Mahendra is an Assistant Professor in the UCLA Department Civil & Environmental Engineering. She received PhD from University of California, Berkeley, and post-doctoral fellowship from Rice University, Houston. Her research areas are microbial processes in natural and engineered systems, applications of molecular and isotopic tools in environmental microbiology, biodegradation of emerging groundwater contaminants and environmental impacts of nanomaterials.

Balaji P. Mandal

Bhabha Atomic Research Centre
Chemistry Division
Mumbai, India
bpmandal@barc.gov.i

Chapter C.13

Dr. Balaji P. Mandal joined the Bhabha Atomic Research Centre (BARC) in 2004. He was awarded the PhD degree in Chemistry in 2009 by the Mumbai University in recognition of his work on high temperature ceramic materials for futuristic nuclear technologies. He did his postdoctoral research at Wayne State University, Detroit, USA during 2011/2012. His research interest is in synthesis and structural elucidation of inorganic materials based on oxides.

Fei Meng

University of Wisconsin–Madison
Department of Chemistry
Madison, WI, USA
fmeng@chem.wisc.edu

Chapter C.17

Fei Meng received his BS degree in Chemistry from Beijing University in 2005. Now he is pursuing doctoral thesis in the Department of Chemistry in the University of Wisconsin–Madison under the supervision of Professor Song Jin. His research focuses on the screw dislocation-driven growth of nanomaterials.

Guowen Meng

Chinese Academy of Sciences
Institute of Solid State Physics
Hefei, China
gwmeng@issp.ac.cn

Chapter E.23

Guowen Meng is a Professor in the Institute of Solid State Physics, Chinese Academy of Sciences (CAS), Hefei. He obtained his PhD in Materials Science and Engineering from Northwestern Polytechnic University, Xi'an, China (1996) and did his post doc work at the Rensselaer Polytechnic Institute, Troy, NY. His research interests include 1-D nanostructures and environmental applications of nanomaterials. He co-authored more than 150 papers (H-index 38) and was awarded the 2nd class of The State Natural Science Award of the P.R. China.

Younès Messaddeq

Université Laval
Department of Physics
Québec, Québec, Canada
younes.messaddeq@copl.ulaval.ca

Chapter C.18

Younès Messaddeq, who holds a PhD in chemistry and a bachelor's degree in solid-state chemistry from the Université de Rennes 1, France, is a researcher in materials development for optics and photonics. He has published over 290 papers in refereed journals and conferences, and presented several of Invited talks related to glass and advanced materials. In 2010, he was appointed to one of the 19 prestigious Canada Excellence Research Chairs (CERC), providing 28M\$ in research funds at Université Laval, Québec, Canada.

Jyri-Pekka Mikkola

Åbo Akademi University
Department of Chemical Engineering
Åbo-Turku, Finland
jyri-pekka.mikkola@chem.umu.se;
jyri-pekka.mikkola@abo.fi

Chapter D.20

Jyri-Pekka Mikkola is a Professor of Sustainable Chemical Technology at Umeå University, Sweden and Åbo Akademi University, Finland. He earned his Dr. Tech. (Chem.Eng.) degree in 1999. Previously he held an Academy Research Fellow position at the Academy of Finland. He received the Incentive Award from the Academy of Finland (2006) and the Umeå University's Young Researcher Award (2009). His research encompasses areas including nanostructured catalysis, ionic-liquid technologies and biorefining.

Melinda Mohl

University of Oulu
Department of Electrical Engineering
Oulu, Finland
memohl@ee.oulu.fi

Chapter B.10

Melinda Mohl received her PhD in Nanotechnology from the University of Szeged, Hungary, in 2011. She performed internships at the Facultés Universitaires Notre-Dame de la Paix, Namur, France (2005–2006) and at Rice University, Houston (2008–2009). Since 2011, she is a postdoctoral research fellow at the University of Oulu, Finland, pursuing research on nanostructures for (photo)catalysis, sensors and electronic devices.

**Aarón Morelos-Gómez**

Chapter A.6

Shinshu University
Institute of Carbon Science and
Technology
Nagano, Japan
amorelos@shinshu-u.ac.jp

Aarón Morelos-Gómez received his doctoral degree in Applied Sciences specialized in Nanoscience and Nanotechnology in 2010 from Institute for Scientific and Technological Research of San Luis Potosi (IPICYT), Mexico. Currently he is a postdoctoral fellow at the Institute of Carbon Science and Technology at Shinshu University in Japan. His research interests are synthesis and physical properties of carbon nanotubes, graphene nanoribbons and carbon inverse opal.

Stephen A. Morin

Chapter C.17

Harvard University
Chemistry and Chemical Biology
Cambridge, MA, USA
smorin@gmwgroup.harvard.edu

Stephen A. Morin received his PhD in Chemistry from the University of Wisconsin – Madison in 2011. His graduate research focused on the synthesis and assembly of functional nanomaterials and enabled the development of the fundamental understandings and strategies for dislocation-driven nanowire, nanotube, and nanoplate growth in the aqueous phase. He is currently a Postdoctoral Fellow at Harvard University in the Lab of Professor George M. Whitesides.

Marcelo Nalin

Chapter C.18

Federal University of Sao Carlos
Department of Chemistry
Sao Carlos, Brazil
mnalin@ufscar.br

Marcelo Nalin is a Professor at the Federal University of Sao Carlos, Brazil. He earned his PhD in Chemistry from both Institute of Chemistry – UNESP (Brazil) and Rennes-1 University (France) in 2002. He did his post-doctoral work at Paris-Sud University (France) and in the Physics Department of Unicamp (Brazil). His research includes the synthesis of glasses and nanoglassceramics for photonics.

**Sebastien Nanot**

Chapter A.4

Rice University
Electrical and Computer Engineering &
Physics and Astronomy
Houston, TX, USA
sebastien.nanot@gmail.com

Sebastien Nanot received his PhD from Université de Toulouse (France) in 2009 under supervision of Professors Bertrand Raquet and Jean-Marc Broto. His thesis focused on individual carbon nanotube properties under very high magnetic fields. He moved to Rice University where he is appointed as a postdoctoral researcher in Prof. Junichiro Kono's Group. His current research focuses on optoelectronic properties of carbon materials.

**Rachelle N. Palchesko**

Chapter F.27

Carnegie Mellon University
Biomedical Engineering
Pittsburgh, PA, USA
rachelle@andrew.cmu.edu

Dr. Rachelle Palchesko received her PhD in Surface Chemistry focusing on the covalent attachment of biomolecules to bone replacement materials at Duquesne University, Pittsburgh, PA. She is currently a Postdoctoral Fellow working with Professor Adam Feinberg and James Funderburgh on tissue engineering the corneal endothelium. Her research focuses on the bottom-up engineering of basement membrane mimics utilizing ECM proteins and biomechanics.

Cary L. Pint

Chapter A.4

Vanderbilt University
Department of Mechanical Engineering
Nashville, TN, USA
Cary.L.Pint@vanderbilt.edu

Cary is currently an Assistant Professor of Mechanical Engineering at Vanderbilt University, where he serves as Director of the Nanomaterials and Energy Devices Laboratory. Cary received his PhD in Applied Physics from Rice University in 2010 and authored over 40 publications focused on growth and applications of carbon nanomaterials. Cary also serves as Associate Editor of Advanced Carbon.

Gael Poirier

Federal University of Alfenas
Institute of Science and Technology
Poços de Caldas, MG, Brazil
gael.poirier@unifal-mg.edu.br

Chapter C.18

Professor Gael Poirier obtained his doctoral degree in Physical Chemistry in 2003 from the Université de Rennes 1, France, and Sao Paulo State University (UNESP), Araraquara, Brazil. Between 2003 and 2006, he also worked in the field of glasses and glass-ceramics for optics also at UNESP in collaboration with Professors Sidney Ribeiro and Younes Messaddeq. He is a Professor of chemistry and solid state science since 2006 at the Federal University of Alfenas, Brazil. He has published 32 papers focusing on new glass-ceramics for optical applications based on germinate and tellurite compositions.

**Thalappil Pradeep**

Indian Institute of Technology Madras
Department of Chemistry
Chennai, India
pradeep@iitm.ac.in

Chapter B.9

Dr. Pradeep earned his PhD from the Indian Institute of Science in 1991 and had post doctoral training at University of California, Berkeley and Purdue University, West Lafayette. His interests are in molecular and nanoscale materials and he builds instruments to perform several of these studies. He develops affordable technologies for clean water and has authored over 275 publications, four books and several book chapters. He is a Fellow of the Indian Academy of Sciences.

**István Pálkó**

University of Szeged
Department of Organic Chemistry
Szeged, Hungary
palinko@chem.u-szeged.hu

Chapter E.22

István Pálkó is an Associate Professor at the Chemistry Institute, University of Szeged. He earned his PhD and DSc from the Hungarian Academy of Sciences. He did postdoctoral works with Professor Seddon at Queen's University of Belfast and Nobel-Laurate G.A. Olah at the University of South California. He is active in diverse areas like synthetic materials science, physical organic chemistry and solution inorganic chemistry.

Raju V. Ramanujan

Nanyang Technological University
School of Materials Science and
Engineering
Singapore
ramanujan@ntu.edu.sg

Chapter B.12

Professor Raju V. Ramanujan is a Fellow of the American Society for Materials. He earned his PhD degree at Carnegie Mellon University (USA). Ramanujan serves on the Editorial Board of Nanomedicine and Materials Science and Engineering C. He serves on the Magnetic Materials Committee of TMS (USA) and is the Vice Chair of the Phase Transformations Committee of TMS and ASM (USA). He received the Nanyang Award for Excellence in Teaching. His research interests include the study of advanced nanomaterials for both functional and structural applications.

Sundara Ramaprabhu

Indian Institute of Technology, Madras
Department of Physics
Chennai, India
ramp@iitm.ac.in

Chapter G.28

After completing PhD in Physics at the Indian Institute of Technology Madras, Chennai, Dr. Ramaprabhu worked at the TU Darmstadt, Germany, for 2 years as an Alexander von Humboldt Fellow and for 5 years at University of Geneva, Switzerland. He joined IITM, Chennai as Assistant Professor and subsequently became Professor. He is a DAAD Fellow, Visiting Fellow to Germany by BMBF & DFG German Science Foundations, Visiting Fellow to South Korea and Japan. He is a member of American Chemical Society and Member of Electrochemical Society. His research areas are nanotechnology, hydrogen energy technology, fuel cell technology, pv, li ion battery, nanofluids, water purification, and CO₂ capture. He has published in 228 International journals of repute and has 32 patents.

**Jayshree Ramkumar**

Chapter C.13

Bhabha Atomic Research Centre
Analytical Chemistry Division
Mumbai, India
jrk@barc.gov.in

Dr. Jayshree Ramkumar is affiliated to the Analytical Chemistry Division of Bhabha Atomic Research Centre. She is also an Assistant Professor Homi Bhabha National Institute, India. Her area of specialization is the development of new separation procedures for different metal ions and toxic substances using membranes and adsorbents. She was awarded the PhD on her work on ion exchange and related studies using Nafion membrane. She has more than 40 international journal publications and pursued her postdoctoral research in 2009 as an MANA Research Fellow at the National Institute of Materials Science (NIMS), Ibaraki, Japan.

**Arava L.M. Reddy**

Chapter G.28

Rice University
Department of Mechanical Engineering
and Materials Science
Houston, TX, USA
leela@rice.edu

Dr. Arava Leela Mohana Reddy obtained his PhD in Physics from the Indian Institute of Technology Madras, India in 2007. He then spent a year as a postdoctoral fellow at the University of Pittsburgh with Prof. Gilbert Walker. He is currently a Research Scientist in the Department of Mechanical Engineering and Material Science at Rice University. His research focuses on nanostructured materials, particularly hybrid nanoarchitectures for applications in lithium-ion rechargeable batteries, fuel cells and supercapacitors. He has published more than 55 papers.

Vincent C. Reyes

University of California, Los Angeles
Department of Civil and Environmental
Engineering
Los Angeles, CA, USA
vincecreyes@ucla.edu

Chapter G.29

Vincent C. Reyes is a PhD candidate in Civil & Environmental Engineering at the University of California, Los Angeles, where he also received his MS. He got his BS in Genetics from the University of California, Irvine. His current research focuses on understanding the interactions of metal containing nanomaterials with nitrogen cycling microorganisms.

Sidney J.L. Ribeiro

Sao Paulo State University – UNESP
Institute of Chemistry
Araraquara, SP, Brazil
Sidney@iq.unesp.br

Chapter C.18

Professor Sidney J.L. Ribeiro obtained his PhD degree working on glasses and glass-ceramics at Sao Paulo State University (UNESP). Post-doc stages were performed at the École Centrale Paris and the CNET-France Telecom, France. Ribeiro published more than 240 papers and 19 patents were deposited. His research includes inorganic chemistry, materials science and education in chemistry.

**William D. Rice**

Chapter A.4

Los Alamos National Laboratory
National High Magnetic Field Laboratory
Los Alamos, NM, USA
wdrice@lanl.gov

William Rice obtained his BSc (Honors) in Physics at Brown University focusing on picosecond ultrasonics and coherent phonons in water. His doctoral work at Rice University centred on electronic spin resonance, exciton dynamics, and magnetotransport in carbon nanotubes and quantum wells. Currently, he is a post-doctoral fellow at Los Alamos investigating photo-induced magnetism in quantum dots.

**Silvia H. Santagneli**

Chapter C.18

Sao Paulo State University – UNESP
Institute of Chemistry
Araraquara, SP, Brazil
santagneli@iq.unesp.br

Silvia Santagneli received her PhD degree in Chemistry from Sao Paulo State University – UNESP, Brazil in 2006. The she spent a post-doctoral period at the same institution. Her research interests include glass materials and solid state NMR technique for applications in materials science. Currently she develops new glasses for photonic and battery devices also at UNESP.

Preeti S. Saxena

Banaras Hindu University
Department of Zoology
Lanka, Varanasi, Uttar Pradesh, India
pssaxena@rediffmail.co

Chapter F.26

Preeti S. Saxena received her PhD from the University of Rajasthan, Jaipur in 2003. At present, she is working as Assistant Professor in the Department of Zoology, BHU. She is doing research in the area of nanobiology, nanotoxicology and biosensing. She has also been a visiting research scholar at Rensselaer Polytechnic Institute, Troy, USA in 2006.

Olga A. Shenderova

International Technology Center
Raleigh, NC, USA
oshenderova@itc-inc.org

Chapter A.8

Olga Shenderova received the PhD degree in Materials Science from the St. Petersburg State Technical University, Russia. She is a Head of the Nanodiamond Laboratory at the International Technology Center and a President of Adamas Nanotechnologies Inc., Raleigh, USA. She works on applied research and commercialization of nanodiamond particles. She authored more than 120 papers and edited 5 books on nanodiamonds.

Rakesh Shukla

Bhabha Atomic Research Centre
Chemistry Division
Mumbai, India
rakesh@barc.gov.in

Chapter C.13

Mr. Rakesh Shukla joined the Solid-State Chemistry Section of the Chemistry Division, Bhabha Atomic Research Centre, Mumbai in 2006. His main research interests are in the chemistry of nanomaterials for various applications. Recently he was a visiting researcher at Wayne State University, Detroit, USA. Presently he is pursuing his PhD (Chemistry) from Mumbai University under the guidance of Dr. A. K. Tyagi.

Shashwat Shukla

Nanyang Technological University
Singapore
shas0002@e.ntu.edu.sg

Chapter B.12

Shashwat Shukla is a PhD student in the School of Materials Science and Engineering, Nanyang Technological University (NTU), Singapore. His research interests include non-equilibrium processing of magnetic nanomaterials, x-ray absorption spectroscopy, electron microscopy, neutron diffraction and kinetic modelling of alloy systems subjected to external driving forces such as mechanical milling and ion irradiation.

Theruvakkattil S. Sreeprasad

Kansas State University
Department of Chemical Engineering
Manhattan, KS, USA
sprasad@k-state.edu

Chapter B.9

Dr. Sreeprasad is a postdoctoral fellow at the Kansas State University. He earned his PhD from the Indian Institute of Technology Madras, India in 2011 and has MSc from the School of Chemical Sciences, MG University, Kottayam, India. His areas of interest include nanosystems and 2-D materials. He has authored/co-authored 26 journal articles, 3 book chapters and is a co-inventor in 8 patent applications.

Anchal Srivastava

Banaras Hindu University
Department of Physics
Lanka, Varanasi, Uttar Pradesh, India
anchalbhu@gmail.com

Chapters F.26, G.31

Anchal Srivastava received his PhD from Banaras Hindu University (BHU), India, in 2002. He continued in the same department as a post doctoral fellow, as a lecturer in 2004 and is currently an Assistant Professor in the Department of Physics, BHU. He specializes in synthesis, characterizations and applications of carbon nanomaterials and has been awarded the Max-Planck India fellowship. He did research at Max-Planck Institute of Solid State Physics, Stuttgart, Germany in Professor von Klitzing's group. He has also been awarded the prestigious BOYSCAST fellowship from the government of India in 2008–2009. He has also been a visiting research scholar at Rensselaer Polytechnic Institute, USA in 2006.

**Saurabh Srivastava**

Chapter G.31

National Physical Laboratory
Biomedical Instrumentation Section,
New Rajender Nagar, New Delhi, India
saurabhnppl@gmail.com

Saurabh Srivastava received his MSc in Physics from Banaras Hindu University (BHU), Varanasi, India, where he is currently pursuing his PhD in Physics. He is a senior research fellow (CSIR) in the Biomedical Instrumentation Section, National Physical Laboratory, New Delhi, India. He is actively engaged in carbon nanomaterials and their derivatives for biosensing application.

**Yan Sun**

Chapter F.27

Beihang University (BUAA)
School of Biological Science and Medical
Engineering
Beijing, China
sunyan@buaa.edu.cn

Yan Sun received her PhD in Biochemistry and Molecular Biology from the Chinese Academy of Sciences (CAS). She is an Associate Professor in the School of Biological Sciences and Medical Engineering of Beihang University (BUAA), China. Her research activities include biomechanics, effect of microgravity on human cells and microorganisms, anti-tumor research of Chinese herbal medicine, as well as biomicrofluidics and micropatterning.

Mária Szabó

University of Szeged
Applied and Environmental Chemistry
Szeged, Hungary
szmaria@chem.u-szeged.hu

Chapter D.20

Mária Szabó is a PhD student at the University of Szeged in Hungary, where she finished her Chemistry BSc and then MSc before. She has also been working as summer trainee at the University of Oulu, Finland. She focuses on the preparation and characterization of nanoparticles for her PhD thesis where she discusses 1-D nanostructures.

John M. Szymanski

Chapter F.27

Carnegie Mellon University
Department of Biomedical Engineering
Pittsburgh, PA, USA
jszymans@andrew.cmu.edu

John Szymanski earned his BS in Materials Science and Engineering from Johns Hopkins University. John is currently performing his doctoral work under Dr. Adam Feinberg in the Department of Biomedical Engineering at Carnegie Mellon University, Pittsburgh. His research focuses on investigating the mechanosensitive properties of extracellular matrix protein nanofibers and how these properties affect cell behavior.

**András Sápi**

Chapter D.20

University of Szeged
Department of Applied and
Environmental Chemistry
Szeged, Hungary
sapia@chem.u-szeged.hu

András Sápi earned his PhD degree in Chemistry at the University of Szeged, Hungary, where he is an Assistant Lecturer in the Applied and Environmental Chemistry Department. His researches mainly focused on 0-D and 1-D nanomaterials, different types of nanocomposites. He has experience in carbon nanotubes, titanate nanostructures, materials science characterization methods and catalytic investigations.

**Reshef Tenne**

Chapter C.16

Weizmann Institute of Science
Department of Materials and Interfaces
Rehovot, Israel
Reshef.tenne@weizmann.ac.il

Reshef Tenne earned his PhD in 1976 in Physical Chemistry from the Hebrew University of Jerusalem and joined the Weizmann Institute in 1979. His interests are focused on the synthesis and study of nanotubes and fullerene-like nanoparticles of layered compounds, like WS₂, which he discovered in 1992. He is the Director of the Helen and Martin Kimmel Center for Nanoscale Science at the Weizmann Institute and a member of the Israel Academy of Sciences and Humanities and Academia Europaea and a Fellow of the Materials Research Society and the Royal Society of Chemistry.

Humberto Terrones

Pennsylvania State University
Physics Department
University Park, PA, USA
hzt2@psu.edu

Chapter A.3

Humberto Terrones obtained his PhD from the University of London, UK. Following a postdoctoral position in Cambridge University (UK), he joined UNAM and IPICYT in Mexico. Then moved to UCL in Leuven, Belgium and ORNL, Oak Ridge, USA. Presently, he is Visiting Professor at Pennsylvania State University, University Park, PA and at the Ceara Federal University in Brazil. His main interests involve theory and experiment of 2-D layered nanostructures.

Mauricio Terrones

Pennsylvania State University
Department of Physics and Materials
Science and Engineering
University Park, PA, USA
mut11@psu.edu

Chapter A.6

Mauricio Terrones obtained his BSc in Engineering Physics with first class honours at Universidad Iberoamericana. In 1994 he started his doctorate with Sir Prof. Harold W. Kroto (Nobel Laureate, FRS) and received his D.Phil. degree from the University of Sussex in 1998. He has co-authored more than 300 publications in international journals with an H index of 63. He has numerous awards including: the Alexander von Humboldt Fellowship, the Javed Husain Prize and the Albert Einstein medal from UNESCO, the TWAS Prize in Engineering Physics, the Carbon Prize given by the Japanese Carbon Society, the Somiya Award by the International Union of Materials Research Societies, among others. He is currently Professor of Physics at The Pennsylvania State University (USA) and distinguished Professor at Shinshu University, Japan.

Nicholas A. Thompson

Rice University
Department of Physics & Astronomy
Houston, TX, USA
nt7@rice.edu

Chapter A.4

Nicholas Thompson is a Graduate student in Physics at Rice University working in Prof. Junichiro Kono's research group. His experimental work involves observation of the optical properties of graphene under strong excitations. He obtained his Master's Degree in Mathematics from Idaho State University.

Bipul Tripathi

Banaras Hindu University
Department of Physics
Lanka, Varanasi, Uttar Pradesh, India
bipultripathi@gmail.com

Chapter F.26

Bipul Tripathi received his BSc (Honors) in Physics from Banaras Hindu University (BHU), India and completed the MSc in Physics with specialization in Biophysics from the same department in 2012. His field of interest includes synthesis of advanced functional nanomaterials for application in nanobiotechnology particularly in tissue engineering and drug delivery.

Ferdinando Tristán López

Shinshu University
Faculty of Engineering, Research Center
for Exotic Nanocarbons
Nagano, Japan
ftristan@shinshu-u.ac.jp

Chapter A.6

Ferdinando Tristan Lopez received his PhD in Chemical Engineering from the Universidad Autonoma de San Luis Potosi, Mexico in 2008. His research interests include catalysis, self-assembly and synthesis of carbon nanostructures. Currently he develops his research at the Research Center for Exotic Nanocarbons in Shinshu University, Japan.

Avesh K. Tyagi

Bhabha Atomic Research Centre
Chemistry Division
Mumbai, India
aktyagi@barc.gov.in

Chapter C.13

Dr. Avesh K. Tyagi joined BARC in 1986. Presently he is heading the Solid-State Chemistry Section. He is a Professor of Chemistry at Homi Bhabha National Institute. His research interests are in nano, functional and nuclear materials. He also awarded a number of prestigious awards such as such as Homi Bhabha Science and Technology Award MRSI Medal; CRSI, Medal; Gold Medal of Indian Nuclear Society; Rheometric-ITAS Award; Dr. Laxmi Award of ISCAS and IANCAS-Dr Tarun Datta Memorial Award, R.D. Deasi Memorial Award of Indian Chemical Society and CRSI-Prof. CNR Rao National Prize for Chemical Sciences. He is a Fellow of the National Academy of Sciences, India, Royal Society of Chemistry, UK, and the Maharashtra Academy of Sciences.

**Géza Tóth**

University of Oulu
Department of Electrical Engineering
Oulu, Finland
geza@ee.oulu.fi

Chapter D.20

Dr. Tech. Geza Toth is a postdoctoral researcher. After his diploma in Physics from the University of Szeged in 2002, he joined the Microelectronics and Materials Physics Laboratories in Oulu, Finland, where he finished his postgraduate studies in 2007. His primary research field is related to materials physics and characterization (electron microscopy); computational analysis (thermomechanics and fluid dynamics by FEM). He authored 30+ papers on laser-matter interaction, and syntheses/applications of nano-structured materials (CNTs, AAO, porous-Si). He has been active in national (Finnish) and European projects as key personnel and coordinator.

**Robert Vajtai**

Rice University
Department of Mechanical Engineering
and Materials Science
Houston, TX, USA
robert.vajtai@rice.edu

Chapter 1

Robert Vajtai is a Faculty Fellow at Rice University, Houston, Texas, in the Department of Mechanical Engineering and Materials Science. His expertise covers synthesis, processing, characterization of physical and chemical properties of new, advanced material forms and structures. Dr. Vajtai's interests are in nanostructured materials, nanocomposites and nanomaterials; as well as their applications in thermal management, energy storage, microelectromechanical systems, sensors and electronic devices. He received his graduate and PhD degrees from the University of Szeged, then named Jozsef Attila University, Hungary.

Sofia M. Vega Díaz

Shinshu University
Research Center for Exotic Nanocarbons
Nagano, Japan
smvd@shinshu-u.ac.jp

Chapter A.6

Sofia Magdalena Vega-Diaz received the MSc degree in 2003 and PhD in 2009 in Chemical Engineering from Universidad Autonoma de San Luis Potosi, Mexico. Her research activities include synthesis and processing of hybrid materials and polymer nanocomposites with nanoclays and nanocarbon structures. She currently develops her research at the International Research Center for Exotic Nanocarbons in Shinshu University, Japan.

Aravind Vijayaraghavan

University of Manchester
School of Computer Science
Manchester, UK
aravind@cs.man.ac.uk

Chapter A.2

Dr. Aravind Vijayaraghavan is currently a Lecturer at the University of Manchester. He received his PhD (2005) and MEng (2002) in Materials Engineering from Rensselaer Polytechnic Institute, Troy, and BTech (2000) from the Indian Institute of Technology, Madras. He was previously an Alexander von Humboldt fellow at the Karlsruhe Institute of Technology (KIT). His current research explores the production, properties and applications of graphene, carbon nanotubes and related nanomaterials, with particular focus on nanoelectronics and biosensing.

**Xiaohui Wang**

Chapter C.14

Tsinghua University
Department of Materials Science &
Engineering
Beijing, China
wxh@mail.tsinghua.edu.cn

Dr. Xiaohui Wang is a Professor of Department of Materials Science & Engineering at Tsinghua University. She received her PhD in Physical Chemistry from Jilin University in 1994 and did her postdoctoral work at the University of Pennsylvania. Her current research activities include the synthesis and characterization of nanomaterials, sintering of nanoceramics and its applications.

**Xuan Wang**

Chapter A.4

Rice University
Department of Electrical and Computer
Engineering
Houston, TX, USA
xw13@rice.edu

Dr. Xuan Wang got his Bachelor's degree in Physics from Nankai University in China. He finished his PhD program in Physics at Florida State University. His research topic was to develop and use the ultrafast electron diffraction technique to study lattice dynamics. Currently, he is a postdoctoral Researcher at Rice University and his research interest are the transport and optical properties of CNT devices.

Qiaoling Xu

Chapter E.23

Chinese Academy of Sciences
Key Laboratory of Materials Physics (CAS),
Anhui Key Laboratory of Nanomaterials
and Nanostructures
Anhui, China
qlxu@issp.ac.cn

Qiaoling Xu is an Associate Professor at the Institute of Solid-State Physics, Chinese Academy of Sciences (CAS). She received her PhD degree in Materials Physics and Chemistry from Institute of Solid-State Physics, CAS in 2009. Her current research interests include the fabrication of 1-D nanostructures and their performance and environmental applications of the nanomaterials.

Robert J. Young

Chapter D.19

University of Manchester
School of Materials
Manchester, UK
robert.young@manchester.ac.uk

Professor Young was educated at the University of Cambridge and in 1986 he was appointed as Professor of Polymer Science & Technology in the University of Manchester. He is interested in all aspects of the relationship between the structure and mechanics of polymers and composites. He has recently focused his attention upon structure/property relations in graphene and chemically-modified graphene for use in high-performance polymer-based nanocomposites. He is listed by HighlyCited.Com for his publications in Materials Science and is a Fellow of the Royal Academy of Engineering.

**Ling Zhang**

Chapter F.27

Carnegie Mellon University
Department of Biomedical Engineering
Pittsburgh, PA, USA
zling03@gmail.com

Dr. Ling Zhang received her PhD in Biophysics from Tsinghua University, China (2008). She has since been a postdoctoral fellow at the University of Pittsburgh and Carnegie Mellon University. Her research interests are using smart biomaterials to manipulate stem cells for tissue repair, especially in neural tissue engineering and neural regeneration. Currently, she is trying to use biomaterials and neural stem cells to treat stroke and traumatic brain injury.

**Shaopeng Zhang**

Chapter C.14

Tsinghua University
Department of Materials Science and
Engineering
Beijing, China
zspthu@gmail.com

Shaopeng Zhang is a PhD course student in the department of Materials Science and Engineering at Tsinghua University. His research works focus on preparation of $(1-x)\text{BiScO}_3\text{-}x\text{PbTiO}_3$ and $\text{Pb}(\text{Zr}_{1-x}\text{Ti}_x)\text{O}_3$ piezoelectric ceramics, size effects study on the structures and properties of ferroelectric/piezoelectric ceramics.

Zhonghua Zhang

Shandong University
School of Materials Science and
Engineering
Shandong, China
zh_zhang@sdu.edu.cn

Chapter [E.21](#)

Zhonghua Zhang received his PhD degree in 2003 from the School of Materials Science and Engineering, Shandong University, where he is now a full professor. He has extensive experience in casting, rapid solidification, amorphous alloys, and shape memory alloys. Now he mainly focuses upon preparation, microstructural characterization, and potential applications of nanoporous metals/alloys through dealloying.

Detailed Contents

Foreword by Claes-Göran Granqvist	V
Foreword by Neal Lane	VII
List of Abbreviations	XXIX

1 Science and Engineering of Nanomaterials

<i>Robert Vajtai</i>	1
1.1 History and Definition of Nanomaterials	2
1.1.1 History of Nanomaterials	2
1.1.2 Definition of Nanoscale and Nanomaterials	4
1.2 Formation of Nanomaterials	6
1.3 Properties of Nanomaterials	10
1.3.1 Morphology of Nanomaterials	10
1.3.2 Bonds and Structures	10
1.3.3 Mechanical Properties of Nanomaterials	12
1.3.4 Electrical, Magnetic, and Optical Properties	14
1.3.5 Thermal Properties	18
1.3.6 Chemical Properties, Reactivity, and Functionalization	20
1.3.7 Behavior of Nanomaterials in Corrosive Environments	22
1.4 Typical Applications of Nanomaterials	22
1.4.1 Catalysts and Catalyst Templates	26
1.4.2 Energy Conversion and Storage	26
1.4.3 Sensors Based on Nanomaterials	28
1.5 Concluding Remarks	31

Part B NanoMetals

9 Noble Metal Nanoparticles

<i>Theruvakkattil S. Sreeprasad, Thalappil Pradeep</i>	303
9.1 Historical Perspective of Gold and Silver NPs	304

9.2	Diverse Nanostructures	307
9.2.1	Physical and Chemical Methods	308
9.2.2	General Issues of Concern	309
9.3	Common Synthetic Routes for the Preparation of Noble Metal NPs	311
9.3.1	Solution Phase Routes by Chemical Reduction	311
9.3.2	The Most Common Methods for Gold NPs	312
9.3.3	Specialized Synthetic Strategies – Anisotropic NPs	314
9.4	Properties of Noble Metal Nanoparticles	322
9.5	Postsynthetic Tuning of Properties	324
9.5.1	Tuning Properties Through Chemical Reactions	324
9.5.2	Modification of Properties – Formation of Superstructures	331
9.6	Functionalized Metal NPs	343
9.6.1	Core–Shell Nanoparticles	343
9.7	Applications of Gold and Silver Nanoparticles	347
9.7.1	Water Purification	348
9.7.2	Bioconjugation and Labeling	357
9.7.3	Optical Contrast Agents	357
9.7.4	Photothermal Therapy	358
9.7.5	Cancer Cell Imaging	359
9.7.6	Surface–Enhanced Raman Scattering Substrates	360
9.7.7	Superhydrophobic Surfaces	360
9.7.8	Mercury Sensor	361
9.7.9	Infrared Absorbing Material	362
9.7.10	Plasmonic Waveguides	362
9.7.11	Biosensors	362
9.7.12	Photovoltaic Devices	362
9.8	New Gold and Silver Materials – Quantum Clusters	363
9.9	Conclusions	366

11 Alloys on the Nanoscale

<i>Giovanni Barcaro, Alfredo Caro, Alessandro Fortunelli</i>	409
11.1 Concepts and Principles	411
11.2 Preparation and Synthesis	413
11.2.1 Solution-Phase Methods	413
11.2.2 Surface Deposition Methods	416
11.3 Characterization of Nanoparticles and Nanoalloys	417
11.3.1 Scanning Force Microscopy (SFM)	417
11.3.2 Grazing-Incidence Small-Angle X-ray Scattering (GISAXS) ..	418
11.3.3 X-ray Absorption Spectroscopy (XAS)	418
11.3.4 Scanning Tunneling Microscopy (STM)	419
11.3.5 X-ray Photoelectron Spectroscopy (XPS)	420
11.3.6 Surface X-ray Diffraction (SXRD)	421
11.3.7 Transmission Electron Microscopy (TEM)	421
11.3.8 Vibrational Sum-Frequency Generation (VSFG)	424
11.4 Properties	424
11.4.1 Structural Properties of Alloyed Nanoparticles	425
11.4.2 Catalytic Properties	437
11.4.3 Optical Properties	442
11.4.4 Magnetic Properties	448
11.5 Nanostructured Bulk Alloys	450
11.5.1 Bulk Materials Incorporating Nanoscale Precipitates of a Different Phase	450
11.5.2 Bulk Nanophase Materials	453
11.6 Applications	457
11.7 Concluding Remarks	458
References	459

12 Magnetic Nanostructures: Synthesis, Properties, and Applications

<i>Shashwat Shukla, Pratap Kumar Deheri, Raju V. Ramanujan</i>	473
12.1 Background	474
12.2 Atomic Origin of Magnetism	475
12.2.1 Quantum Mechanics of Ferromagnetism	475
12.2.2 Atomic-Scale Magnetism and Exchange Effect	476
12.3 Magnetic Length Scales and Origin of Nanomagnetic Behavior	478
12.3.1 Domains in Fine Particles	478
12.3.2 Nanomagnetism	479
12.4 Magnetic Nanostructures	483
12.4.1 Processing of Magnetic Nanostructures	483
12.4.2 Characterization of Magnetic Nanostructures	488
12.4.3 Hard Magnetic Nanostructures	492
12.4.4 Soft Magnetic Nanostructures	498
12.4.5 GMR and Spin Valves	502
12.4.6 Applications	503
12.5 Conclusions	505
References	506

Part C NanoCeramics

13 Nanocrystalline Functional Oxide Materials

Rakesh Shukla, Dimple P. Dutta, Jayshree Ramkumar, Balaji P. Mandal,

Avesh K. Tyagi

13.1	Synthesis Methods	517
13.1.1	Solid-State Route	518
13.1.2	Soft Chemical Routes	519
13.2	Optical Properties of Oxide Nanomaterials	524
13.3	Sorbent Properties of Oxide Nanomaterials	532
13.3.1	Sorbents for Environmental Remediation	533
13.4	Catalytic Properties of Oxide Nanomaterials	536
13.5	Oxide Nanomaterials in Ionics	538
13.6	Conclusions	541
